On account of the occasional failure of this treatment, Kocher proposed to extirpate the mucosa of the sinus. This radical intervention may be performed by a number of comparatively new procedures, viz.:

Nebinger-Praun Method.—The anterior wall is opened by horizontal and vertical incisions and entirely removed. The mucosa is curetted, and the naso-frontal duct dilated. The wound is drained through the external opening.

Jansen Method.—The orbital wall of the sinus is removed and the cavity curetted.

Killian's Method.—This consists in opening the sinus through the frontal wall with temporary resection of the nasal bone. The infundibular cells are broken up to such an extent that free drainage of the sinus by way of the nasal fossæ is insured.

Luc-Ogston Method.—Both frontal and ethmoidal sinuses are opened, and a wide communication is established between the former and the nose. A drain is then passed between these two cavities and the external wound closed.

Czerny Method.—Osteoplastic opening of the sinus. Operation finished as in preceding.

Kuhnt's Method.—The anterior wall of the sinus is removed, together with all the diseased mucous membrane and the upper portion of the fronto-nasal canal. This operation is preferred by most surgeons. According to Hajek, the only objection to its general employment is that it makes no provision for attacking the infundibular cells of the ethmoid, which are almost invariably diseased in empyema of the frontal sinus.

Killian sums up the subject of surgical intervention in chronic empyema of the frontal sinus as follows:

The supra-orbital margin must be preserved, even if only a narrow bridge remains; otherwise great disfigurement results. The general theory of most of these operations involves the opening up of a passage between the sinus and nose for the purpose of drainage through the latter. This passage may be natural or artificial. But these communications often heal up prematurely by granulation, and a permanent passage is insured only after resection of the nasal bone or nasal process of the superior maxillary. This form of intervention also gives access to the ethmoid labyrinth.

The technique of Winkler is representative of our modern knowledge of the treatment of chronic frontal-sinus disease. This procedure is as follows:

1. Tampon the posterior nares.
2. Make an incision through the eyebrow (do not shave the latter beforehand).
3. Exploratory puncture through the incision with probing. An alternative now presents itself, viz.: (*a*) Resect the anterior and orbital walls, leaving the orbital margin; or (*b*) perform temporary osteoplastic resection. If permanent resection is to be performed, the technique is as follows:
4. Remove the anterior wall of the sinus with bone forceps or Winkler's saw, the latter being preferable in fixing the upper limit of the orbital bridge.
5. The floor of the sinus is removed with chisel and forceps, the orbital margin being left as a bridge.
6. Extirpation of the mucous membrane of the sinus.
7. The original incision is prolonged beyond the bridge of the nose and beyond the extremity of the nasal bone.
8. The nasal bone and a small portion of the frontal bone are divided with the chisel; the nasal process of the superior maxillary is then divided with the saw.
9. The skin-bone flaps are now turned backward.
10. Diseased ethmoid cells are removed with bone forceps and curette, and a communication is established between the sinus and nose.
11. The flaps are replaced. Sutures may be applied at once or after two days. No irrigation is allowed until two or three weeks have elapsed.

If an osteoplastic procedure has been chosen, the technique is as follows: The skin is pushed back beneath the orbital margin, and the bone separated from the latter with the chisel. At the outer and middle limits of the sinus this margin is chiselled through. The flap of bone and integument is turned upward and outward. All œdematous and fibrous proliferation, carious bone, etc., are removed with the curette.

INJURIES.—In traumatism of the frontal sinus the violence is always direct. Sharp violence is usually due to knife thrusts and sword cuts; while blunt traumatism proceeds from a great variety of objects, including projectiles, flying fragments, etc. The frontal sinus is occasionally injured by horse kicks, blows of the fist, falls upon the face, and the like. The external wall is almost invariably the part injured. Autopsies occasionally reveal the presence of injury of the cranial wall, such accidents being quite generally fatal. The character of the injury varies from simple fissure or indentation to compound fracture and comminution. Hæmatoma of the sinus usually coexists.

The symptoms of injury of this sinus are either local or cerebral. If the violence does not lay open the sinus, the blood escapes by the nose. Epistaxis and pain are practically the sole symptoms of this type of fracture. While these traumatisms tend to recover without sequelæ, the injury doubtless produces sinusitis in certain cases. A peculiar type of traumatism sometimes seen is detachment of the lining membrane of the sinus.

If the cavity is opened subcutaneously by the violence, respiratory movements are seen in the superjacent skin, and subcutaneous emphysema is readily produced, which may extend indefinitely. It tends to subside spontaneously in a few days.

Trauma with complete exposure of the cavity is of frequent occurrence. This class of wounds is readily infected either at the time of the injury or afterward, so that abscess, periostitis, necrosis, fistula, and endocranial complications may result. If infection does not occur, these compound wounds heal readily. One sequela which may occur independently of infection, however, is pneumatocele.

Diagnosis is usually made without any difficulty. In fracture, emphysema readily occurs. Rhinoscopy is useful in detecting hemorrhage from the sinus.

After injury has occurred infection may be prevented by antiseptic irrigation. The possibility of latent injury of the cranial wall must always be borne in mind. As a general rule the treatment of all subcutaneous injuries is expectant, save when cerebral complications are to be feared or when sinusitis develops. On the other hand, open wounds always require active surgical intervention. The opening should be enlarged, the sinus cleaned, spicula of bone and foreign bodies removed, the cranial wall carefully scrutinized for possible injury, and the cavity well drained. Antisepsis will certainly prevent grave endocranial complications. In very extensive wounds a plastic operation is required.

FOREIGN BODIES.—With a very few exceptions all recorded cases of foreign bodies in the frontal sinus have consisted of projectiles, chiefly from old-fashioned weapons. The velocity of modern projectiles, aside from revolver shots, is too considerable for them to be arrested within the sinus.

These projectiles may heal in the sinus, but as a rule a fistula results. Sinusitis is almost invariably set up. These foreign bodies may remain in the sinus for an indefinite period, even amounting to twenty-five years.

Diagnosis was formerly by no means easy, and exploratory incisions were occasionally necessary. To-day the employment of the Roentgen rays insures rapid recognition of foreign bodies in this locality.

A special type of foreign body in the frontal sinus is the animate, consisting of mature insects or larvæ which reach this cavity by way of the nasal chambers. The recorded material, however, is almost all ancient.

NEW FORMATIONS.—Of benign tumors of the sinus, osteoma is the only one which receives consideration from modern authorities, for polypi and cysts are now regarded as incidental features of chronic sinusitis. Even osteomata are held by some to be of inflammatory origin. They may be attached to the bone by a broad base or peduncle, or they may be simply embedded in the mucosa.

They may even lie loose in the sinus. These formations are practically confined to the periods of childhood and adolescence.

In structure the nucleus and peduncle are cancellous and the rest of the mass of ivory-like hardness. The osteoma may attain the size of an apple. Its growth beyond a certain limit expands the walls of the sinus. The cranial cavity is often encroached upon, as are also the opposite sinus and orbit; but so gradual is the enlargement that little functional disturbance results. Exceptionally, severe ocular disturbances, cerebral compression, etc., are produced.

Osteoma may be complicated with sinusitis in all its phases. It also closely simulates dilating sinusitis, so that exploratory puncture may be necessary for differentiation.

The indication in osteoma is immediate extirpation. In former years the mortality from this intervention was very great. As the operation itself is not difficult, the danger must lie solely in the possibility of infection.

Of malignant growths originating in the frontal sinus such a small number are upon record that hardly anything need be said on the subject. The few cases in literature were all sarcomata, which grew rapidly and broke into the contiguous cavities. Carcinoma has never been known to originate in the sinus, and even the cases of secondary invasion are of extremely rare occurrence.

George Ryerson Fowler.

FRY'S MINERAL SPRING.—Jasper County, Iowa.

POST-OFFICE.—Colfax. Hotels: Fry's and five others.

This is one of a group of ten well-known mineral springs located at Colfax, on the line of the Chicago, Rock Island and Pacific Railroad. Like all the others of the group, this spring has an artesian flow and proceeds from a depth of between 300 and 400 feet. The water of this spring has been analyzed by Dr. Heinrichs, Professor of Chemistry, Iowa State University, and also by Professor Haines, M.D., Chair of Chemistry and Toxicology, Rush Medical College, Chicago. The results obtained are as follows:

ONE UNITED STATES GALLON CONTAINS:

Analysis by Dr. Heinrichs.		Analysis by Dr. Haines.	
Solids.	Grains.	Solids.	Grains.
Sodium chloride	3.85	Sodium chloride	3.842
Sodium sulphate	78.86	Sodium sulphate	77.344
Potassium sulphate	.41	Potassium sulphate	.620
Magnesium sulphate	31.87	Calcium sulphate	31.750
Calcium sulphate	13.07	Magnesium sulphate	10.230
Calcium carbonate	17.51	Magnesium bicarbonate.	25.939
Iron carbonate	.67	Iron bicarbonate	.258
Silica	.29	Alumina	.058
Lithia	Trace.	Silica	.710
Carbon dioxide	7.18	Organic matter	Trace.
Total	153.71	Total	150.751

As seen by the analyses, the water is quite strongly impregnated with mineral ingredients, but not sufficiently so to mar its pleasant taste. Ample bathing facilities are provided. The elevation of the location is 1,100 feet above the sea-level, the surrounding country being of a hilly character. The waters of the spring have been found efficacious in rheumatism, dyspepsia, general debility, and in diseases of the blood, liver, kidneys, and nervous system.

James K. Crook.

FULTON WELLS.—Los Angeles County, California. Hotel and cottages. This resort is located about three miles north of Norwalk station on the Los Angeles Railroad, and thirteen miles from Los Angeles City. The wells were bored by Dr. Fulton, and the resort is conducted by that gentleman. The two principal wells are 350 feet deep and flow copiously. Anderson's analysis shows the following results:

ONE UNITED STATES GALLON CONTAINS:

Solids.	Grains.
Sodium chloride	9.60
Sodium bicarbonate	2.90
Sodium sulphate	.95
Magnesium bicarbonate	17.46
Ferrous carbonate	11.75
Calcium carbonate	12.62
Calcium sulphate	23.41
Silica	2.56
Organic matter	Trace.
Total	81.25
Free carbonic acid gas	Excess.
Free sulphureted hydrogen	Excess.

Temperature of water, 64° F.

This water may be described as a heavy alkaline-chalybeate. It enjoys considerable reputation in the treatment of anæmia, malarial troubles, atonic dyspepsia, congestion of the liver, etc. A large hotel, comfortable cottages, and excellent bathing facilities have been provided for guests.

James K. Crook.

FUMITORY.—The plant *Fumaria officinalis* (fam. *Fumariaceæ*), an annual herb with branching stem, smooth and glaucous compound leaves, and small, rather irregular flowers in axillary racemes; the pods are one-sided, and the juice of the stems and leaves is not milky; in other respects of structure it accords with the poppy family. Fumitory is indigenous to Europe, and an introduced plant in the United States.

The leaves or the flowering herb are collected for use; they have a bitter, saline taste but no odor. They contain a crystalline, bitter alkaline base, *fumarine, fumaric acid,* and a large amount of carbonate of soda.

Fumitory is an old European house remedy for "visceral, obstructive, hepatic, and scorbutic troubles." It is but little employed at present.

ALLIED PLANTS.—*Corydalis* and *Diclytra* ("Dicentra") are pretty flowers, some species of which are cultivated for ornament, and yield drugs which are used to a slight extent. There are several other species of *Fumaria* which have been employed also in medicine.

W. P. Bolles.

FUNGI, EDIBLE AND POISONOUS.—The fungi include a series of plants of very diverse characters, varying among themselves as widely in size, structure, and other characters as do the higher and better known seed-bearing plants. All, however, possess the common characteristics of absence of chlorophyl and some method of reproduction by spores. The first character will distinguish the fungi from other cellular plants like the algæ, while the latter will distinguish them from higher parasitic plants like the dodders, beech-drops, and broom-rapes. All fungi, lacking chlorophyl, must live on some form of organized matter; this they may derive directly from living plant or animal tissues, in which case they are true parasites; others and by far the greater number draw their nourishment from dead or decaying matter and are known as saprophytes.

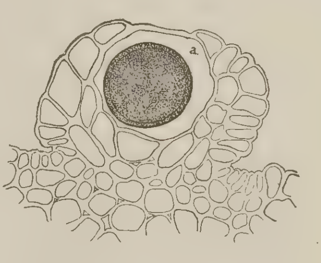

FIG. 2233.—*Synchytrium mercurialis*, producing a Gall on the Epidermis of *Mercurialis perennis*. The fungus is parasitic in a single cell and the resting spore shown at *a*. (After Woronin.)

In structure, some of the simplest consist of minute, naked masses of protoplasm living parasitically within a single vegetable cell which may be a pollen grain, a diatom, the cell of a filamentous alga, or an epidermal cell of one of the higher plants (Fig. 2233); others, like yeast, consist of single cells enclosed in a cellulose covering which does not differ essentially from that of the higher plants; these cells are free floating and derive their nourishment either from saccharine solutions or those containing amylace-

[2] Hajek: Pathologie und Therapie der entzündlichen Erkrankungen der Nebenhöhlen der Nase, Leipzig u. Wien, 1899.

ous substances capable of being transformed into sugar. The more highly organized fungi consist of fine thread-like filaments known as hyphæ which develop primarily from the germination of spores; these hyphæ may be either septate or form continuous capillary tubes and often form a web-like tangle known as mycelium; such a mass entangled with compost, forms the so-called "spawn" from which the ordinary mushrooms of cultivation are grown, and such are the cobwebby films of mould seen on manure piles or on the surface of fruit exposed to a warm moist air. At other times numerous threads of the mycelium become joined to form cord-like strands which sometimes attain the length of many feet. Many of the conspicuous forms of fungi such as the puffballs and ordinary mushrooms are compacted masses of mycelium variously hardened and sometimes mingled with more or less vesicular cells of various sorts; some very hard tissues like those of the woody bracket fungi are developed in the same way, the hardness and toughness depending on the compactness of the fibres and the thickening of their cell walls. The ordinary structures we know as mushrooms, for example, consist merely of the reproductive portion of the plant, and in a general way correspond more or less closely to the fruit of the higher plants; the vegetative portion frequently consists of extensive masses of mycelium concealed underneath the ground, and ramifying in every direction to secure from stores of decomposing vegetable matter the supply of nourishment necessary for their life. This not only serves for their food but from it they manufacture the material from which the reproductive parts above ground are rapidly developed at an opportune time.

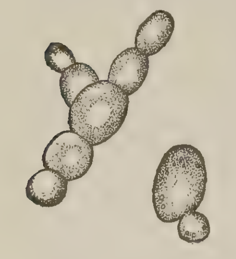

FIG. 2234.—Yeast Cells of *Saccharomyces cerevisiæ* Budding Normally.

Besides developing fungus cellulose which differs only slightly from ordinary cellulose in its reactions, various fungi develop various carbohydrates like sugar, mannite, glycogen, gums, and the like; organic acids especially oxalic, malic, and citric; aromatic acids, fats, ethereal oils, coloring matters of diverse types, resins, albuminous compounds, and alkaloids. The last-named compounds are the sources of poisons found in various mushrooms; while to various combinations of some of the former are to be attributed the nutritious properties and flavors of the various forms of edible mushrooms.

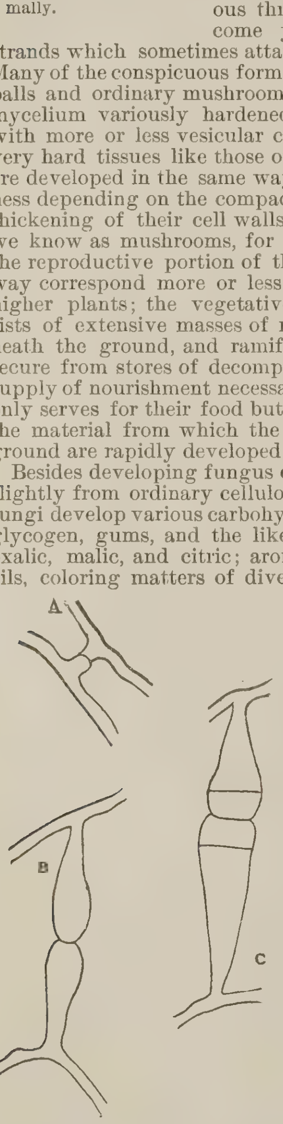

FIG. 2235.—Process of Conjugation in *Mucor stolonifer*, One of the Mucorales. *A*, Two hyphal branches approaching; *B*, the same still further advanced; *C*, suspensors cut apart from the conjugating cells (*gametes*) by septa. The union of the gametes finally produces a zygospore as seen in Fig. 2245. (After De Bary.)

Reproduction is accomplished in various ways. In unicellular forms it may take place by budding (*gemmation*) as in the yeast (Fig. 2234), by self-division (*fission*) as in the bacteria, or by free cell formation (*internal cell division*). In one of the great classes of the fungi, the spores are produced in membranous sacs called *asci* (Fig. 2241), and in the common mushroom they are borne on spicules (*sterigmata*) which rise from enlarged cells known as *basidia* (Fig. 2242). In the various groups of fungi reproductive bodies are produced in a variety of ways which has given rise to an extensive diversity of terms in common use in various works on fungi; some of the more common of these forms are as follows:

1. *Sexual Methods of Reproduction.*

(*a*) By the union of similar elements (*conjugation*) resulting in the formation of a so-called zygospore; the sexual method of reproduction in the ordinary black mould of bread is an example (Fig. 2235).

(*b*) By the union of dissimilar elements resulting in the formation of an oöspore; the sexual reproduction of the downy mildew found parasitic within the leaves of many plants in a good example (Fig. 2236).

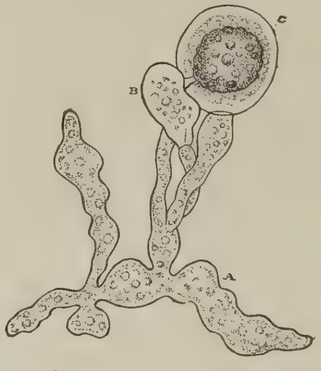

FIG. 2236. — Sexual Reproduction of *Peronospora*; *A*, Mycelium; *B*, antherid; *C*, egg. These structures form inside the leaf of the host.

(*c*) By the union of dissimilar elements, which, followed by the growth of an alternate stage (known as a sporophyte), results in the formation of a sporocarp or so-called spore fruit such as is seen in the common surface mildews of many common plants (Figs. 2237).

2. *Asexual Forms of Reproduction.*

(*a*) The formation of ciliated swarm spores within the cell by the ordinary processes of internal cell division.

(*b*) The formation of solitary conidia on simple or branching hyphæ as in the mould-like growth of the downy mildew that appears on the under surface of many leaves (Fig. 2248).

(*c*) The formation of conidia in chains by the successive cutting off of the ends of certain hyphæ as in the common green mould (Fig. 2252, *C*), the powdery mildew (Fig. 2253, *A*), and the peach rot (Fig. 2238).

(*d*) The formation of sporangia or membranous receptacles containing large numbers of spores formed by a process of internal cell division. Such a type is readily seen in the ordinary method of reproduction of the common mould of manure (Fig. 2246).

(*e*) The formation of pycnidia or special receptacles of more or less elaborate structure, from the walls of which the conidia are produced; such a structure is found in the ordinary leaf-spot disease of the pear (Fig. 2240) and other similar parasitic and often saprophytic fungi.

While many terms are employed for the various reproductive bodies of fungi, it is perhaps better to use only the two terms conidia and spores. In the lower fungi in which there occurs both a sexual and an asexual method of reproduction the term spore is limited to the sexual product, and the term *conidium* (plu. *conidia*) to the asexual. Following the same analogy the characteristic final or mature reproductive body in the higher fungi is also called a spore, even though it does not repre-

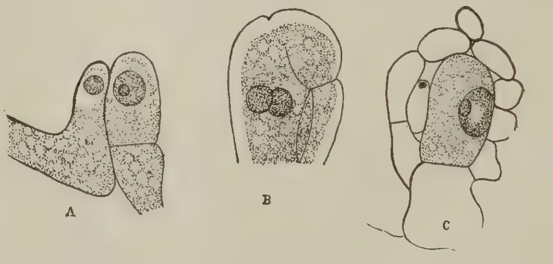

FIG. 2237.—Stages in the Sexual Process of *Sphærotheca Castagnei*, one of the common Powdery Mildews. At *A*, the two sexual cells are distinct; at *B*, they are fusing; and at *C*, the young sporocarp is forming. The mature stage of the sporocarp is shown in Fig. 2253. (After Harper.)

sent the result of sexual reproduction, while any earlier or simpler methods of reproduction are regarded as conidial. Following the same analogy, the spore production among the hosts of imperfect fungi (*fungi imperfecti*) is also regarded as conidial.

By the above discussion it will be seen that the same fungus possesses more than one method of reproduction, and the case is complicated when a parasitic form has one stage of its growth on one plant and the spores or conidia of this stage are then transferred to another host plant and the final growth and a different method of reproduction take place in its new place of abode. Still more complicated are the many cases in which a fungus is parasitic during its conidial stage and passes through its spore-producing stage on some organic substratum as a saprophyte.

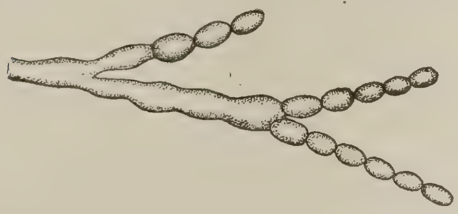

FIG. 2238.—*Monilia fructigena*, the Common Rot of Plums and Peaches; a fragment of a hypha bearing spores produced in chains.

Fungi are of economic importance in a great number of ways: 1. As household pests they invade fruit either fresh or preserved, cereals or other starchy cooked foods, cheese, clothing, and many other things under the name of moulds. 2. As parasites on living plants they prey upon fruits, grains, grasses, the foliage of shade trees, weeds, and many other plants in the form of leaf blights, mildews, rusts, smuts, leaf spots, anthracnoses and the like, often causing immense losses to farmers and fruit growers. 3. As aquatic parasites they attack fish, particularly the young fish in the hatcheries, and often cause considerable destruction. 4. As aerial parasites on living animals they attack flies, grasshoppers, clover weevils, the pupæ of moths and butterflies, and many other animals, sometimes even producing skin diseases in man. 5. In laboratory work with bacteria they often form a disturbing element and a knowledge of their kind and nature becomes a necessity to those who make extensive plate cultures and tube cultures. These moulds are likely to be either (*a*) True Mucoraceæ, (*b*) Conidial stages of certain Aspergillaceæ like the common green mould, or (*c*) Hyphomycetes or moulds with only a conidial reproduction; in some of the latter the spores are light-colored, in others they may be dark-colored or even black.* 6. As agents of fermentation they form the active element of yeast and so are directly concerned in the production of bread and beer, and in all alcoholic fermentation, as well as in the later stages of acetic fermentation. 7. As an article of food they are extensively in use among all peoples whether civilized or not. 8. As destructive agents of timber either in living standing trees or in the form of ties or building material they form a prominent factor in engineering. 9. As remedial agents they are directly concerned with medicine, and finally as malignant poisons they appeal to members of the medical profession for the treatment of the victims of their work.

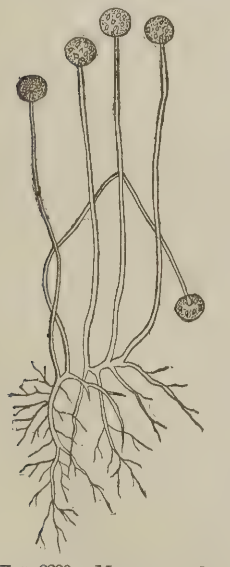

FIG. 2239.—*Mucor mucedo*, showing Root-like Hyphæ and Sporangia filled with Spores at the Summit of Aerial Hyphæ.

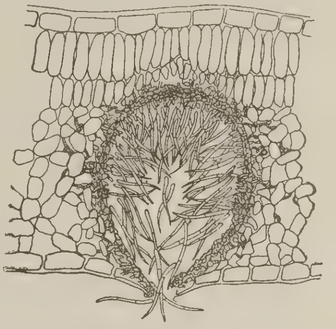

FIG. 2240.—Section of a Pear Leaf taken through one of the Pycnidia of a Leaf Spot caused by *Septoria pirina*. The darkened portions are caused by the fungus mycelium and the spores are formed from the inner wall of the pycnidium and escape at its mouth. (After Duggar.)

There are three principal groups of fungi that may be distinguished as follows:

CLASS I. PHYCOMYCETES — the algal fungi, including mould-like saprophytes as well as various parasites of both animals and plants. These in addition to the more ordinary method of asexual reproduction have a sexual method not unlike that which occurs among various forms of the simpler green algæ, and many of them in fact appear to be little short of degenerate algæ that have lost their power of developing chlorophyl and with it the power of fixing carbon from the carbonic oxide of the air.

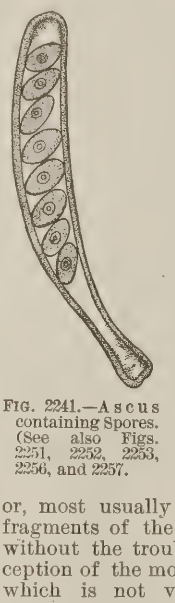

FIG. 2241.—Ascus containing Spores. (See also Figs. 2251, 2252, 2253, 2256, and 2257.

The other two classes of fungi represent distinctly higher types of fungi, whose relations to other members of the plant world are not so clearly marked. These classes are distinguished from the above by their more complicated structure and by the rarity of sexual processes, and are distinguished from each other by the method of spore production which is very characteristic and easily determined in mature material.

CLASS II. ASCOMYCETES, or spore-sac fungi, are characterized by the production of spores in membranous sacs known as *asci* (sing. *ascus*) (Fig. 2241). This character can be readily seen in any mature fungus by making a section for the microscope and examining it for the sacs containing the spores, or, most usually they can be made out from crushed fragments of the spore-bearing surface of the fungus without the trouble of making sections. With the exception of the morels common in spring and *Gyromitra*, which is not very common with us, none of the larger fleshy fungi belong to the Ascomycetes, but rather to the next class.

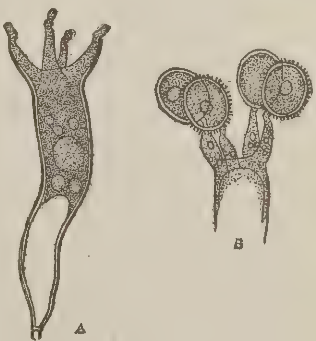

FIG. 2242.—Two Basidia. *A*, With sterigmata bearing very young spores, and *B*, a later development with spores mature.

CLASS III. BASIDIOMYCETES. — These are characterized by bearing the spores naked on enlarged cells known as basidia (Fig. 2242). This class includes besides the parasitic rusts and smuts, all the ordinary mushrooms and toadstools (except the morel noted above), bracket fungi so commonly shelving from trees and stumps, puff-balls and stink-horns, thus including the largest number of conspicuous forms of fleshy fungi as well as the principal forms which contain poisonous principles.

---

* A preliminary paper on these forms has been prepared by Dr. Jelliffe, "Some Laboratory Moulds." Journal of Pharmacology, Nov., 1897.

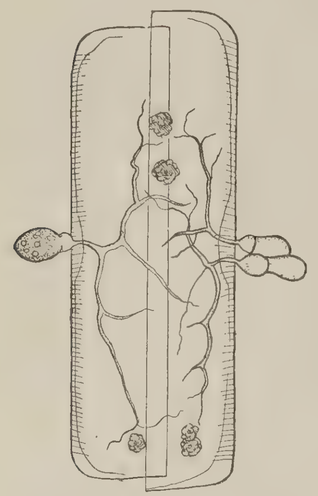

FIG. 2243. — *Septocarpus corynephorus*, One of the Chytridiales, Parasitic on a Diatom. (After Zopf.)

Besides the above groups there are two others closely related in habit and often associated with fungi. These are the bacteria which form the great group often known as the *Schizomycetes* which find a closer alliance with the blue-green algæ (*Cyanophyceæ*), and the slime moulds or *Mycetozoa* which find their alliance in the active form at least with certain of the lowest animals. In their later stages they have some superficial relations with the puff-balls, but really stand at the opposite extreme of the scale.

The general literature on the subject of the fungi is very extensive, but large portions of the earlier writings are now of interest from a historical standpoint mainly. For advanced students of the subject, De Bary's "Comparative Morphology and Biology of the Fungi, Mycetozoa and Bacteria," is still the standard treatise, though it should be supplemented by Brefeld's antagonistic views in his "Untersuchungen aus dem Gesammtgebiete der Mykologie," published in twelve quarto parts (1872–1895). A summary of Brefeld's system may be found in von Tafel's "Vergleichende Morphologie der Pilze" (1892). For the physiology of the fungi, the best general treatment is found in Zopf's "Die Pilze," found in Schenck's "Handbuch der Botanik" (1890), but this must be supplemented by later investigations.

The literature relating to the American fungi is copious but very much scattered and except for synopses of certain small groups no manual or descriptive flora of our American species has been attempted. A guide to the systematic study of the American species with full generic synopses and extended references to our scattered literature is found in Underwood's "Moulds, Mildews and Mushrooms" (1899), and this will serve as a general introduction to the study of our fungi. The literature bearing on particular groups and that relating to the edible species will be referred to under special heads.

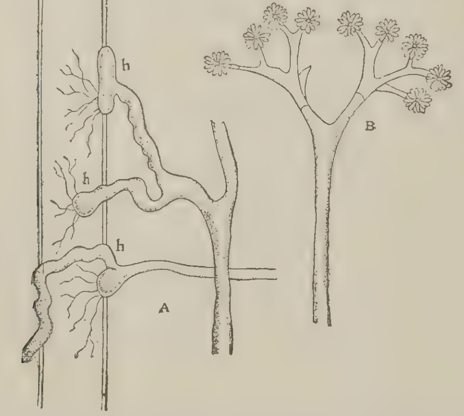

FIG. 2244.—*Piptocephalis freseniana*, a Mould Parasitic on *Mucor*. *A*, Portion of hyphæ showing the haustoria, *h*, *h*, *h*, by which it is attached to the hypha of *Mucor*; *B*, conidia. (After Brefeld.)

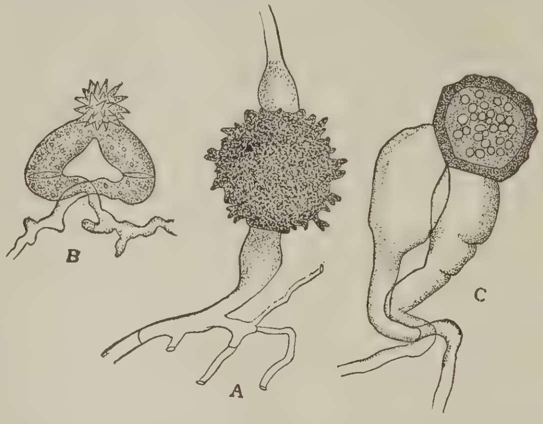

FIG. 2245.—Various Forms of Conjugation in the Mucorales, showing the Zygospore Formation. *A*, *Mucor mucedo*; *B*, *Piptocephalis freseniana*; *C*, *Pilobolus crystallinus*. (After Brefeld.)

CLASS I.—PHYCOMYCETES (*Algal Fungi*).

The Phycomycetes contain five orders of plants:

1. CHYTRIDIALES, which are mostly unicellular endoparasites on algæ, diatoms, infusoria, or rarely on the higher plants; their organization is extremely simple (Fig. 2243) and their method of reproduction is for the most part asexual. Except for the parasitic species of *Synchytrium* (Fig. 2233) the forms have not been studied in this country.

2. MUCORALES, containing the common black-moulds of the household, reproducing asexually by conidia produced either in sporangia as in the common *Mucor mucedo* and *Mucor stolonifer* (Fig. 2239) or more rarely in clusters at the ends of branches as in *Piptocephalis* (Fig. 2244, *B*). A second but less usual method of reproduction is sexual by conjugation as is seen in *Mucor* (Fig. 2245, *A*), *Piptocephalis* (Fig. 2245, *B*), or *Pilobolus* (Fig. 2245, *C*). The last-named fungus is a beautiful but ephemeral plant which appears in crystalline clusters on the surface of horse manure either in stables or often in the open woods. Its sporangial form is most commonly seen as in Fig. 2246.

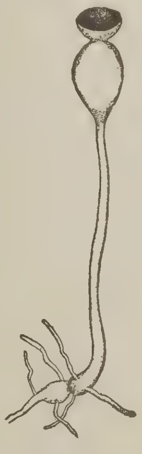

FIG. 2246.—Sporangium of *Pilobolus Kleinii*, one of the Crystalline Moulds Growing on Horse Manure. (After Brefeld.)

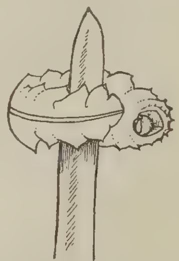

FIG. 2247.—A Larva of the Clover Weevil Affected with *Empusa*, one of the Entomophthorales, coiled about the top of a blade of grass, which is the usual position assumed in the last stages of life. (After Arthur.)

3. ENTOMOPHTHORALES, with similar methods of reproduction as those noted on the last order, but differing widely in habit, living parasitically on insects which they destroy after feeding on their substance. A most familiar example is seen in the fly fungus in which the infested insect attaches itself to a window pane or the wall and becomes surrounded by a halo of white formed by the

conidia. Another species attacks the clover weevil in its larval stage, when the worm crawls to the top of a blade of grass, coils itself around in a regular way and dies (Fig. 2247). Another form attacks the ordinary grasshopper, and he crawls up to a convenient thistle or mullein stalk and dies clasping his perch in a death grip.

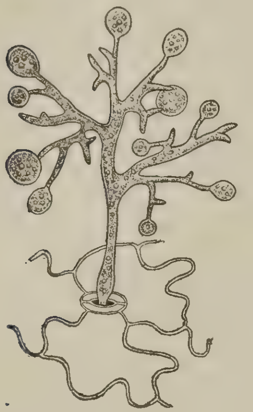

Fig. 2248.—Conidiophores of *Peronospora* emerging from a Stoma on the Under Side of a Leaf, and Bearing Conidia of Various Degrees of Development. (After Kny.)

4. Saprolegniales are water moulds which grow either saprophytically on dead flies or dead fish in the water which is their usual habit, or occasionally become destructive parasites of young fish in hatcheries or more rarely in open streams. Their methods of reproduction are quite similar to those described in the next order, except that they are primarily adapted to the aquatic habit of the plant producing them.

5. Peronosporales, including the downy mildews and the white rusts parasitic on many cultivated plants and occasionally occurring on weeds and wild plants. The potato rot and the downy mildew of the grape leaf which also produces brown rot* in the fruit represent two widespread and destructive diseases caused by members of this order. Reproduction is asexual by means of conidia forming mould-like patches on the under surface of the leaf formed of the minute tree-like conidiophores which bear dust like conidia (Fig. 2248). This method of reproduction is for the purpose of rapidly spreading the disease. A second method of reproduction is sexual by means of the direct fertilization of an egg cell by a differentiated male cell known as an antherid (Fig. 2236); this takes place within the substance of the leaf, and the resting spore resulting from the process of fertilization remains over winter, and on germinating in the spring produces a new crop of the mildew. The mycelium of the fungus penetrates the interior tissues of the plant and draws the nourishment from the cells by means of haustoria, as seen in Fig. 2249. A second member of this order forms the white rust of common crucifers, being most common on shepherd's purse and radish. In this species (*Albugo candida*) the conidiospores are borne in chains (Fig. 2250), many parallel rows forming a white blister underneath the epidermis of the plant. Other species are found on the Canada thistle, amaranth, morning-glory, salsify, and ragweed.

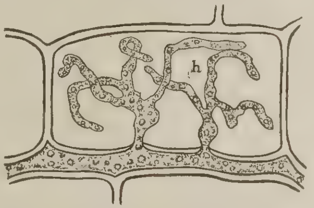

Fig. 2249.—Mycelium of *Peronospora* between the Cells of its Host and Sending Haustoria, *h*, into the Cell. (After Kny.)

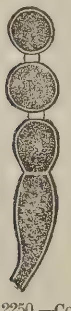

Fig. 2250.—Conidia of *Albugo candida*, the White Rust of Crucifers, Borne in Chains. (After De Bary.)

The best systematic treatment of the groups of this class, particularly the orders Mucorales and Chytridiales, may be found in Rabenhorst's "Kryptogamen Flora Deutschlands, Oesterreichs und der Schweiz," Pilze, Abtheilung IV. Only the parasitic species and the water moulds have been specially studied in our flora by Farlow, Thaxter, Humphrey, and Swingle.

CLASS II.—ASCOMYCETES (*Spore-sac Fungi*).

As stated above, the Ascomycetes are characterized by the fact that they bear their spores in asci or membranous sacs. Besides this method of spore production some of them have other methods of reproduction by means of conidia and other forms of asexually produced spores. The reproductive processes are sometimes complicated by the fact that the different stages of the reproduction are borne on distinct plants and appear at different times of the year, and moreover bear little resemblance to each other. For example, the common ergot appears as a parasitic mould-like fungus in the flowers of rye at one season of the year followed by the formation of the dark hard kernels that take the place of the rye grains and that are known officinally as ergot. The ascosporic stage of the fungus does not appear until the following spring, when the kernels (*sclerotia*) of ergot, after lying on the ground all winter as they do in nature, send up short stems which bear rounded heads in which the perithecia bearing the asci with their spores are found.

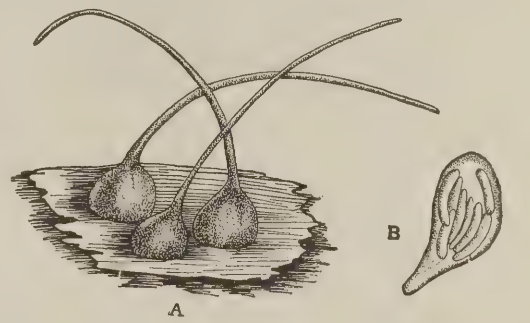

Fig. 2251.—*Ceratostomella pilifera*, one of the Saprophytic Sphæriales. *A*, Three perithecia on a fragment of decaying wood showing the long-beaked perithecia; *B*, ascus, containing the allantoid spores. (After Lindau.)

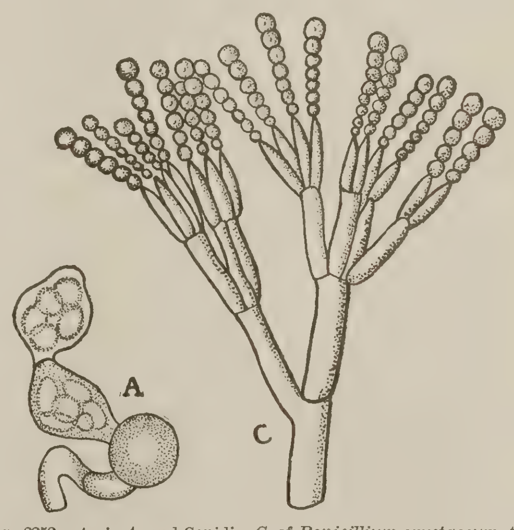

Fig. 2252.—Asci, *A*, and Conidia, *C*, of *Penicillium crustaceum*, the Ordinary Green Mould. (After Brefeld.) The asci are formed in chains.

The asci in the simpler forms are naked and more or less separate from each other; in successively higher forms the asci are found in rounded perithecia (Fig. 2253), in conical perforate perithecia (Fig. 2255, *B*), or in long-beaked perforate perithecia (Fig. 2251); in some cases the perithecia are free from each other and in others, as in the common *Xylaria polymorpha* (Fig. 2254), they are embedded in a stroma composed of compacted hyphæ often very hard. The great majority of the members of this class of fungi are small and inconspicuous; only a few are fleshy and at the same time of sufficient size to warrant their use as food.

---

* Not the *black rot* of the grape which is caused by a very distinct fungus.

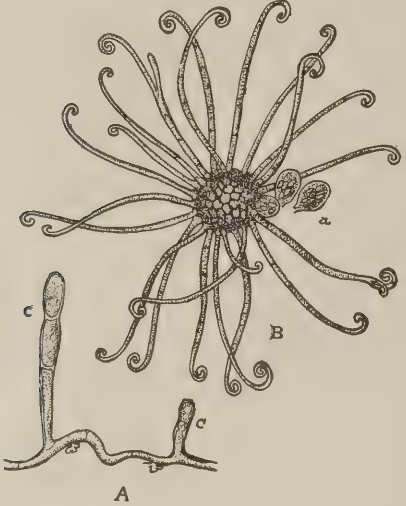

Fig. 2253.—Reproduction of *Uncinula necator*, the Powdery Mildew of the Grape. *A*, Conidial stage showing two conidia at *c*, and one just forming at *c'*; *B*, sporocarp, the result of the sexual process shown in Fig. 2252, showing the escaping asci at *a*. (After Scribner.)

Besides less conspicuous orders the more common forms of Ascomycetes are included in the following orders:

1. Saccharomycetales.—These include the yeast plants which are of economic importance in all matters connected with fermentation. In these the ordinary method of reproduction is by budding (Fig. 2234), but under certain conditions of nutrition they form what have been regarded as free ascospores four in a cell.

2. Aspergillales.—In this group are found two types of fungi, both, however, agreeing in bearing the asci in skeins or chains. One of these types is the common green mould which is well known in its conidial form (Fig. 2252, *C*), but less so in its ascosporic form (Fig. 2252, *A*). The other type of the order is an underground form resembling a truffle but reputed poisonous. It is, however, too small and too uncommon to be considered worthy of much attention here.

3. Perisporiales.—This group includes, besides a few less conspicuous plants, the important group of the Erysiphaceæ or powdery mildews, which are commonly found as parasites on a wide range of hosts among which may be mentioned the hop, grape, gooseberry, lilac, and many others. The perithecia are attached to the surface of the leaf of the host rising from a cobwebby mycelium which draws its nourishment from the epidermal cells; the perithecium is developed from a rather obscure but no less certain sexual reproduction, shown in Fig. 2237, and develops a series of curious appendages around its periphery which are often of complicated and beautiful structure. The perithecia are spherical and imperforate, but they can be easily ruptured under a cover glass when the asci and spores may be studied (Fig. 2253, *B*). A little earlier in the season the conidia are developed (Fig. 2253, *A*) and by their means the mildew is rapidly spread over other plants. The group has been carefully studied by Salmon* and furnishes a delightful introduction to the study of the parasitic fungi.

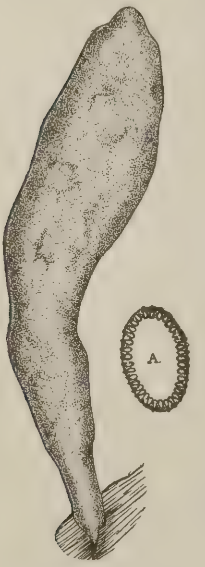

Fig. 2254.—*Xylaria polymorpha*, showing the Plant Natural Size, and a Section at *A* of the Stroma showing the Perithecia around the Margin.

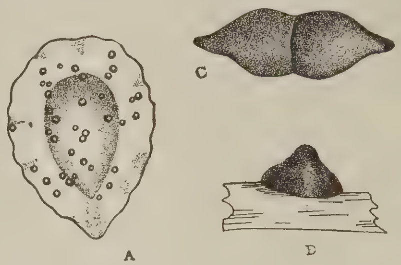

Fig. 2255.—*Caryospora putaminum*, one of the Sphæriales. *A*, Inside of a peach pit showing the scattered perithecia, natural size; *B*, a single perithecium viewed from the side; and *C*, a single spore which is apparently two-celled but has two additional minute cells at the apices.

4. Sphæriales.—This is the largest order of the Ascomycetes, and eighteen families represented by over sixteen hundred species have been described from the United States. Many of them are small or even microscopic in size, and only a few are in any way conspicuous; of the latter, one stromatic form is quite common growing in clusters about old stumps and known as *Xylaria polymorpha*, from its woody character (Fig. 2254). Another form is common on old peach pits that have remained out of doors over winter; this has discrete perithecia as shown in Fig. 2258, *A*. Still another type has long-beaked perithecia (Fig. 2251). The plants of this and three other small orders have formerly been known under the name of Pyrenomycetes and our species have been treated by Ellis and Everhart.† The species of the Sordariaceæ

have been made the subject of a recent study by Griffiths,* and this group furnishes a most valuable introduction to the study of the Ascomycetes in general and especially to the methods of cultivation in moist chambers.

5. TUBERALES.—The members of this order are all subterranean in their habits and include the edible truffle looked upon as one of the dainties of the epicure. The true truffle is found in Southern Europe, where either dogs or pigs are trained to dig them. They vary in size from an acorn to that of one's fist and have a warty appearance on the exterior. They are best when fresh, but are most commonly sold in a canned form. Two moderate-sized truffles sell in the market for about three francs (sixty cents). Various reports are current regarding their occurrence in this country, but so far the true edible truffle has not been reported. A large number of subterranean fungi have been found in California where they have been studied by the late Dr. Harkness, and if truffles are ever found in America they are more likely to occur either in California or in the Southwest where the climatic conditions more closely resemble those of Southern Europe.

6. PEZIZALES.—The cup-fungi form an extensive group which has been comparatively little studied in this country. They vary all the way from the size of a pinhead or even smaller to several inches across, some of the larger fleshy ones being used for food. They all bear the asci in a more or less concave layer in the bottom of the cup (Fig. 2256) and are normally closed above when young, but become concave, plane, or even convex as they mature. Some are stalked as shown in Fig. 2257, but the greater part are either very short-stalked or sessile.

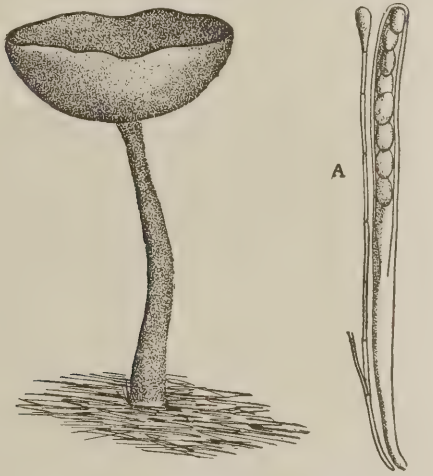

FIG. 2257.—*Peziza macropus*, One of the Cup Fungi (Pezizales), showing an Ascus with Spores and One of the Paraphyses at *A*. (After Lindau.)

7. HELVELLALES.—This, the highest order of the Ascomycetes, contains the largest species of any order and consequently those that are most likely to be concerned with the mycophagist. Two prominent types are represented by two families, which differ technically in the method of discharging their spores; the first include club-like or capitate forms, few of which are of sufficient size to furnish much of a meal though the gelatinous *Leotia* is sometimes eaten. *Mitrula phalloides* (Fig. 2258) is a fairly typical form of this family; in this species the ascospores are confined to the enlarged portion of the club. The other family, known as the Helvellaceæ, contains the morels, the gyromitras, and the helvellas, of which the first is by far the best-known group in this country, being quite widely known as the spring mushroom or in some places as *the* mushroom, it being the one most commonly used for food in certain regions. There are several species of which the most common as well as the best known is *Morchella esculenta* (Fig. 2259). All the morels are edible and delicious articles of food; in Europe they are very commonly dried for winter use and sparingly used as a delicate flavor for soups. The only plant that by any possible chance would be mistaken for them is the *Phallus* or stink-horn fungus, but no one possessed of the sense of smell would possibly mistake that for an edible species. The morel has a hollow stem, hence the plants should be carefully split and cleansed inside before eating as they are likely to contain snails and other animals which also regard them as a delicacy. In cooking, the flavor is improved by parboiling them and rejecting the original water in which they are boiled.

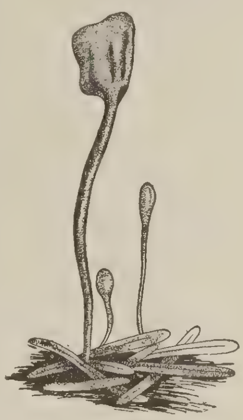

FIG. 2258.—*Mitrula phalloides*, one of the Helvellales, Natural size.

Gyromitra is a much larger fungus; *G. brunnea* has a chocolate-brown convoluted pileus and a white stem an inch or two thick; the whole plant is often five to seven inches high, and single specimens have been found that weigh as much as fourteen ounces; it has been found only in the Ohio valley region. A second species is *Gyromitra esculenta* and is a much smaller plant with a wider distribution, though it is by no means as common in America as in Europe; it is two to three inches high with a strongly convoluted brown pileus, which ranges from

---

* Griffiths: "The Sordariaceæ of North America." Illustrated with nineteen plates. Memoirs Torrey Club, vol. xi., part i., 1901.

chestnut brown to blackish according to the age or state of maturity. In Europe it is regarded as a great delicacy and is often preserved in cans for winter use. It contains a greater or less amount of helvellic acid, particularly when old, and this is a highly poisonous substance; it is soluble in hot water and can be removed by boiling and rejecting the water, but the plant should never be eaten when past its prime—a remark that may well apply to all mushrooms. The symptoms of poisoning are similar to those described for phallin below and there is no known antidote for the poison.

Besides the true Ascomycetes there are a series of forms that are analogous to conidial stages of some of the forms of the Ascomycetes. Some of these are undoubtedly conidial stages of some known or unknown species of ascus-bearing fungi for which the true relations have not yet been ascertained; some may represent forms that have lost all except their conidial stage of reproduction; while on the other hand there are doubtless a number of forms provisionally placed here from some superficial resemblance that really are perfect forms in themselves. They are known as *fungi imperfecti*, and form plant diseases known as leaf spots, anthracnose, blights, and leaf wilts.

The literature bearing on the subject of the parasitic diseases of plants is very extensive, but very widely scattered in the reports and bulletins of the various state and national agricultural experiment stations. Dr. Sturgis, of New Haven, has made an elaborate index of this literature arranged by host plants.*

CLASS III.—BASIDIOMYCETES (*The Basidial-spore Fungi*).

This group is a somewhat heterogeneous one, but contains species of fungi that produce their spores on basidia (Fig. 2242). The group includes four types of fungi as follows: (1) The lower Basidiomycetes consisting of parasitic rusts and smuts; (2) The tremellines or jelly fungi. These are represented by three orders of which the jew's ear, a dark-colored fungus used as food by the Chinese, is all that need be mentioned; (3) The Hymenomycetes, which contain the ordinary mushrooms and toadstools; and (4) The Gastromycetes, containing the puff-ball and their allies representing five distinct orders.

THE SMUTS AND RUSTS.

The smuts (order USTILAGINALES) are more or less familiar from their attacks on corn and the ordinary cereals, all of which are affected by one or more species. The chlamydospores of the fungus, which form the greasy black powder seen in the corn smut or in the smutted heads of grain, germinate with the grain and produce basidiospores, which germinate directly and produce a widespreading mycelium which grows parallel with the growth of the host plant and ultimately matures its spores.

The rust fungi (UREDINALES) are likewise parasites affecting the higher plants and many of them form destructive diseases. They are peculiar in their methods of reproduction in that some species have three distinct methods, developing three sorts of spores; others have two methods in which two different series may be represented; others may have only one method, and it may be any one of the three sorts of reproduction known among these plants. Where two or three methods of reproduction are known, the case is often complicated by one of them occurring on a different host plant from the others. The ordinary wheat rust is the common type which presents as complicated an example as possible.

THE HYMENOMYCETES.

After passing over the three orders of the tremellines or gelatinous fungi we come to the ordinary toadstools and mushrooms which, in accord with modern terminology, form the order AGARICALES. Of these there are three families that contain fleshy species, and these can be easily distinguished by the nature of the spore-bearing surface which appears underneath the pileus; those bearing lamellæ belong to the agaric family (Agaricaceæ); those with pores or tubes to the Polyporaceæ; and those with spines or teeth to the Hydnaceæ; a fourth family also containing fleshy species is devoid of a pileus, but consists of club-like or coral-like fungi often greatly branched and dividing; these are the Clavariaceæ; there is still another family but it is not of importance in the present consideration.

1. AGARICACEÆ.—In the ordinary pileate mushrooms the spore-bearing surface is spread over a series of radiating lamellæ underneath the cap or pileus; on this surface the spores are borne on basidia and at maturity drop and are scattered by the wind; these spores are of different colors in various species, and this fact has been made use of in distinguishing the various genera. The young plant has the pileus commonly closed something after the manner of an umbrella, and the stem is then short so that the whole mushroom at an early stage is massed into the form of a ball. In certain species the whole plant is enveloped in a more or less membranous covering known as the *volva* (Fig. 2261, *C*); as the mushroom expands this volva is ruptured and it is either carried up on the top of the pileus in the form of separable scales or it remains at the base in the form of a cup; this is by far the most important portion of the mushroom as it is the one by which the most dangerous fungi are detected. It is absolutely necessary to have the complete base of the stem certainly to distinguish between edible and poisonous forms. An additional structure to be noted is the *veil*, which in the young form extends from the margin of the pileus to the stem as a complete covering, but which normally breaks away from the margin of the pileus and forms a more or less definite ring (*annulus*), which may be narrow and ring-like or hang down in the form of a skirt. In one genus the veil separates from the stem and hangs in a fringe around the margin of the young pileus; in at least two genera the veil is very slight though clearly marked in young forms but entirely disappears in the older plant so as to appear to be entirely wanting. While it is comparatively easy for one familiar with mushrooms clearly to distinguish the ordinary genera at sight as easily as the maples, oaks, or pines are distinguished among trees, it is more difficult for a novice to distinguish them even with keys at hand for separating them. The following synopsis of the genera containing edible or poisonous species may be helpful in attaining this end.

SYNOPSIS OF THE GENERA OF AGARICS CONTAINING EDIBLE AND POISONOUS SPECIES

- Stem central.
  - Juice milky, white or colored .... LACTARIUS.
  - Juice not milky.
    - Spores white.
      - With a volva and annulus both................ AMANITA.
      - With a volva but no annulus......... .... AMANITOPSIS.
      - Volva wanting but annulus present.
        - Lamellæ free from the stem; pileus normally scaly .... LEPIOTA.
        - Lamellæ united with the stem .... ARMILLARIA.
      - Both volva and annulus wanting.
        - Lamellæ thin with acute edges.
          - Lamellæ free; plant reviving after drying. MARASMIUS.
          - Lamellæ decurrent; stem fleshy........... CLITOCYBE.
          - Lamellæ adnate; plant brittle; stem fleshy; pileus usually bright colored .... RUSSULA.
          - Lamellæ sinuate; stem fleshy............. TRICHOLOMA.
        - Lamellæ in the form of shallow folds with obtuse edges; plant yellow.................. CANTHARELLUS.
    - Spores pink or salmon-colored; with neither volva nor annulus.
      - Lamellæ free from the stem .... PLUTEUS.
      - Lamellæ decurrent on the fleshy stem .... CLITOPILUS.
    - Spores rusty brown; annulus arachnoid disappearing when mature; lamellæ adnate......... CORTINARIUS.
    - Spores dark brown or black.
      - Pileus melting to a black inky fluid when mature COPRINUS.
      - Pileus not melting; spores dark brown.
        - Veil remaining as an annulus; lamellæ free. AGARICUS.
        - Veil remaining as a fringe on the margin of the pileus; evanescent when old.......... HYPHOLOMA.
- Stem lateral or wanting; spores white or lilac-tinted. PLEUROTUS.

Some of the above terms will require some illustration and the following figures will be useful; the lamellæ may be *free* (Fig. 2260, *F*), or variously attached to the stem, in which case they may be *adnate* (Fig. 2260, *A*), *sinuate*, or notched near the stem (Fig. 2260, *S*) or *decurrent* as in Fig. 2260, *D* and in Figs. 2262, 2263.

---

* Report Connecticut Experiment Station, 1897, 182–222.

(*White-spored Series.*)

Amanita.—The white-spored agarics with both veil and volva contain all the most deadly fungi and their characters should be carefully noted. Fig. 2261 gives a characteristic illustration of *Amanita phalloides* which is the more dangerous because it superficially resembles some of the edible species. Its volva and veil have already been noted; it should be observed, however, that in some species of *Amanita* the volva in mature forms may not form a distinct cup at the base at shown in the figure, but may exist in the form of a straggling fringe of teeth at that point, the greater part having been carried up in the form of floccose scales at the top of the pileus. We have quite a number of species besides the four enumerated below, and though some of them are edible the best advice that can be given the amateur is to learn to distinguish the genus *Amanita* and then let it entirely alone.

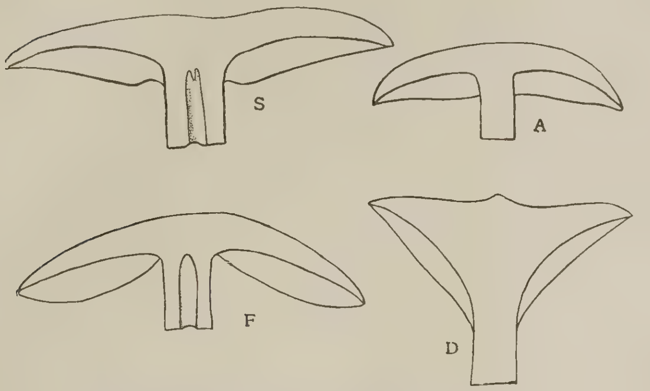

FIG. 2260.—Methods of Attachment of the Lamellæ of Agarics to the Pileus and Stem, shown in Sections. *A*, Adnate lamellæ; *D*, decurrent lamellæ; *F*, free lamellæ; and *S*, sinuate lamellæ. In *F* and *S* the stems are hollow.

The two most poisonous species are the fly-agaric (*Amanita muscaria*) and the poison cup (*Amanita phalloides*). *Amanita muscaria* has a yellowish pileus varying from yellowish-white to yellow orange* and has a white stem, white lamellæ, and white veil. The volva appears at the base of the bulbous stem only in the form of scales, the greater part of it being carried up in the form of loose floccose scales at the top of the pileus. The poison it contains is known as muscarin, which has a very unpleasant taste; symptoms of poisoning from it occur in from a half an hour to two hours after eating. (For an account of the actions, symptoms, and treatment, see *Poisoning*).†

Amanita phalloides is still more dangerous because it contains phallin for which there is no known antidote. The species varies in color, being pure white, yellowish, greenish-olive, or umber in its different forms; the pileus is usually viscid or slimy when moist and in age is often free from any of the remnants of the volva; the lamellæ, stem, and veil are all white; the volva is subject to the greatest amount of variation of any portion, sometimes being largely carried up to the top of the pileus and sometimes remaining more prominently as a cup at the base. It has been something of a question as to whether these variations do not indicate more than one species, but the fact remains that all of them are deadly poisonous. The phallin that they contain is regarded as an albuminous poison and acts directly on the blood corpuscles. There is no unpleasant taste in the fungus to warn the patient, and preliminary symptoms do not commence until from nine to fourteen hours after the poisonous mushrooms are eaten.* Besides these two poisonous species there is one edible species that should be mentioned, since its use as an article of food is historic as well as extensive. In Italy where it has been very extensively used since the time of the Romans, hundreds of bushels are brought into the markets of the cities during its season, and it is equally common in our Southern States, being found rarely as far north as Massachusetts. This is known as Cæsar's mushroom (*Amanita cæsarea*) and is most nearly related in appearance to the fly agaric. It can, however, be readily distinguished by the following marks: the pileus is usually a deep orange yellow, rarely appearing lighter colored; the stem, veil, and gills are all a clear yellow color; the volva appears in the form of a firm cup at the base of the stem and is white, fragments being rarely carried up on the pileus as is so common in the fly agaric. It is often very large, sometimes expanding to ten inches or more across the pileus, though it occurs in much smaller forms.

Amanitopsis.—This genus differs from *Amanita* in having no veil or annulus, and agrees with it in the possession of a volva. *A. vaginata* is very common in some portions of the country and is regarded as a delicacy; it has a thin usually grayish pileus, which is distinctly striate on the margin; the stem and lamellæ are white. .

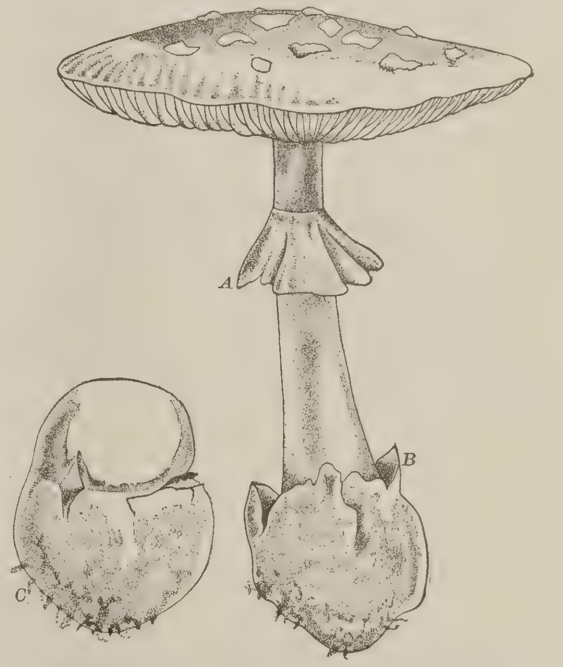

FIG. 2261.—*Amanita phalloides*, the most Poisonous Mushroom. One-half natural size. *A*, Annulus; *B*, volva; *C*, young plant enveloped in volva.

Lepiota.—The species of *Lepiota* are known as parasols and for the most part are edible species. The only exception known is seen in the anomalous *L. Morgani* which differs from all other agarics in the possession of green spores; it is very common in various parts of the Ohio valley and southward and has occasioned severe illness from being used as food; others have partaken of it with no ill effects, but it should be classed as doubtful. *Lepiota procera* is common in the Northern States and can be distinguished by its brownish or reddish-brown pileus, three to five inches across, and its very long hollow stem frequently reaching ten inches in length and bulbous at the base. *L. naucinoides* is a white species with a slightly bulbous base; it is likely to be confused with species of *Amanita* which it resembles closely except that it has no volva; as *Amanita phalloides* sometimes grows in cultivated fields where *Lepiota naucinoides* occurs, the danger becomes all the greater of confusing the two species. There are numerous other species of *Lepiota*, but none of them need consideration here.

---

* In European works this species is figured a bright red, but I have never seen it this color in America.

† Illustrations of the fly-agaric may be consulted as follows: Michael: "Führer für Pilzfreunde," No. 55; Marshall: "Mushroom Book," pl. 1; Gibson: "Edible Toadstools and Mushrooms," pl. 4; Atkinson: "Studies," Figs. 52–54; McIlvaine, "1,000 Amer. Fungi," pl. 9; Cooke: "Illust. British Fungi," pl. 117: Fries: "Sverig. atl. Svampar," pl. 1; Gillet: "Champ. de France," pl. 8.

* Illustrations of the poison-cup may be consulted as follows: Michael: "Führer für Pilzfreunde," No. 58; Gibson: "Edible Toadstools and Mushrooms," pl. 13; Atkinson: "Studies," figs. 55–57; McIlvaine: "1,000 Amer. Fungi," pl. 6, figs. 2 and 3; Cooke: "Illust. British Fungi," pl. 2; Bulliard: "Flore de la France," pl. 2; Gillet: "Champ. de France," pl. 3.

Armillaria.—Only one species of this group needs attention here. It is a gregarious species growing about old stumps, the pileus ranging from whitish to reddish-brown, though brownish-yellow is the more common tint. The lamellæ are white at first but become reddish with age. It is sometimes eaten though is not considered very palatable. It is of most importance as a destructive agent of growing timber, as its widely spreading mycelium penetrates the heart wood of trees at some distance from where the mushroom appears above ground and produces decay to the height of several feet.

Marasmius.—To this genus belongs the fairy ring champignon often seen in lawns and pastures, forming circles or part circles often many feet in diameter. The genus differs from the ordinary fleshy agarics in having a persistent pileus which revives after desiccation and produces a new crop of spores. The pileus is an inch to an inch and a half in diameter.

Clitocybe.—To this genus belong several diverse species, all agreeing, however, in having a fleshy stem and decurrent lamellæ. *Clitocybe illudens* is a large golden-yellow species, often produced in clusters of fifty or a hundred at the base of old stumps. It is a gorgeous species, but has a bad reputation as an article of diet, though it is not known to be poisonous. A smaller species (*Clitocybe laccata*) is sometimes eaten. The general characters of the genus can be seen in the two illustrations (Figs. 2261 and 2262).

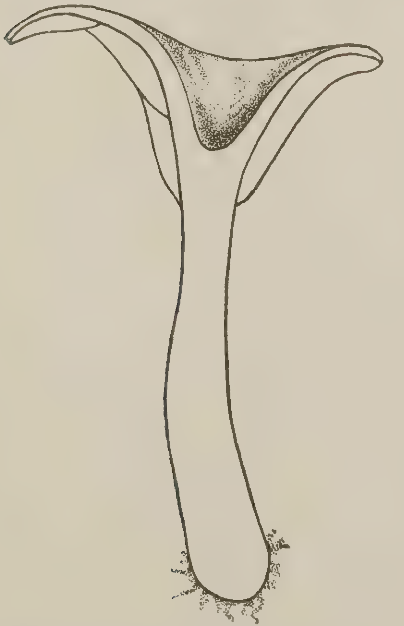

Fig. 2262.—*Clitocybe cyathiformis*, One of the Agarics, showing Infundibuliform Pileus and Decurrent Heterophyllous Lamellæ. (After Cooke.)

Russula.—The species of *Russula* are not well known but are comparatively numerous and common and conspicuous features of every forest and shaded path from their bright colored red or green pilei. Several of the species, among them the poisonous *Russula emetica*, have a strong acrid taste when raw, and the members of the genus unsuitable for food may be distinguished by tasting them in a raw condition. The acrid ones have a peppery taste. *R. emetica*, as its name indicates, produces nausea and from its peppery taste is not likely to be confused with edible species; *Russula virescens* with pale apple-green pileus is often eaten. While bright colors like red and green predominate in the genus, some are white and others clay-colored and brown.

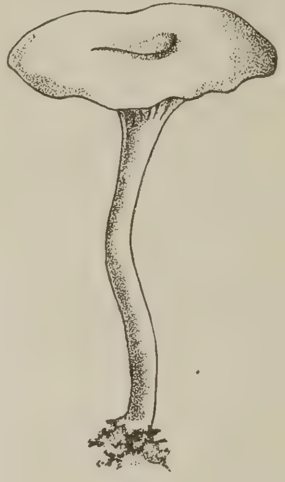

Fig. 2263.—*Clitocybe fragrans*, One of the Agarics, showing Umbilicate Pileus and Decurrent Lamellæ. (After Cooke.)

Lactarius.—The milky fungi are closely allied to Russula structurally, but differ in yielding a milky fluid when bruised or cut. They are often peppery to the taste, and the commonest white species is called *Lactarius piperatus* from this circumstance. By this means the objectionable species can be detected, though even *L. piperatus* is sometimes eaten as its peppery taste is said to be removed in cooking. *L. volemus* is a species with white milk and a reddish-brown pileus and stem; *L. deliciosus* differs from all others in having orange-red milk; as its specific name would indicate, it is a delicate article of diet. We have some forty species in this genus.

Tricholoma.—Only one of the many species of this genus need be considered here; this is *T. personatum*, whose spores are often dirty white instead of pure white as in most of the genus; the whole plant is a pale violet lilac color, and this color is usually constant in the younger conditions of the plant; it is very common late in the season in waste grounds and dumping places. *Tricholoma sulfureum* with a dry yellow pileus is about the only suspicious member of the genus, though even that is not known to be poisonous.

Pleurotus.—The so-called oyster mushrooms are readily distinguished by their lateral habit, either having no stem at all or being attached by a very short lateral stem; none of the species are injurious and many of them have a delicate flavor; *P. sapidus* with violet-tinted spores is the most abundant, and there are several other quite closely allied species.

Cantharellus.—This genus contains the chantarelle or Eierpilz of the Germans, much used for food in Europe where it is more common than with us. *C. cibarius* is the common species of an egg-yellow color. *C. floccosus* is a larger species of a lighter yellow color and forms funnels four to six inches high.

(*Pink-spored Series.*)

Pleuteus cervinus is one of the most abundant species of its group, growing always on decaying logs and characterized by its mouse-colored pileus, its lamellæ separate from the stem and its pink spores. It is reputed edible.

Clitopilus differs from this genus in its decurrent lamellæ; the sweetbread fungus (*C. orcella*) and the allied *C. prunulus* are the only species that are likely to be met and neither is very common.

(*Rusty-spored Series.*)

Cortinarius is a very extensive genus, its species usually appearing in woods from late in the summer to November. They are all terrestrial, by which character the genus is distinguished from its rusty-spored neighbors; when young the species have a cobwebby veil which disappears with age. One of the commonest is the violet

Cortinarius, which has a deep violet color throughout, except the mature lamellæ which become rusty brown from the ripening spores. Our numerous species are not so well known as those of many other genera; none of the species, however, are reputed poisonous.

(*Brown- or Black-spored Series.*)

Agaricus contains the common field mushroom (*A. campestris*) and quite a number of allied species. While this species is generally well known it may be well to add its diagnostic marks: 1. It has no volva whatever at the base of the stem. 2. The lamellæ are pink when young but gradually change to brown or blackish-brown as the spores mature. 3. The lamellæ are free from the fleshy stem, and when young are covered with a veil which later forms a distinct ring around the stem. 4. The stem is stuffed, or filled with a somewhat softer substance. This is the mushroom commonly cultivated from spawn, and immense quantities of mushrooms inferior to those that can be grown in this country are canned in France and imported to this country. It is said that mushrooms may be grown at a profit to retail at twenty five cents a pound, but the price in New York is sometimes six or eight times that amount.*

Hypholoma.—One of our commonest late fall mushrooms is the brick-top often growing in large masses at the base of stumps. Professor Peck distinguished several species, using taste as a guide in separating species. *H. sublateritium* is commonly reputed poisonous in Europe, but many of the closely allied species have a delicate flavor. Specimens used for food should be individually tasted before cooking and those with a bitter taste should be rejected.

Coprinus.—The species of this genus are among the most abundant of the wild mushrooms and three species are common in lawns and waste places. The genus can be very readily recognized by the fact that the pileus melts speedily to an inky fluid when mature, and it has taken the popular name of ink-cap from this circumstance. *C. micaceus* is a small species that grows in prodigious quantities about old stumps, often appearing very early in the spring; it has a thin pileus of a pale buff or yellowish color and narrow lamellæ. *C. atramentarius* grows in clusters often of many individuals; it has a grayish-brown moist pileus and very wide crowded lamellæ; *C. comatus*, popularly called the shaggy mane, is cylindrical in shape and has a shaggy pileus formed of yellowish-brown scales on a white foundation. It is more common in the autumn, usually growing in waste grounds.

In recent years the subject of edible mushrooms has become considerable of a fad in this country and several works of greater or less value have appeared treating the subject in a more or less popular manner. Among the best of these are Miss Marshall's "Mushroom Book," Gibson's "Edible Toadstools and Mushrooms," and Atkinson's "Studies of American Fungi," while McIlvaine has published a more aspiring work under the title "One Thousand American Fungi." All are extensively illustrated, the first and third named with many reproductions of photographs. The best general work on the subject of edible species, however, is Michael, "Führer für Pilzfreunde." The text is in German, but the principal edible and poisonous species, most of which are common to Europe and America, are illustrated with excellent colored plates.

The nutritious character of mushrooms has been greatly overstated in many works of a popular nature. The nitrogen supposed to be the nutrient element in mushrooms is found to belong in part to proteid substances of low food value, and a portion is found in substances that are indigestible and hence not available for food. The mushrooms are to be regarded as a delicacy rather than as a staple article of food, and their nutrient value, instead of being comparable to meats as was formerly supposed, is rather to be compared with succulent vegetables. Their cultivation and study, however, are worthy of much greater attention than they have been given heretofore in this country.*

2. POLYPORACEÆ.—Certain of the fleshy species of bracket fungi, such as are seen growing on old tree trunks, are edible. Among these *P. sulfureus* with bright-yellow pores and dainty pinkish-yellow pileus is best known; it is a large species often growing in large overlapping masses which are conspicuous from their brilliant color.

P. frondosus, a brownish species with extensive compound branches, is also said to be edible. Most of the bracket fungi, however, are curious and ornamental merely as they are of a woody consistence; the two mentioned above indeed are useful for food only when very young. It is said that the substance of *Polyporus officinalis* has been used as a substitute for quinine, but its properties have never been thoroughly investigated. The beefsteak fungus (*Fistulina hepatica*) grows as a fleshy tongue-like mass from chestnut trees and can be easily recognized by its fibrous beef-like consistency and its tubes whose mouths are entirely separate from each other. It has much the same appearance as real beefsteak and is cooked in the same way.

Most of the fleshy spore-bearing fungi, however, belong to the genus *Boletus*, of which we have many common species. Some of them have a bitter taste like the common *B. felleus* and should be rejected; one entire section of the genus has tubes whose mouths are a lurid red, a totally different color from the rest of the tube; these are regarded as poisonous and are to be carefully avoided; other members of the genus change the color of the flesh to a bright blue when wounded and exposed to the air. This is particularly true of a species which in one of our popular works on mushrooms has been figured under an incorrect and misleading name †; it has a reddish pileus and the flesh instantly changes on exposure to injury. It is a dangerous species, the more so because it has been figured as an edible one.

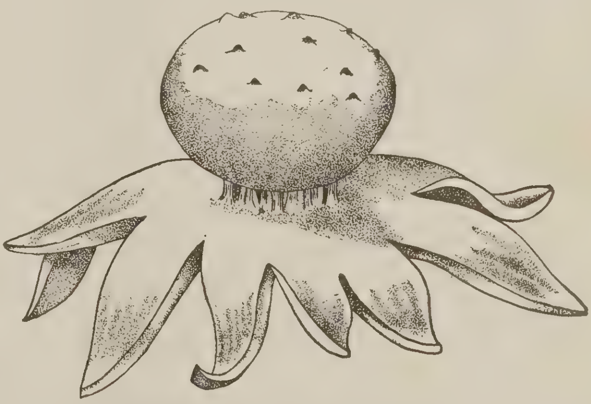

FIG. 2264.—*Myriostoma coliforme*, a Rare Member of the Puff Ball Family (Lycoperdales).

Many of the *Boleti* are edible, but the species are difficult to distinguish by a description; like most fungi they have distinctive characters by which they may certainly be known when seen and the safest guide is some one already familiar with the species. Once learned in this way the species of mushrooms are as easily distinguished as the ordinary fruits or vegetables.

3. HYDNACEÆ.—Two types of edible toothed fungi are found. One consists of white coral-like masses in

---

* There are numerous works bearing on mushroom culture, but the following are as good as any: Falconer: "Mushrooms; how to Grow Them," 1896, and Robinson: "Mushroom Culture; Its Extension and Improvement," 1870. The Department of Agriculture at Washington has also issued a free bulletin on the subject.

* Concerning the nutrient value one can profitably consult Dr. Mendel's results of chemical analysis in American Journal of Physiology, I: 225–238, 1898.

† Palmer's: "Mushrooms" as *Boletus subtomentosus*; its true name is *B. miniato-olivaceus*.

which *the teeth all point downward* when growing; all the species are found on tree trunks. They are easily recognized by their teeth, and the three common species, *Hydnum coralloides*, *H. erinaceus*, and *H. caput-ursi* are all equally edible.

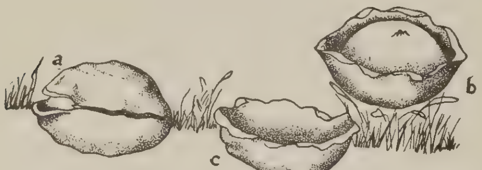

FIG. 2265.—*Catastoma circumscissum*, One of the Lycoperdales. Natural size. *a*, Shows the outer peridium rupturing at the equator; *b*, shows the upper part removed and overturned with the inner peridium rupturing with a single crater at a point originally at its base; and *c*, shows the lower half of the outer peridium left as a cup in the earth after the removal of *b*. (After Morgan.)

Two pileate species are also edible; *H. repandum* with yellowish or whitish-yellow pileus and teeth very brittle, and *H. imbricatum*, brown with overlapping scales on the pileus and grayish teeth.

4. CLAVARIACEÆ.—The club-fungi growing in the form of coral-like masses *with the branches pointing upward in growth* contain several edible species. None of them are dangerous, and they form a good subject for experimentation as they are often abundant in moist woods.

It will be readily seen from the above sketch that no hard and sharp rules can be given that will distinguish edible species of mushrooms from poisonous. Like the higher plants there are good, bad, and indifferent species, and the separate species can best be learned as good or bad by intimate acquaintance with them, the same as we have become able to distinguish apples from pears and carrots from radishes by learning each one separately.

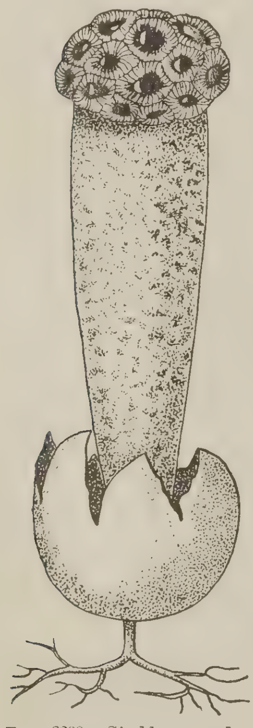

FIG. 2266.—*Simblum rubescens*, One of the Phalloids. In life the stem is reddish; in the early stage the entire plant is enclosed in the cup-like base, then in the form of an egg. (After Gerard.)

THE GASTEROMYCETES.

The last group of fungi are represented by the puff balls and their allies that in some respects represent some of the highest developments among the fungi. It is scarcely necessary to call attention to the peculiarities of the various orders and families, but attention can be called to a few typical forms, since some of them are abundant and excellent articles of food. Among these is the giant puff ball (*Calvatia Bovista*), which sometimes reaches a prodigious size and often is large enough to furnish a meal for several people. Smaller species ranging from three to six inches in diameter are *Calvatia cyathiformis* and *Calvatia craniiformis*. In the former the mature spores are purplish, in the latter they are olive brown. It is only when the flesh of the puff-ball is pure white and much the consistence of cottage cheese that it is suitable for food, and any indication of darkening, caused by the ripening of the spores, should cause the plant to be rejected.

A smaller fungus is commonly seen in *Bovista plumbea*, which is only an inch or so in diameter, but is considered a delicacy in some places. The numerous smaller species of *Lycoperdon* are likewise edible, but are usually too small to be considered available for food. Allied to the puff balls are the curious earth-stars of which no less than three genera are represented in America. Fig. 2264 represents the least common form. *Geaster*, more common, differs mainly in being attached to the outer peridium at one point and opening by a single crater.

Another puff ball with the curious habit of overturning and opening at the bottom of the inner peridium is seen in *Catastoma*, whose life history was first studied by Morgan (Fig. 2265).

The stink-horns belong to an order (Phallales) distinct from the puff balls (Lycoperdales). These well-known members of the group are reputed poisonous and all doubtless contain phallin as one of their constituents. They form underground in the shape of an egg, and this bursting allows the rapid distention of the stem by means of which the spore mass is carried up where flies may be attracted to it and aid in their dispersion. Three of the larger species are more or less common throughout the country, and there are several curious forms less widely known, one of which is represented in Fig. 2266.*

Lucien M. Underwood.

FURUNCLE. See *Boil.*

GAINESVILLE (GA.) MINERAL SPRINGS. — The town of Gainesville is located in Hall County on a small tableland 1,300 feet above the sea-level, and lies between the headwaters of the Oconee River, which flows into the Atlantic, and those of the Chattahoochee, which finds its way to the Gulf. The Alleghanies, stretching around the place to the north and west, form a natural bulwark which breaks the force of the northern winds of winter. The town thus enjoys a dry, bracing climate, without extremes of either heat or cold. Daily observations made for the United States Signal Service during the period of ten years showed a mean winter temperature of 44° F. and a mean summer temperature of 71° F. The health tables of the United States census show a lower death rate in this portion of Georgia than in any other section of the country. White, in his "Statistics of Georgia," makes the statement that no case of consumption was ever known to originate in Hall County. In close proximity to the thriving and rapidly growing little city are numerous mineral springs, some of which have come into use as health resorts. We have thought it advisable to consider these springs in the following group:

Gower Springs form one of the chief attractions of the city. They are located just beyond the corporate limits, and are connected with the city by a street-car line. These springs are chalybeate in character, the iron being held in solution by carbonic acid, which makes it readily assimilable. The following qualitative analysis was made some years ago by Prof. W. J. Land, of Atlanta:

Free carbonic acid.
Hydrosulphuric acid.
Iron carbonate.
Manganese carbonate.
Iron apocrenate.
Potassium sulphate.
Sodium sulphate.
Iron crenate.
Lithium phosphate.
Calcium sulphate.
Magnesium sulphate.
Potassium bromide.
Oxygen gas.
Nitrogen gas.

An excellent hotel is maintained at the Springs, and we are informed that an increased number of visitors come to the resort every year. The waters are recommended in general debility, digestive disorders, and kidney affections.

The *Deal Spring*, located two miles from the city, wells up in a basin of solid rock, and is said to possess excellent properties in the treatment of indigestion and dyspepsia and in the dentition period of children.

---

* The present illustrations are reproduced from a series used to illustrate an introductory work on fungi, by the author of this article, "Moulds, Mildews, and Mushrooms," New York, Henry Holt & Co.

The *New Holland Springs* are also within two miles of Gainesville, on the Southern Railroad, which has a station at the Springs. The improvements consist of a hotel and cottages for two hundred guests. The situation is in a beautiful and extensive grove of native oaks, and the Springs furnish about two hundred gallons of water per minute. The water is recommended for indigestion and general debility, but we are unable to present a complete analysis in verification of its claims. An old qualitative examination showed the presence of the following ingredients:

Calcium carbonate.
Magnesium carbonate.
Potassium carbonate.
Iron, probably combined with carbonic acid.
Sodium chloride.
Carbonic acid gas.

James K. Crook.

GALACTAGOGUES.—(Gr. *γάλα*, milk, and *ἄγειν*, to lead.) The secretion of milk is normally associated with pregnancy, but may occur in pseudocyesis, and in ovarian and uterine tumors. It is often seen during the first week of life, in both male and female children. The secretion of milk may be established and maintained by the application of a nursing child to the breast of a woman who is not at the time and never has been pregnant. In one case a child eight years old nursed her mother's infant for some months, and in another a woman, fifty-nine years old, ten years after the cessation of menstruation, nursed a child for some time.

The length of time during which the milk may continue to be secreted varies from nine to sixteen months, but in rare cases this period may be prolonged for as long a time as five years, if the child be allowed to nurse.

The causes of defective lactation are various in character. Thus, for example, there may be some mechanical interference with the escape of the milk, as when the lactiferous tubes and acini are not developed, or the epithelial cells are imperfect, or a previous injury or disease has caused total destruction of the glandular tissue. These conditions are not amenable to treatment. On the other hand, when there is simply a lack of development, or the gland and nipple have received some trifling injury, the condition should be investigated and treated before the end of gestation. The breast of every pregnant woman should be examined by her physician three or four months before the expected confinement, and if the breasts are found to be small and poorly developed and the nipples fissured or depressed, appropriate treatment should be instituted. If the nipples are hard, the application of some bland aseptic oil or ointment—*e.g.*, lanolin and boric acid—will be found useful as a means of softening them. The breast should be massaged, and at the same time the nipples should be drawn out by grasping them between the thumb and finger, while with the other hand the breast is stroked toward the nipple. This should be done daily for five or ten minutes at a time. The adoption of these measures will enable the child, when placed at the breast—which should be done as soon after labor as the mother's strength will permit—to grasp the nipple effectively. After this first attempt at nursing, the child should be placed at each breast, alternately, every four hours. Should the child be unable to grasp the nipple, the latter should be drawn out with the breast pump or a clay pipe, and, if this does not prove sufficient, a glass nipple shield, with rubber nipple, should be employed. The sucking of the child is the best stimulus to the flow of milk, and should always be obtained if possible; but, if the child cannot be made to nurse, then suction will have to be made with the breast pump for five or ten minutes every four hours. The breast at the birth of the child contains colostrum, and at the end of from thirty-six to sixty hours ripe milk. During the first period the child should be nursed every four hours, but afterward, on the appearance of ripe milk, it should be nursed every two hours.

Another cause of defective lactation is a plethoric state of the body, a condition which readily responds to treatment. The diet should be carefully regulated, milk being made one of its chief constituents, and all stimulants should be avoided. The extract of thyroid gland should also be prescribed in five-grain doses. Under this plan of treatment, combined with the occasional administration of a dose of castor oil, the obstruction to the flow of milk should soon disappear. In these cases the use of the thyroid gland extract not only increases the flow of milk, but at the same time improves its nutritive quality.

Torpor of the mammæ is another cause of inactivity of their secretory apparatus, and when this is the case great benefit may be derived from the application of electricity. Both poles having been moistened, the positive one is placed deep in the axilla or on the back, while the negative one is applied gently over the nipple. The current employed should be no stronger than is agreeable to the patient, and this mode of applying it should be continued for about two minutes. Afterward, the negative pole should be glided along the sides of the breast, in a stroking fashion, for another two minutes. Then, finally, the poles should be applied to the sides of the breast for the same length of time. Electricity may be applied in this manner once a day for a period of four or five days; and usually it will be found that a single such séance will fill the breasts after the milk has disappeared for some days.

Among the other local therapeutic methods which have been used with varying success may be mentioned the application of warm poultices made of a weak mixture of mustard (not strong enough to burn) or of calabar bean, or of the leaves of the castor-oil plant. Gentle massage alone will often suffice to start the flow, or we may combine with it inunction of olive oil or of castor oil. Repeated applications of the breast pump and enveloping the breast with warm cloths are also very efficient methods.

The internal administration of drugs, for their galactagogue action, has not proved very satisfactory. Jaborandi will, it is true, increase the flow of milk, but its action is only temporary and cannot be depended upon when a prolonged effect is needed. It is best given in the form of the fluid extract of pilocarpus, in half-drachm doses; this preparation being less nauseating than the jaborandi itself. Or the effects of the drug may be obtained from hypodermatic injections of pilocarpine hydrochlorate, in gr. $\frac{1}{12}$ doses.

Physostigmine increases temporarily the flow of milk. So also do the preparations of ammonia—the carbonate and the acetate—when given in moderately large and continued doses. The alcoholic stimulants, such as ale, porter, and beer, and the malt preparations possess the power of increasing the quantity of milk secreted, but the quality is thereby deteriorated. To such a degree is this true that they should rarely be used except in small quantities. The volatile oils, especially the oil of anise, impart a pleasant flavor to the milk, and in consequence the child will be likely to draw much better. In this indirect manner they may serve to increase the flow of milk.

The most usual cause of defective lactation is anæmia. It is a well-known fact that the functional activity of an organ is directly proportional to the supply of blood furnished to that organ, and this is a very important law to remember when we are dealing with such a gland as the mammary. We may therefore expect to secure the greatest improvement in the secretion of milk from the taking of those substances and the adoption of those hygienic measures which tend to increase the supply of blood and to improve its nutritious qualities. The mother should be in the best possible condition before and after the arrival of the child, and this result should be secured by the administration of tonics, such as iron, arsenic, nux vomica, and quinine, and by the patient's taking proper food and exercise. The diet suitable for a nursing mother should be nutritious and easily digested. For the first few days of the puerperal period the mother should have milk, animal teas and broths, eggs, gruel, soups of beans and peas, and small amounts of tea, cocoa, or coffee, with toast and crackers. It is well to avoid the limited diet of tea and toast which so many women take at this time. Later on in this period and during that of lactation, the mother should have an abundant supply of water, soups, meats, milk, eggs, and vegetables. Of the latter turnips, carrots, beets, potatoes, spinach, asparagus, and lettuce will aid in the formation of milk. The mothers of the working class will be found to give milk in larger quantity and of a better quality than do those who live under higher social conditions. This is due to their simple mode of living and to their outdoor life.

Systematic exercise in the open air should be taken as soon after confinement as the mother's condition will permit, for by this means the proteids will be diminished in amount and the fat increased, thus creating a milk which is easily digested by the child.

The mother should at the same time avoid those drugs which decrease the milk supply, namely, belladonna, when taken in large amounts or used locally, and saline and hydragogue purgatives; for the removal of large amounts of fluid from the body will greatly diminish the supply of milk. It is also desirable to prevent, as far as possible, any nervous shock or worriment, for the effect upon the mother is likely to be such that her milk will be rendered unfit for the child.

The proper care of the breast during lactation is important. The nipple and breast should be washed with a saturated solution of boric acid both before and after nursing, and these parts should be kept covered with soft sterile lint or gauze held in place by a breast binder which gives support and ease to the breast. If this course is adopted there will be fewer cracked nipples and abscesses of the breast. In cases in which fever occurs during lactation it is often possible to retain the secretion of milk for three or four weeks, if the breasts are gently massaged and emptied three or four times a day with the breast pump. Then, when the temperature returns to normal, the child may again be put to the breast. In those cases in which there has been an abscess of the breast in early infancy, or during a former lactation, the danger of the formation of a fresh abscess is only slightly greater than it is in a perfectly normal breast. If care is taken to keep the parts thoroughly clean, and if they are not allowed to become engorged, we may rightly expect that such a breast will furnish a sufficient supply of good milk. *Stricker Coles.*

GALANGA; GALANGAL.—Lesser Galangal. The rhizome of *Alpinia officinarum* Hance (fam. *Zingiberaceæ*), a perennial herb of flag-like habit and the floral peculiarities of ginger and cardamom plants. It is an inhabitant of Hainan and other parts of Southern China, where it is also cultivated as an article of commerce. Galanga has been long known in Europe, as well as in Asia, and was formerly esteemed as a domestic spice or flavor.

The dried rhizome is cylindrical, often branched, about as large as the little finger, and in pieces two or three inches in length. The nodes are close together and very prominent, as slender annulations. Texture hard, tough; color deep brown; odor aromatic, curcuma-like; taste pungent. It contains an *essential oil* to which its odor is due, and probably some pungent resin. The oil is reddish-yellow, with the odor of cajeput and the taste of camphor. It has a specific gravity of 0.921, and contains cineol. Its qualities as a medicine are essentially those of ginger. As a medicine galanga is obsolete in Europe, and nearly so as a spice, although it is said to be used with other things in flavoring cordials, in veterinary mixtures, etc. *Henry H. Rusby.*

GALBANUM.—"A gum-resin obtained from *Ferula galbaniflua* Boiss. et Buhse (fam. *Umbelliferæ*), and probably from other species" of *Ferula* (B. P.; no longer official in the United States). It is not certain whether the product of the "other species" always comes separately, as it certainly sometimes does, or whether the drug is sometimes a mixed product. The plants are huge perennial herbs of Persia and the adjacent region.

The galbanum exists, like other gum resins, in the plant as a fragrant creamy latex, and exudes spontaneously from the crown and stem, or flows upon puncture, in white drops that soon become thick and sticky, and finally hard and brittle, by the action of the air. As they dry, they also turn to a light yellow-brown or buff color. These drops or tears, collected when nearly dry and not sticking together, compose the "Galbanum in tears"; when collected in a softer state, and running more or less completely into a granular or even homogeneous mass, they are the more common "galbanum in mass." The pharmacopœial description was as follows: "In tears from the size of a pin's head to that of a pea, and larger; mostly agglutinated, forming a more or less hard mass; externally yellowish, or pale brown; internally milk-white, bluish-white, or yellowish, with a waxy lustre; odor peculiar, balsamic; taste bitter and acrid. When moistened with alcohol, galbanum acquires a purple color on the addition of a little hydrochloric acid."

Like other substances of its class, galbanum makes a yellowish emulsion with water, and contains a varying amount of *essential oil* (six per cent., more or less) according to its freshness and softness. It consists, besides, of about three-fourths *resin* and one-fourth *gum*, excluding a variable amount of coarse impurities. The oil is a colorless, pleasant-smelling hydrocarbon of the turpentine type. It is an article of commerce, and described by Schimmel as having a normal specific gravity of 0.930, boiling between 165° and 300° C., and containing *cadinene*. The resin is a yellowish-white amorphous substance, soluble in alcohol, and remarkable for yielding by dry distillation a brilliant *blue*, rather thick *essential oil* (see German Chamomile for similar substance), and the crystalline substance called *Umbelliferon*, which, in its turn, melted with potash, yields the derivative *resorcin*.

Galbanum was used by the ancient Hebrews as an ingredient of some incenses. Along with other gum resins it has had, in its day, some reputation as an emmenagogue and antispasmodic, and it is still occasionally given with these qualities in view. Somewhat more often it is administered in chronic bronchitis or laryngitis as an expectorant. Rarely it is given in rheumatism, with probably no benefit. The principal present employment of this antiquated medicine is as an ingredient of stimulating plasters.

It should be heated and strained, to separate dirt and refuse, before employment in pharmacy. 1 gm. (gr. x.–xx.) may be considered a full dose, and can be administered in pill form or as an emulsion.

Henry H. Rusby.

GALBRAITH SPRINGS.—Hawkins County, Tennessee.

Post-Office.—Galbraith Springs. Hotel and cottages.

Access.—Viâ Southern Railroad (formerly East Tennessee, Virginia, and Georgia) to Russellville, Hamblen County, thence 9 miles north by private conveyance to Springs.

For the last half-century these Springs have been known and resorted to by the inhabitants of the surrounding districts. In *ante-bellum* days they were frequented by hundreds, who made their temporary abodes in pole cabins around the Springs. The location is in a broken, mountainous country, 1,400 feet above the sea-level. The immediate surroundings of the Springs are uniquely charming in their wealth of vale and wood, brooks, rivulets, and waterfalls, and other features to please the fancy. The situation of the Springs is one mile distant from the Holston River, in a romantic glen, 330 feet above the base of Short Mountain. A path leads to the United States Signal Station on the top of Short Mountain, which is 1,320 feet above the Springs and 2,702 feet above the sea-level. From this point one of the most extended and charming views to be found among the mountains of East Tennessee is revealed to the eye. The hotel is a very comfortable establishment, where the visitor will soon learn that all the needful arrangements for his comfort and diversion are at hand. Among the amusements at Galbraith Springs may be mentioned bowling, dancing, and music. Hunting and fishing may also be indulged in. The springs are four in number. An analysis was made in 1884 by Prof. W. A. Noyes, of the University of Tennessee, with the following results:

LIGHT CALCIC-CHALYBEATE.

ONE UNITED STATES GALLON CONTAINS:

Solids.	Grains.
Calcium carbonate	3.84
Calcium sulphate	.92
Calcium nitrate	Trace.
Calcium phosphate	Trace.
Magnesium carbonate	.47
Lithium carbonate	Trace.
Sodium sulphate	.26
Sodium chloride	.07
Potassium sulphate	.16
Iron carbonate	.41
Alumina	.03
Silica	.68
Total	6.84

Temperature of water, 55° F.

This analysis shows a very light mineralization, yet the water seems to possess considerable merit as a ferruginous tonic, and can be taken in large quantities. It is also an excellent table water. *James K. Crook.*

GALLACETOPHENONE. — $C_6H_2,CH_3CO,(OH)_3$. A derivative of pyrogallol, $C_6H_3(OH)_3$, one atom of H being replaced by an acetyl group. It is a pale-yellow, crystalline powder, almost insoluble in cold water, very soluble in hot water, alcohol, ether, and glycerin.

It was introduced as a substitute for pyrogallol (Rekowski: *Therap. Monat.*, September, 1891), the advantage claimed for it being its freedom from toxic and irritating action. Pyrogallic acid and its derivatives owe their therapeutic properties to their reducing action which is usually too rapid and causes an excessive irritation. Gallacetophenone possesses this reducing action in a lesser degree than the others, although sufficiently strong to prove an efficient antiseptic. A further advantage is that it does not discolor the skin, the hair, or the linen with which it comes in contact. It also is devoid of any irritating or toxic action.

It was recommended for the treatment of skin diseases, particularly for psoriasis. In this condition its beneficent effects were said to be manifested in twelve hours, the patches becoming paler and thinner, and disappearing after ten or twelve days.

This drug has not been much employed. Dr. Herman Soldenburg (New York *Medical Journal*, February 6th, 1892) reports his success with it in several cases of long duration. It is employed in the form of a solution or in that of an ointment, the strength in either case being ten per cent. *Beaumont Small.*

GALLANOL—gallic acid anilid, gallanilid [$C_6H_5.NH.CO.C_6H_2(OH)_3$]—is obtained by boiling together tannic acid and anilin. It occurs in colorless crystals or gray micaceous scales, slightly soluble in cold water, soluble in boiling water, alcohol, and ether, and insoluble in benzol. It is bitter and astringent. Having found this tannin compound free from the undesirable properties of pyrogallol and chrysophanic acid, yet as effective in treatment, Cazeneuve and Rollet introduced it in 1893 as a remedy in psoriasis, chronic eczema, and other skin diseases. For eczema it is employed in ointment of three to twenty per cent. strength, or with talcum as a dusting powder. For favus, ringworm, psoriasis, or prurigo it is used in twenty-per-cent.-solution in alcohol with a little ammonia. Before this remedy is applied, the skin should always be cleansed with an alkaline soap solution. *W. A. Bastedo.*

GALL BLADDER AND GALL DUCTS, DISEASES OF.—(*Krankheiten der Gallenwege; Maladies des voies biliaires.*)

I. CATARRHAL INFLAMMATION OF THE GALL BLADDER AND GALL DUCTS.—(*Catarrhal jaundice; Icterus simplex; Icterus catarrhalis; Icterus gastro-duodenalis; Catarrh der Gallenwege; Inflammation des voies biliaires.*) Since the investigations of Wyss, Charcot, Legg, and others, a broader significance has been given to catarrh of the bile ducts than formerly; and at the present time pathologists are wont to include in the term all forms of jaundice save that due to stenosis and non-inflammatory occlusion of the ducts (by foreign bodies, growths, external pressure, etc.), or to a narrowing occurring as a sequence of a previous inflammation—catarrhal, suppurative, or exudative (see the section on Stenosis, etc., farther on). For a full discussion of these questions, see *Icterus;* suffice it to say that to a catarrh of the finer bile ducts has been attributed the jaundice of acute yellow atrophy of the liver, of phosphorus and other forms of poisoning, and of the various fevers, thus narrowing the limits of hæmatogenous jaundice. This section will be devoted only to an account of catarrhal inflammation of the bile ducts in the common acceptation of the term.

ETIOLOGY.—A predisposition to catarrh of the bile ducts is said to exist in persons of a bilious temperament. Persons liable to catarrh of other mucous membranes are prone to this affection. It arises very frequently from an extension of catarrhal inflammation from the stomach and duodenum, and the causes which excite the latter condition are prominent in the etiology of the former. Hence an attack may occur as the result of exposure to cold and dampness, of checking of the perspiration, of errors in diet, of over-eating, and of the ingestion of rich or fatty food, and of acrid substances, as well as of certain drugs and stimulants. A debauch is often followed by an attack, and the inhalation of noxious vapors and foul gases has been known to excite the disease. The so-called "epidemic" jaundice is thought to be due to a poison introduced from without through the food, drink, or air. Some epidemics, however, have the characteristics of an acute infectious disease and are attended with considerable mortality. Mennert's report of the Saxony epidemic of 1889 includes 518 cases, of which 73 per cent. were in children. There were 30 deaths. Weil's disease (infective jaundice) has been considered by some to be a modified typhoid infection. Several cases of typhoid fever with marked jaundice at the onset have been reported by Ogilvie (*British Medical Journal*, January 12th, 1901), and their resemblance to this disease noted. The Widal reaction should be of great value in this regard. Dalgleish[1] speaks of an extensive epidemic of catarrhal jaundice, at Bloomfontein, which bore a strange relation to the prevalent typhoid and dysentery. Whole families might be attacked, but more frequently it was seen that one or two of a household might have jaundice while the others would be affected with typhoid or dysentery. The disease in most instances ran an afebrile course, was attended with marked gastric symptoms, and was not of as long duration as simple catarrhal jaundice. The possibility of this epidemic being a modified typhoid infection has not escaped notice.

An extensive epidemic occurred in Michigan during the summer and fall of 1897. Six hundred and seventy-five cases were observed, mostly in children. The affection was commonly more severe in adults. Whole families were attacked. Usually after a few days of indisposition, slight fever, gastro-intestinal disturbances, and jaundice, more or less marked, would appear, the symptoms then abating. Jaundice in this epidemic was always of short duration. The liver was rarely enlarged.[2]

In addition to the causes which set up the catarrh of the bile ducts, either coincidently with, or secondarily to, the gastro-duodenal catarrh, there are other local causal conditions existing in disturbances of the portal circulation. Obstructive cardiac disease and impeded pulmonary circulation from lung disease or feeble heart lead to portal congestion, and hence to a venous stasis and consequent catarrh of the mucous membranes. Tumors in the abdominal cavity, enlarged glands, or the enlargement of any of the organs, by interfering with the portal circulation, may set up a catarrh. Dutton Steele reports a case of jaundice apparently due to kinking and obstruction of the bile duct from extreme gastro- and entero-ptosis.

Catarrhal inflammation of the bile ducts, with or without gastro-duodenal catarrh, is frequently caused by malaria, by syphilis (in the secondary stage), and by gout (Murchison). Acute phosphorus-poisoning and lead-poisoning are often attended with gastro-hepatic catarrh. The jaundice that accompanies cholera, typhus, typhoid, pneumonia, pyæmia, septicæmia, and other fevers, is due to a catarrh of the bile ducts.

Direct irritation of the mucous membrane of the ducts by mechanical causes, as by the passage of gall stones or by the presence of parasites, frequently causes a catarrh which may be local or diffused. Finally, it is said that pathological states of the bile itself irritate and excite inflammation of the ducts. In persons who are starving, from choice or necessity, it is said that the bile, which is retained in the gall bladder, becomes acrid and sets up an active inflammation. The jaundice that in rare cases accompanies cirrhosis, amyloid and fatty liver, is due to a catarrh of the ducts.

The season of the year is believed to have some influence on the production of biliary catarrh,—spring and autumn being the favorable periods; hence the terms icterus vernalis, autumnalis, etc. Sex exercises no influence on the frequency (Ewald, von Schüppel); yet, in our cases, excluding "epidemic" jaundice, the males were largely in preponderance. The disease is most frequently seen in the early period of life, and after forty a jaundice is not likely to be due to primary catarrh, although a case of one of the writers was seventy years of age. Firemen, puddlers, stokers, and laborers who are exposed to extremes of temperature are liable to the affection.

Morbid Anatomy.—In the milder forms post-mortem inspection reveals nothing, for, as we often find in a laryngitis so severe as to cause stenosis, the congestion and œdema subside after death. In the more severe varieties, redness, swelling, succulence, and often ecchymosis of the mucous membrane, are observed. The lumen of the ducts, if not occluded by the flaccid lining membrane, is filled with proliferated epithelium and mucus. The latter may be bile-stained, especially at first, or may be clear and viscid. A plug of firm mucus often stops the orifice. The papilla stands out prominently on the duodenal mucous membrane and is red and softened, but a probe readily penetrates the duct, and bile may be forced out by pressure of the hand on the gall bladder, although the feeble "vis à tergo" of the biliary secretion during life is not sufficient to overcome the obstruction. The duct, beyond the seat of the catarrh, is stained with bile. In the more advanced or prolonged cases the ducts are completely blocked by a somewhat firm, gray mucus, intermingled with proliferated epithelium and leucocytes. The congestion is more intense, ecchymoses are more common, and a more marked thickening of the mucous membrane is observed, due to cellular infiltration. Now it is that denudation of the epithelial surface takes place, ulcerations develop, and the terminal ducts undergo inflammation and dilatation from retention of, and irritation caused by, the imprisoned bile. Anatomically, catarrhal inflammation of the ducts may be divided into an acute form of ten days' duration (no lesions after death, or only congestion and œdema), a subacute form, lasting from two to six weeks (with the above lesions, cell proliferation and mucus formation in abundance), and a chronic form, continuing from two to six or eight months (excessive catarrh, abrasion, ulceration, dilatation, stricture, and retention abscesses or cysts). Catarrhal inflammation results either in the return of the parts to a normal condition, or in a stricture of the ducts (see the section on Stenosis of the Ducts, farther on) and its sequences, or in a "biliary" or "hypertrophic" cirrhosis of the liver.[3] Dropsy of the gall bladder occurs also as a sequence of catarrh of the cystic or common duct, with occlusion.

The seat of the catarrhal inflammation may be limited to the finer ducts, to the common duct, or to the cystic duct and gall bladder. Thudichum (1863) describes a catarrhal inflammation of the finer ducts in which perfect biliary casts are formed. Meckel regards such casts as frequently forming the nuclei of gall stones and has given the name of "lithiatic catarrh" to the condition. Robson suggests the term "desquamating angio-cholitis." The *pars intestinalis* was formerly considered to be the only portion of the common duct involved in catarrhal icterus. If the finer ducts are the seat of catarrh, as in phosphorus-poisoning, the larger ducts are pale and covered with a film of mucus or a small amount of thin bile. If the gall bladder be the exclusive seat, its mucous membrane undergoes changes similar to that of the duct; its contents are a dark-colored inspissated bile, and mucus in abundance, or a thin, watery mucus or muco-pus fills the bladder. According to Mayo Robson, catarrhal cholecystitis, or chronic catarrh of the gall bladder, without jaundice, forms a distinct and definite disease frequently mistaken for cholelithiasis and only recognizable at operation, when nothing but thick, ropy mucus is found in the bladder or ducts. This mucus, often in the form of sago-like plugs, gives rise, in its passage, to the gall-stone-like attacks. In these, as a rule, medical treatment is sufficient, but in persistent attacks, in which no gall stones are passed in the fæces, no jaundice develops and no tenderness is present in the gall-bladder region, the operation of opening and draining the gall bladder is urged. Robson reports the cure of several cases by this procedure.

The histological changes in the parenchyma of the liver vary. Either the appearances of a liver long stained with bile are found, or the atrophic and degenerative alterations seen in stenosis of the ducts are observed, or a "biliary" cirrhosis develops (consult these sections).

Symptoms, Course, and Duration.—These depend upon the cause; if this be one that is readily removed or that passes off quickly, the symptoms are mild and the duration is brief, as in the catarrh that succeeds the passage of a gall stone. If the affection arise from obstructive heart or lung diseases, the symptoms are mild, but the duration is long. The catarrh that accompanies malarial disease or a gastro-duodenitis is the most severe and protracted. The mode of onset also varies with the cause. The gastro-duodeno-hepatic form is usually preceded by gastric symptoms for three or four days; while that due to other causes follows the usual manifestations of that cause.

The description which follows is that of a catarrhal inflammation of the ducts supervening upon duodenal catarrh, which may be regarded as a type of the disease under consideration.

The affection may begin in any of several different ways:

The gastro-duodenal symptoms may precede the hepatic by three or four days; or the first observed symptom may be jaundice; or the attack may be ushered in by a chill, followed by fever with gastric symptoms and, in a few days, by jaundice. Loss of appetite, a tongue covered with a heavy yellow fur, pasty and bitter buccal secretions, and an offensive breath, are prominent. Nausea in the mornings, or at the sight of food, and vomiting of a glairy mucus, or, early in the attack, of a bitter, bile-stained, acrid fluid, may occur. At the same time there are epigastric distress, weight and fulness, some tenderness on pressure, soreness, or even marked pain. Later, there are pain and tenderness in the right hypochondrium and over the liver. It is denied by some authorities that the liver and gall bladder are enlarged, but I have observed enlargement of the former constantly in chronic cases. The abdomen is usually distended with gas, and eructations of gas and the imperfect products of digestion occur. The bowels are constipated, or a diarrhœa from indigestion may occur in the early stage. In a few days jaundice appears; first the conjunctiva, then the face, and in a short time the entire body is discolored. The icterus varies in extent and degree. The conjunctiva alone may be affected, and it may be merely of a faint yellow tinge, or, in chronic cases, of a deep bronze. The fever, which is from 100° to 103° F., generally subsides with the advent of the jaundice, but it may continue for ten days or two weeks as a simple continued fever, the so-called "gastric" or catarrhal fever. The well-known symptoms and effects of obstructive jaundice are present (see article on *Icterus*).

It is important, however, to remark the uniform persistence of the jaundice. Probably the most characteristic symptom is the slow pulse, which often distinguishes this form from other varieties of jaundice. Fagge calls particular attention to this symptom. Headache is present often in the beginning, with or without vertigo. After the jaundice becomes developed, the usual nervous symptoms of the disease are manifested.

If the case be a mild one, the gastric symptoms first subside, and then the jaundice gradually disappears, without any serious disturbances of nutrition. In the more protracted cases, however, anæmia, emaciation, and prostration are marked, the degree depending on the duration of the disease.

The mild idiopathic cases continue for from ten days to three weeks, the more severe ones for from six to ten weeks, and the more obstinate cases as long as five or six months.

Should stricture of the duct take place as a sequence of the catarrh, and should suppuration of the ducts occur, and abscesses form, fever of an irregular type, often with chills, and with exhaustive sweats, will usually be present. A similar fever, or one of an intermitting character, also accompanies the development of secondary cirrhosis. In these instances the liver and gall bladder are enlarged.

Inflammation of the gall bladder alone is characterized by pain and tenderness in the right hypochondrium, by enlargement of the gall bladder, and by slight fever, with, at times, nausea. Jaundice may not be present, but in many cases a gall stone in the gall bladder or cystic duct may give rise to jaundice from an inflammatory occlusion of the common bile ducts by extension. Riedel is quoted by Gumprecht[4] as stating that two-fifths of the cases of jaundice in cholelithiasis arise in this way (Mayo Robson).

Diagnosis.—The presence of one of the causes or antecedent pathological conditions just noted, the early age and previous good health of the patient, the sudden and uniform development and persistence of the jaundice, and the absence of the physical signs of organic disease of the liver, clearly indicate simple catarrhal icterus. Care must be taken not to confound it with the jaundice of acute yellow atrophy, and it must not be forgotten that, in apparently the most simple jaundice, grave cerebral and other symptoms due to acute atrophy may arise. Acute yellow atrophy may occur at an early age in the pregnant female; the more marked epigastric pain, the jaundice of the upper portion of the body, the vomiting of blood, the cerebral symptoms, and the alterations in the size of the liver and spleen serve to distinguish it.

The jaundice due to obstruction by gall stones develops quickly, is quite marked, and varies in its intensity from time to time; paroxysmal and persistent pain is more pronounced than in the simple form; the patient is usually a female, and the attacks occur late in life. The diagnosis must be made between jaundice from simple obstruction and that caused by pressure on the ducts. The physical signs and clinical history of the many forms of external pressure must be considered (see section on Stenosis, etc.). Pain, fever, sweats, increase in size and tenderness of the liver and gall bladder, with prostration and emaciation, occurring late in the disease, indicate stricture and the formation of abscesses, or purulent inflammation of the ducts. If the jaundice continues longer than two months, if the pulse is frequent from the first, if sweats are marked, if emaciation rapidly ensues, and if the patient is over thirty years of age, it is more than possible that some affection other than simple catarrh, and not revealed by physical signs, is present. An important observation in this connection is, that frequently in malignant disease of the liver or bile ducts, jaundice due merely to an associated catarrh may disappear under treatment, the disease meanwhile persisting and progressing. The jaundice due to pressure or obstruction will be little, if at all, influenced by any means (Mayo Robson). It has occurred to the writers that the existence of a diarrhœa in the course of catarrh of the bile ducts would indicate closure at the orifice; for then the pancreatic duct would likewise be occluded, and diarrhœa, a well-known symptom of pancreatic disease, would ensue. The presence of fat and blood in the stools would also point to this conclusion.

Prognosis.—This is usually favorable, but depends more or less on the cause. Gastro-hepatic catarrh terminates favorably. The presence of symptoms indicating purulent inflammation of the duct renders the prognosis grave. Prolonged jaundice, with the advent of marked cerebral symptoms, is very serious. The possibility of the development of icterus gravis should not be forgotten. We are inclined to think that the prognosis is seriously modified by inactivity of the kidneys, and that cerebral symptoms are not so liable to occur if the renal secretion is abundant. Hemorrhage, in any of its forms, is of bad omen.

Treatment.—The line of treatment to be adopted depends entirely on the cause of the catarrhal inflammation. If it arise from cold and exposure and is seen early, a warm bath or a vapor bath, and the use of saline cathartics, or of small doses of tartar emetic, are of service. Full doses of quinine and Dover's powder at bed-time, with a light purge in the morning, will often relieve the general symptoms of "cold," and exert a favorable influence upon the local catarrh. If the cause of the disease is a coexisting gastro-duodenal catarrh, a mechanical emetic, repeated twice on each of the first two days, is often of service. Large draughts of hot water, either at bed-time or repeated throughout the day, are grateful and beneficial. They are made more palatable by the addition of some one of the alkaline citrates. At the same time an alkaline purgative, largely diluted, should be employed, and then gastric sedatives or the mineral acids. Patients with catarrhal jaundice rarely apply for treatment until some time after the jaundice has appeared, and as this is generally due to a gastro-intestinal catarrh, a system of treatment that has usually been successful in these cases may here be presented. First, in the acute form: a mercurial purgative is first administered. We usually prescribe from one-twelfth to one-third of a grain of calomel, in combination with from three to ten grains of bicarbonate of soda every two hours, until eight or twelve powders are taken. If the bowels are not acted on freely by this combination, it should be followed by a saline laxative. At the same time light sinapisms are applied to the epigastrium. After the bowels are freely opened, it will often be found that the tongue has already become somewhat cleaner, and the bad taste, the nausea, and the vomiting have been relieved. If this happy effect has been produced, a weak acid or an alkali and bitter may be used. On the other hand, if the symptoms are not relieved, and the tongue is clean, denuded of epithelium or pointed, and red at the tip, a sedative is indicated. In the more chronic cases in which the gastro-duodenal catarrh has subsided, we have other conditions to deal with, and the indications are to remove the obstructing mucus and reduce the inflammation and thickening of the ducts. These indications may be met by remedies that in a measure increase the secretion of bile and thereby drive away the obstruction, or by drugs that render the mucus less viscid and that relieve the congestion. Among the remedies of this latter class the alkalies are of great service, and may be given in the form of the alkaline effervescing waters, as the Carlsbad, Vichy, or Hathorn waters, or the salts of ammonium, sodium, or potassium may be used. Bartholow advocates the phosphate of sodium in drachm doses; Guiteras, iodide of potassium in small doses freely diluted, and taken fasting. The muriate of ammonium is one of the most reliable alkalies; it may be given in ten- or twenty-grain doses, three or four times daily, combined with an equal quantity of powdered licorice, and dissolved in water. Ipecacuanha has been advocated in small doses, as one-half of a grain or one grain, frequently repeated, for the same purpose.

To increase the secretion, nitro-hydrochloric acid, the vegetable hepatic stimulants, benzoate and salicylate of soda, and alkaline waters are of service. The alkalies should be taken in a large amount of water, preferably hot, on an empty stomach, and by slowly sipping the fluid. Emetics are also used for their mechanical effect, but care must be observed lest their too free use incite a fresh catarrh or aggravate the one already existing.

Mosler and afterward Krull have successfully treated catarrhal jaundice with enemata of cold water. They inject, once in twenty-four hours, from one to four pints of cold water (59° F.) slowly into the rectum, and require the patient to retain it as long as possible. With each injection the temperature of the water is gradually raised, otherwise it will not be retained.

By pressure on the fundus of the gall bladder, if it be readily grasped, directing the force toward the vertebral column, Gerhardt has succeeded in overcoming the obstruction and relieving the jaundice. The same author recommends the application of electricity. A strong induced current with slow interruptions is used; one electrode is placed over the gall bladder, the other on the back at a point directly opposite, and close to the spinal column. No doubt Kussmaul's treatment of intestinal obstruction, by washing out the stomach, would be of service in this affection.

The diet should be bland and non-irritating. Fats, sugars, and, as a rule, starches, should be excluded, as well as spirituous or malt liquors. Light broths, beef-tea, milk, and later, meats, fish, eggs, and oysters should be the chief articles of diet. Afterward tomatoes, lettuce, spinach, celery, and the like may be used.

The troublesome, and at times serious, effects of the jaundice will be treated of under that heading. (See *Icterus.*)

II. PURULENT, ULCERATIVE, AND CROUPOUS INFLAMMATION OF THE GALL BLADDER AND GALL DUCTS (*Cholecystitis et Cholangitis Suppurativa, diphtherica, exulcerans, and crouposa* (Schüppel); *Exsudative Entzündung der Gallenwege* (Frerichs); *Cholécystite et Angéiocholéite*).

Etiology.—According to Bloch, in disease of the gall bladder and bile ducts the bile soon becomes infected with various micro-organisms, principally B. coli communis, staphylococci, and streptococci. Any condition obstructing the flow of bile invites bacterial infection (Charcot et Gombault, *Archives de Phys. et Path.*, 1876; Netter, *Prog. Méd.*, 1886; Terrier, *Revue de Chirurg.*, 1895). Hence foreign bodies, such as gall stones or parasites, in the biliary passages, stenosis and occlusion of the ducts in any part of their course, readily pave the way for any infecting agent.

Fütterer has shown that in a very few minutes after the injection of organisms into the circulation they appear in the bile. Flexner and Chiari have demonstrated the constant presence of typhoid bacilli in the bile in patients dying of typhoid fever, the latter observer describing acute inflammatory lesions in thirteen of nineteen such cases without any gross obstruction in the biliary passages. Camac records an instance of acute cholecystitis with operation in the first few days of an attack of typhoid fever. Cases of acute cholecystitis due to the Bacillus typhosus without previous history of typhoid fever are reported by Cushing and Mitchell. Hunner describes another occurring eighteen years after an attack of typhoid, with operation and isolation of the typhoid bacillus. It can safely be assumed that bacterial infection exists in all cases, and that acute inflammatory infection of the biliary passages may occur without obstruction in many of the acute infectious diseases. Cases of acute phlegmonous cholecystitis and gangrenous cholecystitis are probably only instances of very severe infection, which may spread so rapidly that general peritonitis may occur in a few days. Pratt,[5] in his recent article, shows the frequency of cholecystitis due to the Bacillus typhosus. It therefore seems probable that cholecystitis may begin as a primary local typhoid infection. Pearce[6] has described an instance of the presence of a leptothrix in an acute cholecystitis, the organism being also found in gall stones present in the gall bladder.

Ulcerations of the biliary passage are most frequently due to gall stones. Carcinoma is a common cause, and ulcerations have been met with in typhoid fever and in cholera. The sequelæ of ulcerations, stricture, perforation, fistula, etc., make the condition more serious than it might otherwise be.

Croupous or membranous inflammation of the gall bladder and ducts may occur as the result of irritation from the passage of a gall stone, or it may be a further stage of catarrhal inflammation. Powell (Med. Trans. Coll. Phys., 1829) noted that membranous enteritis was frequently accompanied by gall-stone-like attacks, and it has been suggested that gall-stone colic may be the exciting cause of membranous enteritis. Robson thinks a membranous or croupous formation in the gall bladder or ducts, with passing of the membrane or pieces thereof, accounts for the painful, gall-stone-like attacks. Fenwick (*Br. Med. Jour.*, April 23d, 1891) discovered a true cast of the gall bladder in the fæces twenty-four hours after a very severe attack of hepatic colic. A similar cast had been found two weeks previously under similar conditions. In all suspected gall-stone attacks, in which no stones are found in the fæces, search should also be made for fleshy, tube-like structures or fragments thereof, as they alone may be responsible. Robson is of the opinion that the gall-stone-like attacks seem not infrequently, in subjects of membranous enteritis, to indicate involvement of the biliary passages in a similar condition. Extension of purulent inflammation from adjoining veins or from hepatic abscesses appears to have been the cause in some instances. It is certainly true that a multiform inflammation of the ducts may occur by extension of inflammation from some one localized focus, as an ulceration due to gall stone. This form of biliary inflammation is usually met with in advanced life. Croupous inflammation of the biliary passages is also caused by gall stones.

Morbid Anatomy.—The cases that have been observed by the writers presented nearly all the anatomical appearances that occur in cholangitis and cholecystitis.

There are observed a swollen, thickened mucous membrane, of a pale ashen or slate-gray color; uniform or saccular dilatation of the ducts; and abscesses in the periphery of the duct or along its course. Often a gangrenous appearance of the duct wall is seen. The dilated canals and the abscesses contain yellowish-green bile and pus, sometimes thick and ropy, and often ichorous. The dilatation is most frequently confined to, or most marked in, the left lobe of the liver, and Legg says that the dilated pouches and ducts are lined with columnar epithelium. Ulcers are often found, superficial in character, large and irregular, or quite deep and small. From the healing of the ulcers and the contraction of the cicatrix, the ducts beyond the obstruction are obliterated. This may also occur after exudative inflammation; and in the liver fibrous bands, the remains of the biliary channels, are often seen. The tissue of the liver beyond becomes sclerosed, and the cells proper undergo atrophy and degeneration. The abscesses of the liver may extend into a contiguous vein, or may ulcerate toward the surface; hence a perihepatitis is often seen. Sometimes one large abscess alone is found; rarely do abscesses become encapsulated. The ulcers that have formed are often covered with a gray, gangrenous detritus, which is removed with difficulty. This characterizes the diphtheritic form. In the croupous inflammation of the ducts, fibrin cylinders, well moulded and easily removed, are found. The hepatic structure undergoes some changes: in the mild forms either a connective-tissue overgrowth lights up, or a diffuse hepatitis arises; in the chronic forms with jaundice the liver cells are icteric, compressed into various shapes, and present the appearances of having undergone fatty or granular degeneration.

As a sequence of purulent or exudative inflammation of the gall bladder, marked phenomena are observed. The mucous membrane undergoes the usual changes, the walls become thickened, and the cavity is filled with pus, muco-pus, or pus and bile. Ulcerations, simple or diphtheritic in nature, are formed, and may penetrate to the peritoneal cavity.

Adhesions take place between the gall bladder and neighboring structures, fistulæ develop, and often the adjacent tissues are filled with pus. The ulcers are single or multiform. In mild cases a fibrous thickening of the walls of the gall bladder and its surroundings takes place, followed by contraction and obliteration of the organ. Twice the writers have found the gall bladder firmly contracted around imprisoned gall stones, and in one case numerous sacculi had been formed, each sac containing a gall stone surrounded by bands of fibrous tissue. On the other hand, the gall bladder may undergo extreme dilatation and enlargement, producing an empyema. If the phlegmonous inflammation be confined to the walls, this structure may undergo calcareous degeneration (so-called "ossification").

Symptoms, Course, Duration.—The symptoms are those of the causal condition,—as one of the infective fevers, gall stones, etc.,—combined with the local inflammatory manifestations. Often the condition is not recognized during life, or there may be present only an irregular fever, with rigors. If, after an attack of hepatic colic, fever of an irregular type, chilly sensations, or sharp rigors, occur, and prostration ensues, independently of any paludal affection, we may suspect ulcerative inflammation of the bile ducts. In these cases, the jaundice, which is usually present, deepens, pains in the hepatic region are marked, and a fixed local pain in the right hypochondrium is complained of. If the gall bladder is involved, the physical signs of enlargement of that organ are observed (see the section on Enlargement of the Gall Bladder). As the inflammation proceeds, the symptoms of perihepatitis, local or general peritonitis, occur. In addition to pain in the region of the gall bladder, we have pain and tenderness frequently in the epigastrium. With or without this local inflammation, vomiting is frequent, hemorrhages occur from the stomach and bowel, and often a diarrhœa is started. Budd believed that many cases recovered. If so, the burrowing of the pus must have been in the direction of the stomach or duodenum. An increase of local tenderness, and the presence of tumefaction and redness, show that the direction which the pus is taking is toward the surface. Discharge of the abscess in this position leads to the formation of a cutaneous biliary fistula. If this fortunate termination does not occur, and in a cholangitis it is not to be expected, the fever continues, the gastro-intestinal digestion gives way completely, a typhoid state of the system arises, cholæmia frequently occurs, and finally death. A fatal result may occur from exhaustion, due to the combined influences of the fever, the suppuration, the gastro-intestinal disturbances, and the jaundice; or a peritonitis from perforation or rupture of the gall ducts, or a pylephlebitis, may hasten the fatal termination. Hemorrhages are also liable to occur if the jaundice is of long duration, and they will add to the extreme debility. Cholecystitis, due to foreign bodies or to obstruction of the cystic duct, may run its course, and the contents of the bladder be discharged into the neighboring hollow viscera, or externally, without the supervention of grave general symptoms; local phenomena and physical signs alone indicating its presence. The lodging of a gall stone in a common duct is often and usually associated with a peculiar fever and train of symptoms, the so-called hepatic intermittent fever of Charcot. Osler, Fenger, and Courvoisier describe a ball-valve action of gall stones lodged in the diverticulum of Vater, the bile readily flowing by the stone but becoming easily obstructed and infected under certain circumstances, producing the characteristic ague-like paroxysms which may be frequently repeated (the recurring jaundice deepening with each attack), or may occur at intervals of months or years. Each attack probably represents an infective cholangitis which may quickly subside or may run into the more serious conditions already mentioned as occurring in infection of the biliary passages. Leucocytosis, more or less marked, absence of the malarial parasite in the blood, resistance to quinine, the irregularity of the paroxysms, and the deepening jaundice should distinguish the conditions from malaria. There is usually a history of previous gall-stone colic. Robson states that in his experience several impacted stones were as frequently found as a single stone, freely movable, and acting like a ball-valve.

Diagnosis and Prognosis.—The diagnosis is uncertain, and when the symptoms are latent it is manifestly impossible to make a diagnosis. Pain and swelling of the liver, with tenderness on pressure, irregular chills and fever in a person who is jaundiced, or who has had an attack of gall stones, are strong evidences of exudative inflammation. Cholecystitis may be recognized by local symptoms (see section on Enlargement of the Gall Bladder). The prognosis is very unfavorable on account of the many accidents that may arise.

Treatment.—Stimulants, tonics, quinine, medicines to allay gastro-intestinal irritation and dyspepsia, and morphine or other preparations of opium to relieve pain, are the only means at our command for combating the disease. Unless the disease shows signs of resolution it is now generally advised to open and drain the gall bladder in cases of cholecystitis. In infective and suppurative cholangitis, opening of the gall bladder offers the only chance and is followed in many cases by cure. Terrier (*Revue de Chirurgie*, 1895) and Robson insist upon the value of this proceeding. Removal of stones from the common duct is now performed and is indicated in persisting evidence of obstruction and infection (Halsted).

III. Stenosis and Occlusion of the Gall Ducts.—The canal is occluded when it is completely closed; partial closure, sufficient to cause obstruction, is denominated stenosis. These conditions may be congenital or acquired; the acquired forms alone are treated of in this connection. The causes of each are the same, and the results are similar.

The obstruction may be due to foreign bodies within the duct, to diseases of the duct walls, or to external pressure.

1. The foreign bodies which may find lodgment within the ducts are gall stones, parasites, or, in rare cases—if the orifice of the duct is very patulous, as occurs after the passage of a gall stone,—cherry pits, plum stones, or raisin seeds. The gall stones are generally impacted in the cystic duct, or at the mouth of the common duct. The common round worm has been found in the lumen of the duct. The liver fluke also causes stenosis; but complete obtruction is not effected without the intervention of local inflammatory symptoms. The rupture of an echinococcus sac into the ducts and the discharge of the vesicles cause temporary obstruction. Complete closure is caused by multilocular echinococcus tumors, which cause infiltration, thickening, and ulceration of the wall of the duct. The hepatic and cystic ducts are chiefly involved.

2. The obstruction may be due to chronic catarrhal inflammation, to purulent and ulcerative inflammation, to carcinoma or other morbid growths of the ducts, or to a perihepatitis with thickening of the investing membrane, leading to hypertrophy of the subserous connective tissue and occlusion of the duct. In the inflammatory forms, granulations in apposition coalesce, and the formation of a stricture ensues. When ulceration has previously occurred, the stenosis is due to the contraction of the cicatrix. The causes mentioned in the sec-

tions treating of those affections are the primary causes, therefore, of the stenosis. The lumen of the duct becomes absolutely imperforate in the inflammatory varieties, and the occlusion may extend over a variable length, though it most frequently exists in the common duct. The lumen is not completely occluded in cicatricial stricture, but is impermeable, and is not unlike a urethral stricture. Local or extended thickenings of the duct causing stenosis are due to a connective-tissue hyperplasia, which originates in a previous catarrhal inflammation. The cicatrix of a duodenal ulcer sometimes includes in its grasp the duodenal opening of the common bile duct.

Carcinoma of the biliary passages will be treated of in a separate section. The perihepatitis, which includes in its course the investment membrane of the ducts, is caused by general peritonitis, by right-sided pleurisy, by affections of the liver and adjacent organs, which set up irritation (as, for example, cancer, cirrhosis, ulceration, etc.). As the peritoneal thickening and the new inflammatory tissues grow in age, they contract and thus encroach on the lumen of the ducts. Syphilis is said to be a cause of this local inflammation.

3. External pressure is caused by disease or displacement of contiguous organs. Named in their order of frequency, it is often found that affections of the pancreas, the lymphatic glands in the hepatic fissure, the duodenum, the stomach, the omentum, and the kidney are the sources of pressure. Carcinoma or hypertrophy of the pancreas, carcinoma, tuberculosis, amyloid disease or lymphosarcoma of the lymphatic glands, carcinoma of the stomach, duodenum and omentum, and tumors of the kidney (hydronephrosis or carcinoma) are the essential pathological conditions which lead to the occlusion. Aneurisms of the aorta (Hatton) and of the hepatic artery (Gairdner) cause obstruction. Very rarely tumors of the ovary and uterus, and fæcal tumors, are the cause of occlusion.

The anatomical sequences of occlusion and stenosis of the biliary passages are dilatation of the ducts or gall bladder behind the obstruction, catarrhal or suppurative inflammation of the ducts, enlargement of the liver, at first from the excessive dilatation of the canals, and then from a hypertrophic or biliary cirrhosis, and subsequent atrophy of the liver from pressure of the ducts on the secreting tissue, or destruction of the cells by the connective-tissue overgrowth.

The dilatation of the duct is often extreme. The common and hepatic ducts may be as large as the intestine, and their walls thin, although rupture rarely takes place. The ducts in the liver are also dilated to the size of the finger throughout their extent, even to the surface, causing it to have a vesicular appearance. The walls are not greatly thickened, and are lined with columnar epithelium. The mucous membrane is pale and smooth. The ducts terminate in large pouches, and numerous recesses are seen in the course of the cylindrical canal. Retention cysts are often found. At first the biliary channels are filled with bile only, but after a time this fluid is replaced by a secretion from the glands of the mucous membrane, which is limpid, viscid, and serous in character. The chemical and microscopical examination of the fluid gives no indication of bile constituents. The reaction of the fluid is neutral; it contains albumin. When this fluid is found in the bile ducts, bile is not secreted in them, and the mucous membrane of the ducts is in truth a cyst wall. Whatever bile is secreted is at once absorbed.

The liver is icteric and anæmic; flaccid at first, cirrhotic afterward. The cells undergo atrophy, contain bile pigment and minute oil globules; while cloudy swelling of the protoplasm is observed. The changes peculiar to "hypertrophic" cirrhosis are observed later.

A description of the changes in the gall bladder is reserved for the section on Enlargement of the Gall Bladder.

The *Symptoms* are complex, and include the symptoms of the primary cause and those of biliary obstruction. Aside from the physical signs and symptoms of the causal disease, jaundice[7] is the first symptom. As a rule, the yellowish tinge gradually changes to a deep olive-green color, and with it the changes in the urine take place; gastro-intestinal dyspepsia is developed, and finally a veritable catarrh supervenes, with its full train of symptoms. Early in the disease weight and tension in the epigastrium and hypochondriac region are complained of, and enlargement of the liver and gall bladder is observed. After a time pruritus comes on, and in from two to four months hemorrhages ensue. Loss of flesh and strength rapidly takes place. Soon, if death has not in the mean time resulted from the original cause or from some intercurrent disease, the symptoms of cholæmic intoxication are likely to arise, and death results from this condition.

One cannot, within the limits of this article, discuss in detail all the forms of biliary stenosis and occlusion, and their differential diagnosis; persistent jaundice, the absence of bile in the stools and its presence in the urine, clearly indicate obstructive jaundice. There are some organic diseases of the liver, however, which give rise to jaundice in some other way than by means of occlusion. They should be distinguished from other forms of obstructive jaundice, on account of the opposite methods adopted for their treatment. Reference is made to atrophic and hypertrophic cirrhosis, to carcinoma, to simple and multiple abscesses, to simple and multiform hydatid disease, and to amyloid disease. The recognition of any of these is not difficult. The atrophic variety of cirrhosis is easily recognized by its well-known symptoms, but not so the so-called hypertrophic cirrhosis. The jaundice is intense, the liver enlarged and smooth, ascites is absent, paroxysmal pains occur, and irregular fever is present.[8] In other forms of obstruction the liver is not so large, the gall bladder is enlarged, while a distinct cause for the jaundice—as, for example, a tumor—may be discovered.

Having discussed the question of occlusion due to any one of the etiological factors previously noted, we may now be permitted to refer briefly, for diagnostic purposes, to these causal conditions.

1. FOREIGN BODIES.—If the obstruction be due to *worms*, the latter may be recognized by the age of the patient, and by the presence of the parasite in the ejecta. Their presence is further indicated by an attack of hepatic colic, but an absolute diagnosis cannot, and practically need not, be made. This, however, is not so in the case of hydatid cysts, which burst into the bile ducts, with symptoms of hepatic colic. The diagnosis, under these circumstances, can be more readily made: first, by the previous history and physical signs of an hydatid tumor; second, by the disappearance of the tumor after the colic; third, by the subsequent occurrence of fever and local inflammation; and lastly, by the appearance of sacs or hooklets in the vomited or aspirated matter.

Gall Stones.—It is of the utmost importance to determine the presence of biliary calculi. To accomplish this, is sometimes a very difficult matter; in fact, it is often a task impossible of accomplishment. The varying symptoms of cholelithiasis are so many that it is not possible to name one of them, or to present a group of them, for the purpose of making a diagnosis, without being able to give an exception to each and every one. The only absolutely definite sign is to see or feel the calculus. If one has been passed by the rectum, it probably was the cause of the obstruction; if it have facets, a fellow-calculus may be the cause.[9] If it is not detected in the stools, exploration of the gall bladder and bile ducts may be resorted to by opening the abdominal cavity. Martin-Solon (*Jour. des Conn. Méd.-Chir.*, Paris, 1849, xxxiii.) reports a case in which the stones could be detected on palpation if the patient took a forcible inspiration, the hand being on the gall bladder. He considered it a new mode of diagnosis.

Aside from these positive methods, a correct conclusion cannot be arrived at without a study of the case in its entirety; the age and sex of the patient, the habits, the family history, the temperament, all are important elements to be considered. If these circumstances are favorable, and if, in addition, the patient has had previous attacks of hepatic colic, *followed* by jaundice and the symptoms of duodenal catarrh; if constipation and putty-colored stools accompany the jaundice, the diagnosis is very probable. Then if, after impaction has taken place, the nutrition of the patient remains good for a long time, and the liver enlarges only slightly, while the gall bladder increases appreciably in size, it is scarcely possible to name any other affection as the probable cause of the symptoms.

Campbell (*Brooklyn Annals*) suggests that if, after aspiration of the gall bladder, bilious stools are present, calculi may be assumed to be the cause of the obstruction. The relief of the tension allows the stone to recede and the bile to escape.

2. DISEASES OF THE DUCTS.—*a.* Congenital closure. In an infant, a jaundice that continues for over four weeks, with supervening cholæmia, is due most frequently to this condition. *b.* Closure of the ducts by chronic catarrh of the duodenum, by adhesive inflammation of the ducts, by the cicatrization of an ulcer in the duct or at the duodenal orifice, and by fibrous bands. The first may be recognized partly by the history of the case and partly by the exclusion of attacks of catarrhal jaundice. Adhesive inflammation of the ducts is due either to the passage of biliary calculi or to a previous catarrh. The respective symptoms of the two must be considered in each case.

Ulcers in the bile ducts are due to gall stones, or are secondary to cancer or an infectious fever, as typhoid or cholera. In the former case, in addition to the symptoms of gall stones, we have, accompanying the ulceration, irregular chills and fever and extreme exhaustion, conditions not likely to be present in the early stages, at least, of simple impaction. If the symptoms of occlusion become developed after such phenomena or after an infectious fever, the exciting cause is probably the cicatrization of an ulcer in the duct. The well-known symptoms of duodenal ulceration precede for a long time the symptoms of obstruction of the biliary passages from this cause, and while it may be said that the gall bladder is enlarged under such circumstances, it is not necessarily so when the seat of ulceration is in the duct. Closure of the ducts by fibrous bands may be inferred, if the cause (as syphilis) and the symptoms indicate a perihepatitis, and if other evidence of previous inflammatory trouble be present, as atrophy of the liver, or ascites, etc., due to pressure on the portal veins.

3. DISEASES EXTERNAL TO THE DUCTS.—*a.* Carcinoma and other neoplasms of the liver and surrounding organs. A recognition of these affections can be obtained by the exclusion of other causes of obstruction, by the presence of tumors or nodules, and by the physical signs discoverable on palpation, etc.; also, when these are present, by the alterations of the functions of adjacent organs, and by the presence of the symptoms of malignant disease of these organs; and finally by the duration of the disease, the stenosis from carcinomata being of shorter course than that due to other causes. *b.* Enlarged lymphatic glands. Obstruction from this cause is probable, if there be elsewhere present any of the well-known causes of hypertrophy of these glands, as carcinoma, tuberculosis, amyloid disease, etc. Amyloid disease but rarely causes jaundice, except in this way; its symptoms are too well known to be detailed in this article. *c.* Aneurism. This rare form of occlusion may be recognized by the pressure symptoms of a tumor located in the region of the duodenum, and by the physical signs of aneurism.

The *course* of the disease, in occlusion of the biliary duct, is a chronic and most frequently a progressive one. It is a gradual march to death, except in cases in which foreign bodies cause the occlusion. Under these circumstances their removal by ulceration or the escape of bile around them may be followed by recovery. Death is the result of the original cause of the disease in many cases. Exhaustion or cholæmia often brings about a fatal termination. The duration varies with the cause, and is modified by the onset of accidental complications. Complete occlusion may terminate in recovery even after a lapse of six years. The prognosis is unfavorable, depending on the nature of the causal lesion. Hemorrhages render the prognosis very grave. The supervention of symptoms of cholesteræmia is serious. The return of color to the stools is of more favorable import than is a change in the skin discoloration.

The treatment is mainly directed to the relief of symptoms. Medicinal remedies are of but little avail, and resort must be had to surgical measures. The regulation of the diet is of the utmost importance to the conservation of life (see section on *Catarrhal Inflammation*, etc.). Means must be taken to overcome the gastro-intestinal symptoms that result from the absence of bile in the intestines. The bowels must be regulated, the secretion of the kidneys kept active, and the activity of the cutaneous glands promoted. Cholecystotomy, with the establishment of a permanent fistula, may be resorted to, and it may, by relieving pressure in some cases of gall stone or parasitic obstruction, promote a cure. Cholecystduodenostomy has resulted in success in some instances and the advisability of resorting to it should be considered in a case of complete occlusion.

IV. ENLARGEMENT OF THE GALL BLADDER.—Under this caption all forms of enlargement of the gall bladder will be described, as it is by the clinical study of this manifestation of the disease that we, to a large extent, determine the nature of the ailment and the indications for treatment.

The gall bladder is enlarged from the accumulation within it of bile, of pus, of mucus, and of gall stones, and from disease of its walls—carcinoma. Increase in size from bile, pus, or serum is usually styled simple dilatation. Carcinoma of the biliary passages will be treated of in a separate section. Accumulation of the fluids just indicated is due either to obstruction of the duct, or, in rare cases, to a paralysis of the muscular coat of the gall bladder from overdistention. The dilatation from bile or pus may be temporary, and in such a case is caused by an obstruction catarrhal in nature, or by the presence of a gall stone, which acts as a ball-valve in the lumen of the ducts. Enlargement from accumulation of bile is not common, but may occur with a concretion in the common duct. It is usually of short duration, the bile being absorbed and replaced by mucus.

The walls of the gall bladder are uniformly distended and thinner than normal, the mucous membrane is smooth, and there are no adhesions to the surrounding parts. Sometimes the dilatation is extreme. From a patient of Babington's, three wash-basinfuls of fluid were withdrawn, and in another case the gall bladder was so distended as to give the patient the appearance of having an ascites (Coupland). Lawson Tait and Kocher report cases in which distended gall bladders were mistaken for ovarian cysts. Waring mentions a specimen in which the lower end of a distended gall bladder formed the contents of a sac of a femoral hernia. The contents may consist at first of bile, but as the obstruction continues, this becomes more and more intermingled with mucus.

If serum accumulates, causing enlargement (hydrops cystidis felleæ), the obstruction is usually one that has existed for a long time. The inner surface of the mucous membrane is like a serous membrane in appearance, and the accumulated fluid is the result of secretion from this membrane. Adhesions are also absent in dropsy of the gall bladder, and the walls of this organ are much attenuated. It is usually found that in cases of obstruction by gall stone in the common duct the gall bladder is small and contracted, due probably to repeated irritations from stones, the subsequent fibroid changes successfully resisting distention. Distention of the gall bladder with marked jaundice is more frequently met with in new growths of the bile ducts or of the head of the pancreas. The chemical character of the fluid has already been described in section III.

Empyema or abscess of the gall bladder results from an infection by micro-organisms, either following upon some obstruction or irritation, or developing spontaneously. The condition is most frequently associated with gall stone, but tumors of the bile duct, typhoid and other fevers may be predisposing factors. Robson considers that "infection by pyogenic organisms is probably in every case the true exciting cause." The same anatomical changes are presented as have been described in the section on Purulent, Ulcerative, and Croupous Inflammation of the Gall Bladder, etc. The walls of the organ are friable and easily ruptured. Adhesions to the surrounding parts are usually formed, and a fistula is established. Pus, or pus and bile, and almost always gall stones, make up the contents. The accumulation of gall stones in the gall bladder, causing enlargement, is not uncommon.

Symptoms.—The presence of a tumor in the region of the gall bladder is common to all forms of enlargement. The nature of a tumor observed in this region is determined by its position, size, and shape, by the characters revealed by palpation, and by the nature of its contents. The gall bladder may be known to be enlarged when it is situated under the free border of the ribs, at a point where it is crossed by a line drawn from the tip of the right shoulder to the symphysis pubis (Janeway). As enlargement progresses, the direction which it takes is usually toward the umbilicus, or into the iliac fossa. An area of resonance intervenes between the tumor and the liver, and the intestines are never in front of the organ. The tumor may be pyriform, oval, semiglobular, reniform, or heart-shaped. The size of the tumor varies from that of a walnut to that of a child's head; it may even distend the ribs on both sides (Coupland). On palpation, the tumor may be found to be fixed or movable, tender on pressure, firm, elastic, and fluctuating. If enlarged by gall stones, a grating sensation may be experienced on palpation, and the mass will be hard and firm.

The general condition of the patient and the symptoms presented depend on the cause of the obstruction (see the section on Purulent Inflammation, etc.).

Diagnosis.—A differential diagnosis must be made between enlargement of the gall bladder and many forms of abdominal tumors—hepatic, gastric, duodenal, pancreatic, and lymphatic tumors (see section on Occlusion, etc.). Abscess of the liver and hydatid disease must be excluded. In the former, the cause, the general and local symptoms, the absence of jaundice, the induration, and then the softening and fluctuation of the swelling, should be noted. The painless, slow course of hydatid disease, the broad base of the cyst, the fremitus, and the result of tapping will serve, if taken with the negative symptoms of enlargement of the gall bladder, to render the recognition of this disease possible. In multilocular hydatid disease the tumor resembles an enlarged gall bladder containing calculi; like the latter, it is nodulated, hard, and tender, but it is associated with early jaundice, ascites, an enlarged spleen, œdema of the lower eyelids, great emaciation and prostration, with rapid decline of the patient's general health—conditions which, excepting jaundice, are not likely to be present in gall stones. Floating kidney and renal and ovarian tumors have been mistaken for enlargement of the gall bladder. Such an error will not often be made if it be remembered that the enlarged gall bladder is more movable at the lower than at the upper portion; that one end is larger and more rounded than the other; that fluctuation may be present, and that biliary symptoms generally exist; while the absolute sign of floating kidney, an abnormal area of resonance in the renal region, is absent. Tapping would also be invaluable as an aid. In sarcoma of the kidney, in hydronephrosis, and in pyonephrosis, there are changes in the urine to call attention to them. Those renal tumors at first always have the intestines in front of them; they are not influenced by respiratory movement, nor is their area of dulness on percussion continuous with that of the liver; in hydronephrosis a previous renal colic and possibly frequent discharges of urine followed by diminution in size of the tumor occur. These questions of diagnosis arose in the study of the case of Kocher. He relied much on the results of exploratory puncture, as previously discussed. A connection between the tumor and the uterine appendages and the seat of origin and direction of development of the growth are the points in favor of ovarian tumor; in addition to which, if the fluid be characteristic, the diagnosis of such a tumor would be doubtless correct. A recognition of the various forms of enlargement of the gall bladder can be made by attention to the results of palpation and exploratory puncture and by a consideration of the history of the case. A cancerous tumor of the gall-bladder is fixed, painful, not very large, and is attended by gastric symptoms and cachexia.

Course, Duration, Prognosis.—These all depend upon the cause. Abscess of the gall bladder is manifested by active symptoms and runs a rapid course. It may terminate favorably by communicating with the exterior, or the stomach, or the intestines, although long-continued discharge from the fistula might be serious. The prognosis of this condition depends on the direction in which the pus may burrow. Accumulations of bile are serious, on account of the cause of the collection, and the course and prognosis depend upon the concomitant pathological phenomena. Dropsy of the gall bladder is latent and chronic; the prognosis is not unfavorable.

Treatment.—Tapping of the gall-bladder is indicated in cases of accumulation of bile or serum, although to-day a surgeon will prefer to open directly into the gall-bladder; purulent collections are practically always to be treated in this manner. At the same time a supporting and stimulating line of treatment must be carried out. The same indications are to be met in accumulations of bile in the gall bladder as in occlusion of the biliary passages.

V. MORBID GROWTHS OF THE GALL BLADDER AND GALL DUCT.—Here and there may be found an isolated report of a case of polypus, fibroma (submucous), myxoma, or tuberculosis of the biliary channels, but they are uncommon. Rolleston reports an instance in which a papilloma of the bile duct in intimate association with a stone was removed; some months later the patient returned with a growth in the same region, probably malignant. Bishop (*Lancet*, July 18th, 1901) described a large, non-malignant, cystic growth of the gall bladder and cystic duct. The epithelial lining of the cavities was regularly formed and no sign of cancerous formation could be detected. Kelynack (*Med. Chron.*, November, 1897) has collected instances of fibroma, myxoma, adenoma, and papilloma, though he considers most of the latter to have been epitheliomata. Primary cancer is more frequent than is generally supposed, the secondary form is very common. One of the writers (Musser) has tabulated seventy-eight cases of primary cancer of the gall bladder, and ten cases of cancer of the bile ducts. Kelynack amongst 4,278 cases of cancer finds 8 instances of the former and 2 of the latter. Fütterer (1897) and Rolleston (*Clin. Journ.*, 1897) have reviewed this question.

Primary Cancer of the Gall Bladder. (Musser: "Cancer of Gall Bladder and Bile Ducts.")—*Etiology.*—The *age* was not recorded in 8 cases. Two cases occurred under thirty; 13 between forty and fifty; 19 between fifty and sixty; 14 between sixty and seventy; 13 between seventy and eighty, and 1 in a patient over eighty years of age. The variety of carcinoma was not recorded in 28 instances. In the remainder, at no period of life was there any remarkable tendency to one variety rather than to another. The extreme age at which the growths were found is noteworthy. The *sex* was recorded in 75 cases, of which 61 were in females and 14 in males. The varieties were equally distributed among the men. Among the women, 18 had encephaloid, 8 scirrhus, 6 epithelioma, 5 colloid, and 2 villous carcinomata; 2 others had sarcomata. Occupation, heredity, and habits played no part in the etiology. Nor did previous health, mental states, or accidents in any way predispose to the disease. Four cases were recorded with antecedent history of gall stones. In the reports of the autopsies, however, it is noted that in 52 of the 78 cases gall stones were found. Kelynack's article (*Med. Chron.*, November, 1897) includes the most valuable collections of cases up to this time; very complete statistical reports are given.

Symptoms. (Musser: "Cancer of Gall Bladder and Bile Ducts.")—Jaundice was present in 51 cases. It developed rapidly in 1, was slight in 6, recurring in 1, and continued for periods varying from one week to three months. The cancerous cachexia was observed in 12 cases. Pain was present in 39 instances. It was seated in the right hypochondrium in 22 cases. Nine suffered from epigastric pain. It was described as colicky (8 cases), as lancinating, as paroxysmal, as wandering, as constant, and as severe. Tenderness on pressure was elicited in a few instances. Fever was present in a large number, viz., in 13 cases. It was intermittent in 2, continued in the others.

The gastro-intestinal symptoms were marked. Nausea was noted in 5 cases, and vomiting in 30. The appetite was lost in 14; constipation was present in 19 cases, diarrhœa in 11. Ascites developed in 16 cases; œdema, appearing late in the disease, in 9. Exhaustion ensued in 15; emaciation continued and became excessive in 36 instances. Hemorrhages occurred, late in the disease, in 5 cases, and grave cerebral symptoms in 7. Physical signs: A tumor was observed in 34 instances; hard and firm, 19 times; irregular and nodular, 8[10]; round, oval, pyriform, cylindrical, and smooth, were the terms used to describe it. In 8 it was movable, in 6 fixed. It disappeared on pressure in 1 instance. It varied in size from a hazelnut to a child's head. Ten times a record of pain in the tumor was made; 4 times the tenderness was marked. The tumor was said to be situated in the region of the gall bladder (10), in the umbilical region (7), in the right hypochondrium (10), or in close proximity to these situations. The liver was enlarged (21), atrophied (1), hard (2), irregular (2), nodular (3), or tender (2). The veins over the surface were enlarged in 2 instances.

In fine, emaciation, jaundice, cachexia, pain in the region of the gall bladder, with fever, nausea, vomiting, and loss of appetite, with or without diarrhœa, are the prominent symptoms of cancer of the gall bladder. To corroborate the surmise of its presence, a tumor in the right hypochondrium, tender on pressure, and the seat of pain, and nodular in character, would usually be found.

Morbid Anatomy.—The encephaloid variety is found most frequently, the scirrhous next, and then the epitheliomatous, colloid, and villous. Kelynack gives epitheliomatous growths the first place in order of frequency, with scirrhous next. The growth begins at the junction of the cystic duct with the bladder and involves the entire organ, leaving scarcely a trace of it, or infiltrates the coats and encroaches on the cavity. Again, a few nodules are seen underneath the mucous membrane, or a dense thickening of the walls, caused by new formations, takes place, especially at the cystic duct, or finally the gall bladder is represented by a nodular mass. The mucous membrane is destroyed entirely or ulcerated at various points over the cancer, or is the seat of intense inflammation. Fungoid cauliflower or villous excrescences grow into the cavity of the bladder, or the surface of the mass may be covered with papillæ with bulbous extremities. The tumor may be dense, firm, without juice, or a soft, pulpy mass. In some instances the gall bladder is reduced in size, very often it is enlarged, even enormously distended. The peritoneal investment is intimately adherent and thickened; subperitoneal nodules are seen, or the external surface in the colloid variety partakes of its peculiar characters. Adhesions are formed between the diseased gall bladder and the adjacent organs; degeneration of the walls, and at times rupture, take place. Ulceration and perforation are very common. Fistulous communication is thus established between the gall bladder and the duodenum, the colon, or the stomach. In the course of the disease gall stones are often discharged in this way. The centre of the carcinomatous mass is made up of soft, pulpy detritus, or of a thick, creamy matter. In it gall stones are also found, sometimes firmly encapsulated by the growth; or, if the cavity of the gall bladder remains, it is filled with calculi, with pus, bile, blood, or mucus, singly or combined. In 52 instances out of 78, gall-stones were present. The new formation spreads to contiguous structures;—thus the liver, colon, stomach, etc., may be involved. Changes are found in the liver and in the ducts, due to obstruction of the large bile ducts. (See Sections II. and III., for description.) Peritonitis (local) is usually present; an acute inflammation is set up by rupture. Secondary deposits may also be found in the abdominal lymphatic glands, the omentum, the suprarenal bodies, and the pleura.

Diagnosis.—The marked symptoms detailed in the clinical history are to be borne in mind. The character of the tumor, its seat, its mode of growth, its immobility, pain, and tenderness, are important. The occurrence of jaundice and vomiting, the passage of calculi (by a fistula leading to the colon) per rectum, without relief to obstruction, and the occurrence of emaciation, make a diagnosis almost positive. The age and the sex are important factors, and a history of the jaundice is of aid in the diagnosis.

Relation of Gall Stones to Carcinoma.—This is believed to be causal. The frequent occurrence of this disease in the same sex in which biliary calculi are most common, is strong evidence. But a case of Quetsch's (*Berl. klin. Wochenschrift*, 1885, No. 42, p. 672) confirms this opinion more decidedly than does any previous clinical evidence. The patient, a female, was subject to biliary calculi, and a biliary cutaneous fistula had been formed. Subsequently, a carcinoma of the gall bladder developed in the presence of the calculi which did not pass, and, no doubt, were the cause of the local irritation. Zenker found gall stones in 85 per cent. of cases of cancer of the gall bladder. Similarly high percentages were found by Courvoisier, Brodowski, Gayle, Bertrand, and others; Siegert, in 95 per cent. of primary carcinomas of the gall bladder, found stones associated, but in only 15 to 16 per cent. of secondary carcinomas was this the case. In 4 cases of primary carcinoma of the liver, reported by Beadles, stones were also present, while none were seen in 36 secondary hepatic carcinomatous growths. Others believe that the calculi develop secondarily from stagnation of the bile and precipitation of its constituents.

Duration.—This has been placed at several years by Villard; in other cases death occurred within three months after the first symptoms developed.

The *prophylactic treatment* consists in the removal or prevention of formation of the calculi, and the *treatment* of the disease, after it is once manifested, is purely symptomatic. Robson, however, has removed the gall bladder and part of the liver in five cases, with more or less encouraging results in four of them. As one of the cases was shown at operation to be a chronic inflammatory condition of ducts, gall bladder, and adjoining viscera instead of carcinoma, the value of an exploratory operation is certainly suggested.

VI. PRIMARY CANCER OF THE GALL DUCTS.—It may develop within the liver or in the larger ducts. The most common point of origin is at the mouth of the common duct or at the junction of the cystic and hepatic ducts. A firm mass of newly formed tissue surrounds the duct or invades its walls. The lumen is almost or completely obliterated; its inner surface is the seat of ulceration, at certain points, or of papillary growths. A fungous growth projected from the mouth of the common duct in a case reported by Stokes. The anatomical changes of occlusion and stenosis are seen in the liver and ducts. Secondary deposits are found generally in the liver only, along the ducts. Kelynack[11] discusses primary cancer of the ducts and has collected 26 cases. A diffuse growth was most frequently met with post mortem. Edes[12] and Rolleston[13] are more recent contributors to the subject, dealing particularly with cancer of the extreme end of the common bile duct. Halsted[14] has removed a columnar-celled carcinoma from the ampulla of Vater.

The symptoms common to carcinoma and to biliary obstruction are present. Rarely is the growth large enough to be recognized by palpation. Death is rapid and due to occlusion of the ducts, leading to bile intoxication or purulent inflammation.

VII. Congenital Defects of the Gall Bladder and Gall Ducts.—The gall bladder may be absent entirely, without serious inconvenience; a shrivelled pouch or a contracted tube takes its place. In atresia of the ducts, jaundice, umbilical hemorrhage, and marasmus are present during life. The jaundice is present at birth, or makes its appearance a few days afterward, persists, and deepens. The stools show an absence of bile; the urine is bile-tinged. There is from the first a tendency to hemorrhages, and this increases ecchymosis under the skin; bleedings from the mouth, nose, or bowels take place.

Umbilical hemorrhage, occurring after the separation of the cord, is especially marked. As the child grows older it loses in flesh, becomes extremely weakened, and dies of cholæmia or exhaustion, in spite of an ability to take much nourishment. At first the liver is normal, but if the child lives it becomes very large, and the spleen is likewise increased in size. Ascites may develop. If hemorrhages do not occur, the child lives many months. In a case reported by Lotze, the child lived seven months.

R. Lomer [15] reports a curious case. It was one of congenital obliteration of the right hepatic and the cystic ducts. The whole right lobe had undergone cystic degeneration and was shrunken, the gall bladder was obliterated, but the left lobe remained normal. He analyzes a series of cases, and, from the fact that usually the parents are syphilitic and several of their children are similarly diseased, he holds that an intra-uterine hepatitis of syphilitic origin is the cause of the disease. This is the usually accepted explanation of the pathology of congenital disease of the ducts. The obstruction, which is fibrous, may be in a main duct or in one of its branches. The gall bladder may be normal, but contains a serous fluid. It may be obliterated or remain as a fibrous cord. The ducts in the liver may be dilated, or some may appear like fibrous cords. Sometimes the portal fissure is the seat of local perihepatitis, and usually the surface of the liver is involved. The liver is icteric, the seat of connective-tissue overgrowth, or atrophied. Some parts become cystic. Rolleston and Hayne [16] describe a congenital obliteration of the bile ducts giving rise to an advanced hepatic cirrhosis; Thompson (Allbutt's "System of Medicine" and Thesis, Edinburgh, "Congenital Obliteration of Bile Ducts") has collected fifty such cases. Ford [17] gives cases of congenital obstruction producing the so called biliary cirrhosis.

The jaundice due to congenital defects of the ducts is to be distinguished from that jaundice-like discoloration of the integuments, conjunctiva, etc., that is physiological. In this condition, which is common in new-born infants, bile is present in the stools. Jaundice of the simple catarrhal variety also occurs in infants. It usually responds promptly to treatment, and has not the malignant aspect of disease dependent upon deficiency of the ducts. Then, again, a pylephlebitis occurs sometimes in infants. In this case fever and the usual evidences of pyæmia are present.

VIII. Parasites.—They may develop within the biliary passages (distoma), they may emigrate from the intestines (round worm), or they may find their way into the ducts by ulcerative action (echinococcus). Rarely, the latter develop within the ducts.

1. *Distoma hepaticum* (*large liver fluke*) *and Distoma lanceolatum* (*small liver fluke*).—Common in sheep and cows, rare in man. The large fluke is found in the gall bladder or large bile ducts; the small one generally in the finer ducts. Both species may occur in the same subject. The latter variety produces the most notable changes in the liver.

The presence of these parasites sets up a chronic catarrhal and suppurative inflammation of the ducts. Enlargement of the gall bladder and ducts occurs secondarily. A fibrous inflammation of the walls takes place, with secondary calcareous degeneration of the products of inflammation; the ducts become much enlarged and thickened, and the lumen is dilated. Occlusion of the ducts results on account of the inflammatory disease and the presence of the parasites in the canal. By necessity, therefore, we have the symptoms, previously noted in this section, of the above anatomical changes, and of obstructive jaundice. In addition, nervous symptoms of a reflex nature—as syncope, convulsions, or aphonia—may be present. A positive diagnosis can be made only by finding the parasites in the vomited matter, or in the fæces. Death occurs sometimes on account of the inflammatory complications, or from exhaustion.

2. *Round Worms* (*Ascaris lumbricoides*).—They usually wander from the intestines, and are found with their head toward the liver. Rarely, after adhesive inflammation and fistulous communication between the gall bladder or ducts and the intestine, worms are found in the biliary passages. The number of them varies—from one to three or four, usually. They are often found alive on making an autopsy, or have died before the death of the patient, and are soft and macerated. Their presence excites catarrhal inflammation, causes occlusion and, secondarily, a purulent cholangitis, a dilatation of the ducts, and subsequent atrophy of the liver, or the formation of multiple abscesses. When limited to the gall bladder, they cause enlargement and inflammation of that organ. The dilatation of the ducts is usually general; sometimes local sacculated dilatations are observed, in which worms lie rolled up.

The symptoms—if the worm has recently migrated into a duct—are like those of hepatic colic. Later, the symptoms and signs of obstructive jaundice occur, and then those of purulent cholangitis. A history of an attack of worms, the presence of the parasite in the ejecta, and the age of the patient furnish valuable corroborative evidence. Further, intestinal and nervous symptoms due to worms are said to be present.

3. *Echinococcus* (*Hydatid Disease of the Bile Ducts*).—Either an hydatid cyst may press upon one or more of the ducts, causing occlusion of them, or complete obliteration of their lumen, or entire destruction of them (Leroux); or the sac may ulcerate into the ducts or bladder, and the vesicles pass by this route into the intestines, with symptoms of hepatic colic; or, finally, it may cause occlusion, dilatation, and inflammation of the biliary passages. This process may terminate in suppuration and gangrene of the cyst, and is usually fatal. The symptoms of obstructive jaundice of a high degree, and of the local inflammatory changes, indicate this pathological condition. The presence of hydatid hooklets in the ejecta from the stomach or bowels, a previous history of a painless enlargement of the liver, and the results of tapping or exploratory puncture, would confirm one's opinion of the presence of hydatid disease. Finally, the gall ducts are seriously invaded in that rare manifestation of hydatid disease known as multilocular echinococcus. In this instance the walls of the ducts are thickened, hard, and rigid, and the lumen is effaced, by the presence of the vesicles in the tissues. Secondary inflammation, suppuration, and dilatation, etc., may arise in these cases. The symptoms of this manifestation have been considered in the section on Occlusion of the Ducts.

It is interesting to note that the bile, some authorities believe, is capable of killing these parasites.

GALLIC ACID.—By exposure, to the atmosphere, of galls in the presence of water, chemical conversion of the tannic acid of the galls takes place, resulting in the formation of gallic acid, $HC_7H_5O_5,H_2O$. This body is official in the United States Pharmacopœia under the title *Acidum Gallicum,* Gallic Acid, and presents itself as "white, or pale fawn-colored, silky, interlaced needles, or triclinic prisms; odorless; having an astringent or slightly acidulous taste; permanent in the air. Soluble at 15° C. (59° F.), in 100 parts of water, and in 5 parts of alcohol; in 3 parts of boiling water, and in 1 part of boiling alcohol. Also soluble in 40 parts of ether, and in 12 parts of glycerin. Very slightly soluble in chloroform, benzol, or benzin" (U. S. P.). On heating, the acid first loses its water of crystallization, then melts, and finally is decomposed, and consumed without residue.

Gallic acid is purely but feebly astringent, and seems practically devoid of any other physiological property. Taken internally, it does not poison, nor constipate, nor even disorder the stomach unless in excessive dosage. It does not coagulate albumin, and so, when swallowed, is readily absorbed. After absorption it appears speedily in the urine, as is demonstrable by chemical tests. *Therapeutically,* the only reputation of gallic acid is for internal giving for the control of hemorrhages from inaccessible parts—for which purpose the efficacy of the medicine is esteemed very differently by different practitioners. Since, in the application in question, the acid must act by local contact as presented to the bleeding vessel in solution in the blood, it is evidently necessary for success that the charge of acid to blood shall be as great as possible. Full and frequent doses, therefore, are required by the indication. Gallic acid has been given without untoward effect in dosage of 0.65 gm. (gr. x.) every three hours, unremittingly, for three weeks. It may be prescribed in pill, powder, or mixture. *Edward Curtis.*

GALLICIN $[C_6H_2COOCH_3(OH)_3]$ is prepared by heating a methyl alcohol solution of gallic or tannic acid with strong sulphuric acid, or by passing dry hydrochloric acid gas through the solution. It crystallizes in rhombic prisms or fine needles, which are freely soluble in water and alcohol. It is used as an antiseptic, non-toxic dusting powder, and, in solution, in conjunctivitis.

W. A. Bastedo.

GALLOBROMOL—dibromogallic acid $[C_6Br_2(OH)_3COOH]$—is a colorless or slightly grayish-red powder, composed of fine acicular crystals, and obtained by the action of bromine on gallic acid. It is slowly soluble up to ten per cent. in cold water (Merck), and dissolves readily in boiling water, alcohol, or ether. It has been used as a bromide in neurotic conditions and epilepsy, but has been found by Lépine to cause in a dog slowing of the heart, depression of respiration, fever, hæmoglobinuria, convulsions, and death. It is of more use locally, as an antiseptic and astringent, as in eczema, or in gonorrhœa, cystitis, or epididymitis. For cystitis it is used as an irrigation in two to four per cent. solution; for urethritis as an injection; and for eczema as a lotion, ointment, or dusting powder of one to two per cent. strength.

W. A. Bastedo.

GALLOFORMIN $[C_6H_2(OH)_3COOH(CH_2)_6N_4]$ is a condensation product of gallic acid and hexamethylene tetramine. It forms very hard, refractive, acicular crystals, soluble with difficulty in water, alcohol, ether, and glycerin, and insoluble in benzol and fixed oils. It is very unstable, readily yielding formaldehyde gas, so is used as an antiseptic both internally and externally. It is decomposed by heat, acids, or alkalies.

W. A. Bastedo.

GALL, OX.—Fel Bovis.—"The fresh bile of *Bos Taurus* L. (class *Mammalia;* order *Ruminantia*)," (U. S. P.)

A brownish-green or dark green, somewhat viscid liquid, having a peculiar, unpleasant odor, and a disagreeable, bitter taste.

Specific gravity: 1.018 to 1.028 at 15° C. (59° F.).

It is neutral, or has a faintly alkaline reaction on litmus paper.

A mixture of 2 drops of ox gall and 10 c.c. of water, when treated, first, with a drop of a freshly prepared solution of 1 part of sugar in 4 parts of water, and afterward with sulphuric acid, cautiously added, until the precipitate first formed is redissolved, gradually acquires a brownish-red color, changing, successively, to carmine, purple, and violet.

Purified Ox Gall, Fel Bovis Purificatum (U. S. P.).

Fresh ox gall, *three hundred cubic centimetres*....	300 c.c.
Alcohol, *one hundred cubic centimetres*..........	100 c.c.

Evaporate the ox gall, in a tared porcelain capsule, on a water bath, to about *one hundred* (100) *grams,* then add to it the alcohol, mix the whole thoroughly, and set it aside, well covered, for three or four days. Then decant the clear solution, filter the remainder, and, having mixed the liquids and distilled off the alcohol, evaporate the remainder to a pilular consistence.

A yellowish-green, soft solid, having a peculiar odor, and a partly sweet and partly bitter taste.

Very soluble in water and in alcohol.

A solution of 1 part of purified ox gall in about 100 parts of water behaves toward sugar and sulphuric acid in the same manner as the solution mentioned above.

An aqueous solution of purified ox gall should be clear, and should remain transparent upon the addition of an equal volume of alcohol (evidence of proper purification).

This complex substance in its crude condition consists of about ten per cent. of solids and ninety of water.

The most important solid constituents are the *sodium salts* of *taurocholic* and *glycocholic acids,* and several not very well distinguished coloring matters (*bilirubin, biliverdin,* etc.). Besides these it also contains a number of decomposition products, *cholesterin, urea,* etc., and some *fats* and *mucus.*

Further than to show its practical identity with that of the human subject, the study of the specific composition of ox gall is unimportant.

For the same reason the study of its action pertains wholly to physiology. We know that bile has no business in the stomach, although it appears that its entrance there, in certain morbid conditions, may exert a stomachic effect, without seriously inhibiting digestion, and its therapeutic use may be serviceable in this way. It must, however, be remembered that the properties of the bile itself are subject to change in the stomach, so that suitable measures must be taken in its administration (see below), when the intestinal action is desired.

It is equally well established that bile in the circulation acts as a poison, although there are some facts to suggest that its antitoxic action there may at times more than counterbalance such objection.

It is then in the intestine and in the liver that we must look for the beneficial effects of the administration of bile. In the former it is a valuable antiseptic, peristaltic stimulant, chemical synergist of certain purgatives, and promoter of the absorption of fat. None of these processes requires discussion. All can be effected by ox gall, properly administered, as by the natural secretion. Upon the liver, the drug has the effect of a direct cholagogue, that is, an agent increasing the actual secretion of bile, and about the only one known. Since the constituents of the bile decomposed in the intestine are returned to the liver to be again recombined, we should naturally expect this increase to be produced. It appears, however, that the increase is greater than the ratio thus accounted for, and it is apparent that the bile salts exert a stimulating effect upon the secreting mechanism. The following concerning the use and administration of the drug may well be reprinted from the last edition of this work.

The action of ox gall in assisting the absorption of fats and oils, and its aid in maintaining intestinal antisepsis, has suggested its use as a proper means of treating typhoid fever. Dr. Adolph Zea reports the result of ten cases in his own ward, and forty-eight cases treated by medical friends, as very gratifying. His method of conducting the case is as follows: If the case is seen early, a dose of calomel is given to relieve the digestive tract of its contents; alcohol in the form of whiskey is given at first as a stimulant, and, if additional stimulation is required, strychnine, caffeine, ammonia, camphor, or small doses of quinine; dilute muriatic acid in large quantities of water as a beverage, and fel bovis purificatum siccum, in doses of two to four grains, three to six times a day in pill form or capsule. The diet consists of fluids—milk, gruel, beef-tea—in small quantities frequently given. The milk should always be boiled, but may be given hot or cold according to the wish of the patient. Preparations of beef extracts and juices may also be given.

The benefit of this treatment is shown in a reduction of the temperature after the drug has been given for a few days, and a freedom from all distressing abdominal symptoms and complications. Convalescence is also thought to be more rapid than under any other line of treatment.

It has been very properly pointed out that the enclosing of the dose in *keratin* tends to prevent changes in it by the acid gastric juice, in its passage through the stomach.

Its injection into the rectum, in twenty-grain doses well diluted, tends to clear that organ of fæces.

Henry H. Rusby.

GAMBOGE.—Cambogia.—"A gum resin obtained from *Garcinia Hanburii* Hook. f. (fam. *Guttiferæ*)" (U. S. P.). (The family is now called *Clusiaceæ.*) This genus comprises about forty species of Eastern tropical evergreen trees with yellow juice. Other species yield the Mangosteen fruit and bark, and the Kokum butter. The gamboge tree is a native of Cambogia, Siam, and Cochin China, whence the supply of the gum resin for European and American consumption is obtained; but there are besides several other species of *Garcinia* in India, China, and the Asiatic islands, which supply similar products, if not exactly the same. Gamboge is collected by cutting or wounding the twigs or trunks, when the bright yellow latex flows slowly out, and is collected in vessels, usually bamboo joints, fastened at the lowest part of the incisions. Here it slowly hardens, or is perhaps dried over a fire, until a solid mass results, of the shape, usually cylindrical, of the containing vessel. The bamboo is then split off, and the gamboge is packed in large boxes for transportation.

That thus collected in bamboo joints is known as "pipe-gamboge." Saigon, or "purse" gamboge, is collected in pockets of leaves or cloth, six or eight inches long by three or four broad. It is usually a little darker than the former. When run or massed into large blocks or tubs, it is called "cake gamboge," or "gamboge in sorts."

The pipe gamboge is preferred, not only because it represents the typical quality, but because it is almost invariably pure and clean. The large cakes are liable to extensive adulteration with stones and pieces of iron. Being often formed in tubs or boxes, the gamboge is very apt to come into contact with nails or other metal, which turns it dark for a considerable distance from the offending body.

Gamboge has been used in China and India as a pigment for many centuries, and appeared as a purgative in Europe early in the seventeenth century. Its use in medicine, however, has always been insignificant in comparison with its consumption as a yellow paint, for which use it is hardly excelled by any pigment.

The best of that which reaches us is in cylindrical pieces, usually hollow at the centre, 2 to 5 cm. (1 to 2 in.) thick, longitudinally striate on the surface; fracture flattish-conchoidal, smooth, of a waxy lustre, orange-red; inodorous; taste very acrid; powder bright yellow, sternutatory, free from starch.

Gamboge should yield not less than seventy per cent. of resin and not over three per cent. of ash.

It does not dissolve in water, but forms a very fine, smooth, yellow emulsion with it, and it is wholly soluble in potassa solution.

Gamboge contains about seventy-two (Christison) per cent. of yellow resin called *gambogic acid*, an orange-yellow, tasteless, and odorless mass, soluble in alcohol and ether, but not in water, having the purgative properties of gamboge, but less intensely than the crude gum resin itself. It also contains fifteen or more per cent. of *gum*, a little water, and some impurities. Its activity is proportional to the percentage of resin in it.

Action and Use.—This is one of the most violent of hydragogue cathartics, producing abundant watery stools and considerable griping, on which latter account it is not often now given alone, or for its full effect. It is, however, frequently added in small doses to the other cathartic combinations, and experience has proved its usefulness. It is especially valuable in such conditions as lead colic and seasickness, where the bowel requires powerful stimulation.

The full dose of gamboge is about 0.3 gm. (= gr. v.), but less is advisable in compositions; the maximum daily quantity is stated by the German Pharmacopœia to be 1 gm. It is an ingredient in the compound cathartic pills (*Pilulæ Catharticæ Compositæ*, U. S. P.), each of which contains about a quarter of a grain.

W. P. Bolles.

GANGLION. See *Bursæ.* (*Surgical.*)

GANGRENE. (PATHOLOGICAL.)—The term gangrene is loosely applied by the clinician to any form of local death of tissue occurring within the living body, in which the necrosed area becomes discolored, resembling more or less tissues which have been burned. By the pathologist it is used to indicate a necrosis accompanied by putrefactive processes. A number of designations are used partly as synonyms and partly to express different varieties of this condition: mortification, putrescence, putrefaction, sphacelation, etc.; but the essential idea of gangrene is that of necrosis accompanied by putrefaction. The presence of putrefactive or saprophytic bacteria is, therefore, to be regarded as the most distinctive feature of gangrene.

Gangrene may be either *primary* or *secondary*. In primary gangrene the condition is due directly to the infection of the tissues by some specific bacterium and is to be regarded as a specific affection. In secondary gangrene there is first a necrosis due to some other cause with a subsequent infection by putrefactive bacteria. According to its manner of origin gangrene may be *traumatic* or *inflammatory*, and according to its behavior it may be *circumscribed, diffuse, spreading, phagedenic*, etc. Clinically, various forms occur: *thermal, toxic, infectious, neuropathic, diabetic, senile, hospital, idiopathic*, etc..

Primary Gangrene.—A number of specific infections may be included under this head: infection with the Bacillus aërogenes capsulatus, B. œdematis maligni, B. diphtheriæ, B. anthracis, B. coli communis or closely related organisms, and probably a number of other imperfectly known bacteria. Any one of these may produce severe inflammatory processes followed immediately or very quickly by gangrene, which is apparently due to the originally infecting bacterium, though in some cases there may be a secondary infection by saprophytes.

Secondary Gangrene.—This is the more common form. The preceding necrosis may be caused by circulatory changes, pathological conditions of the blood-vessels, burns, freezing, mechanical injury, pressure, corrosive poisons, intoxications, infections, etc.; the secondary infection of the dead tissue being caused by various forms of saprophytic bacteria.

When gangrenous tissues are exposed to the air their fluids may be lost by evaporation and become hard and dry (*mummification, dry gangrene, gangræna sicca*). If evaporation does not occur and the dead parts remain moist, the condition is known as *moist gangrene* (*gangræna humida, sphacelus*). Between the moist and dry forms there is no hard-and-fast line; dry gangrene may develop from a moist gangrene through subsequent evaporation; or by the absorption of fluids from the surrounding tissues a dry gangrene may be converted into the moist form. If the gangrene is very foul-smelling it is usually spoken of as *putrid* or *septic gangrene*. The formation of gas in gangrenous parts gives rise to the condition known as *emphysematous gangrene*. If the tissues affected contained much blood before death, they become black or greenish in color (*black gangrene*); if anæmic, they may remain light in color though always discolored to some extent (*white gangrene*). Clinically *warm* and *cold gangrene* correspond to these forms respectively, the presence of heat depending upon the flow of blood in the neighboring tissue, the warmth being most marked when there is a severe reactive inflammation about the gangrenous area. Black gangrene may become a cold form by the complete shutting-off of the blood supply.

Dry Gangrene.—The evaporation of fluids from the surface of gangrenous tissues exposed to the air gives to the dead part an appearance somewhat resembling that of mummy tissue. The drying of the umbilical cord may be taken as a physiological prototype of this process. Putrefaction goes on very slowly in the dried mass and may cease entirely. Only rarely, however, does mummification of necrosed tissues occur without some putrefactive changes. There is almost always an odor about the parts involved in dry gangrene and this is in itself an evidence of the occurrence of putrefactive processes. The odor, however, is always much less marked than in the case of moist gangrene. Dry gangrene occurs most frequently in the parts of the body most exposed to evaporation; gangrene of the tips of the ears, nose, fingers, and toes is almost always of this variety. The loss of the epidermis is a favoring factor.

In the great majority of cases dry gangrene is due to arterial or venous obstruction through embolism or thrombosis, whenever the collateral circulation is insufficient to keep up the nutrition of the affected part. It occurs frequently after freezing, the peripheral vessels being occluded by thrombi. Severe burns, as well as the effects of strong corrosives, are frequently followed by dry gangrene. It is as a rule found in ergotism and the symmetrical gangrene of Raynaud's disease, and occurs frequently in diabetes and in cases of senility with vascular changes, especially in individuals whose general nutrition is lowered. The fœtus papyraceus is considered by some authors to be an example of dry gangrene, the mummification of the dead fœtus being caused by premature loss of the amniotic fluid and the pressure exerted upon the former by its living twin. In the absence of putrefactive changes this condition can hardly be regarded as being of the nature of gangrene.

Moist Gangrene.—This form occurs very frequently after severe traumatism to the extremities, especially contusions and crushing with resulting great injury to the blood-vessels. It follows obstruction of the venous circulation more quickly than that of the arterial. Diabetic gangrene is not infrequently of this form, senile more rarely so. It may occur in the course of the acute infectious fevers, either in the skin or in the mucous membranes. It forms a feature also of certain skin diseases. Decubitus (bed-sores), malum perforans, hysterical gangrene, noma of the mouth and genitals are varieties of moist gangrene. The internal and external female genitals may suffer moist gangrene from mechanical injury received during severe labor or as the result of infection following childbirth. Of the internal organs the lungs are most often affected. Pulmonary moist gangrene may follow infarction, non-resolution of croupous and purulent pneumonias, inspiration pneumonia, pulmonary abscess, atelectasis, bronchiectasis, new growths, etc. Pressure upon the trachea or bronchi, or upon the branches of the vagus by œsophageal diverticula, tumors or aneurisms not infrequently gives rise to pneumonia followed by moist gangrene. Embolism or thrombosis of the mesenteric arteries with infarction of the mesentery is always followed by moist gangrene. Intestinal obstruction, intussusception, strangulated hernia, obstruction or strangulation of the appendix usually lead to moist gangrene of the affected parts. Traumatic injury to the pancreas or inflammation of this organ from unknown causes may give rise to moist gangrene (gangrenous pancreatitis). Torsion of the pedicle of new growths, floating spleen, kidney, etc., may by shutting off the blood supply cause a necrosis which through secondary infection often becomes gangrenous. Infiltration of the perineal tissues with urine, excessive œdema, extreme passive congestion, are also conditions leading to moist gangrene. Gangrenous inflammation of the urinary bladder may be caused by long-continued retention of urine.

Gross Appearances.—Dry gangrene is usually circumscribed. The affected part becomes discolored, yellow, brown or black, though in rare cases the dead tissues may appear bloodless and pale. The consistence of the part may be hard and tough. In advanced stages the necrotic area resembles leather or mummy skin. An odor of putrefaction is usually present in the early stages, but is never very marked. The process of mummification may be preceded by the formation of vesicles or blebs which rupture leaving the corium denuded. Evaporation is in this way greatly aided. In many cases the skin remains intact, and in this event the amount of putrefactive change may be very slight.

Moist gangrene is characterized particularly by a foul odor and progressive softening of the affected area. The color is usually reddish-purple in the early stages, but later becomes dark brown or black from the changes occurring in the blood pigment. If hydrogen sulphide is formed, the color becomes greenish from the formation of a hydrogen-sulphide compound with the iron-containing blood pigment (pseudomelanosis). Blebs are usually formed in the skin; these contain dirty-brown fluid which derives its color from broken-down blood pigment. Ultimately the entire part affected becomes very soft and partially liquefied. With the growth of putrefactive bacteria in the dead tissues the various phenomena of putrefaction are presented exactly as in the cadaver. Hydrogen sulphide, ammonia, indol, skatol, fatty acids, amins, carbonic acid, and other gases which give rise to the very marked fœtid odors characteristic of this process are formed, and as the result of gas formation a local or widespread emphysema may occur. The fluids arising from the liquefaction of the dead tissues or from the infiltration of lymph are also discolored by the destruction of the blood pigment.

Between the living and dead tissues in both dry and moist gangrene there is usually a more or less sharply marked line of demarcation which represents the point at which necrosis and putrefaction cease. At this boundary line there is very frequently present a zone of inflammatory reaction, particularly in dry gangrene and those forms of moist gangrene due to vascular changes. In other varieties of moist gangrene, particularly in that occurring in diabetes, neither the inflammatory zone nor a sharp demarcating line is present. In advanced stages of moist gangrene sequestration of the dead tissues from the living may occur, and the former either be cast off, absorbed, organized, or calcified, etc. When internal the gangrenous area usually becomes encysted. In hard parts, cartilage, bone, etc., the process of sequestration is much slower than in softer tissues.

Microscopical Appearances.—The differential diagnosis of moist gangrene from other forms of necrosis by means of the microscope depends entirely upon the presence of putrefactive bacteria and the chemical products of putrefaction. Sections of tissues in a state of dry gangrene show a marked shrinking of the cells and disappearance of the nuclei, the changes resembling very much those occurring in the horny layer of the epidermis. If putrefactive changes have been slight, the nuclei may stain faintly, even for some length of time after the advent of necrosis; and the outlines of the cells, though greatly shrunken, may still show. In advanced stages of evaporation the dry tissues become hyaline and horn-like, resisting cutting. In the blood-vessels disintegrated red blood cells are found, often forming brownish or yellow hyaline clumps. If moist gangrene preceded the evaporation, the chemical products of decomposition as well as evidences of greater disorganization of the tissues will be present.

In moist gangrene the tissues show either a simple, cheesy, coagulation, or liquefaction necrosis; or, as is usually the case, all of these forms of necrosis may be present in different parts of the sections. Necrosis of the parenchymatous cells first takes place, the nuclei disappear, and the cells become fluid or granular. Fatty degeneration of an extensive degree is often present. Muscle cells lose their striations, swell, and finally fragment or liquefy. Zenker's necrosis is usually present to a greater or less degree. Adipose tissue and nerve sheaths break up into free fat or fatty acids. Axis cylinders may either fragment or fibrillate. Connective tissue, yellow elastic tissue, fascia, cartilage and bone are changed more slowly, but all tissues may ultimately become liquefied. Hemorrhages are present in the early stages, usually by diapedesis from the early degenerative changes in the vessel walls. Rupture of the damaged vessels may also occur. Disintegration of the extravasated blood takes place, and brown or yellowish granules of hæmatoidin and hæmosiderin are formed from the diffused hæmoglobin. If hydrogen sulphide is present, black granules of hydrogen-sulphide-hæmosiderin are formed (pseudomelanin). Crystalline pigments derived from hæmoglobin may also be present. Fatty-acid crystals, tyrosin, leucin, cholesterin, crystalline and amorphous phosphates and carbonates may be formed as intermediate or end products of the putrefactive process. The coffin-lid crystals of calcium phosphate are often abundant. By means of proper staining methods the presence of putrefactive organisms in large numbers may be demonstrated. If the process has advanced slowly and the reactive inflammation is marked, the dead tissues may contain large numbers of leucocytes which also necrose ultimately, but retain their staining power much longer than the tissue elements. At the line of demarcation there is often an extensive formation of fibrin in the lymph spaces and also coagulation of the blood in the blood-vessels. Beyond this, toward the living tissue there is a more or less well-marked zone of inflammation. If the gangrenous process comes to a standstill, granulation tissue may be formed at the line of demarcation gradually encapsulating the dead area. The latter may shrink away from the border and be cast off as a sphacelus or slough, or it may be gradually disposed of in the slow process of healing by organization. If internal, the encapsulated mass of dead tissue may undergo calcification or liquefy, in the latter case forming a cyst.

Varieties of Gangrene.—In the circumscribed form the line of demarcation shows a zone of marked inflammatory reaction, and the necrosed part is either cast off as a slough or encysted. In the diffusely spreading forms there is no limitation, and the process advances until the death of the individual occurs or the necrosed portion, together with the cause of the gangrene, is removed from the body by surgical operation. In these cases the tissue resistance is either greatly lowered or the poisons produced by the infecting bacteria infiltrate the surrounding lymph spaces causing a spread of the necrotic process, or the bacteria have the power of invading and destroying tissue not previously damaged. In the circumscribed form the infection is less virulent or the surrounding normal tissues are able to resist the spread of infection. In metastatic gangrene bacteria are carried through the blood or lymph and set up secondary foci of inflammation and gangrenous necrosis. This can happen only in the case of primary gangrene, due to infection with a specific organism.

Senile Gangrene.—This is usually of the dry, circumscribed form, and is due almost wholly to disturbed circulation from arteriosclerotic changes, thrombosis, embolism, etc. Chronic wasting diseases, poor nutrition, weakened heart's action, exposure to cold, etc., are favoring factors. The lower extremities, more often the left, are chiefly affected.

Diabetic Gangrene.—The gangrenous processes which occur rather frequently in connection with diabetes are more probably the result of arterial disease than of some more obscure cause dependent upon or associated with the altered metabolism existing in this disease. Wallace (St. James' Hospital) examined twenty-four cases, in twenty-three of which he found decided atheroma. The views most commonly held at present incline toward the belief that gangrene never occurs in diabetes without the presence of arterial changes sufficient in themselves to have caused it. The extremities are chiefly affected and the dry form is more common, but moist gangrene is not infrequent. It has been stated that diabetic gangrene differed from other forms in that no sharp line of demarcation or zone of inflammatory reaction is present. Recent observations show no essential differences between diabetic gangrene and any other form due to arterial obstruction. Cutaneous gangrene, moist gangrene of the lungs, etc., have also been observed in association with diabetes, but must be regarded as coincidences. Favoring factors, such as disturbed nutrition, central nervous disturbances, etc., no doubt exist in diabetes, but the primary cause of the gangrene which occurs in this disease is to be sought in other conditions than the disturbed metabolism.

Gangrene with Acute Infections.—Gangrene may occur as a rare complication of any one of the acute infections, particularly in measles, varicella, scarlatina, diphtheria, typhus, typhoid fever, and malaria. In varicella and scarlatina it usually occurs several weeks after the attack. The gangrene is usually multiple but not symmetrical. The skin and adjacent structures are more frequently affected than the extremities, and usually no previous vascular disturbance is noticed. It occurs more frequently in cachectic children, but also in those apparently in good nutrition. The gangrenous process may affect the eyelids, conjunctiva, ears, mucosa of mouth, lips, and adjacent structures (noma, cancrum oris), external genitalia, particularly those of the female. The term noma has come to be applied to all of these forms, as well as to spontaneous gangrene of these regions occurring without any relation to the acute infectious fevers. It is undoubtedly a specific infection and a number of micro-organisms have been described, but the diphtheria bacillus seems to be the one most constantly present.

Spontaneous gangrene is reported also as occurring in pertussis, acute rheumatism without apparent cardiac involvement, beri-beri, influenza, croupous pneumonia, erysipelas, catarrhal jaundice, and in association with infantile syphilis. In the majority of these cases no bacteriological examination was made, and the exact nature of the process remains unknown. In the case of erysipelas, a number of instances are reported in which gangrene was caused by long-continued application of cold to the affected parts. Under these circumstances the resulting thrombosis of the peripheral vessels is sufficient to account for the gangrene.

Multiple Gangrene.—There are three classes of multiple gangrene:

1. Raynaud's Disease. In this condition there are previously well-marked vascular disturbances in the extremities as shown by syncope, asphyxia, or hyperæmia. The gangrene is often symmetrical, and is usually slight in extent, being confined to the fingers or toes, more rarely to the tips of the ears or nose tip. The disease occurs

chiefly in neurotic and poorly nourished individuals of early adult life. It has been regarded as a gangrene due to trophic disturbances of central origin, but the necrosis is to be looked upon as secondary to vascular phenomena of vaso-motor origin.

2. Multiple Spontaneous Gangrene Occurring in Young and Middle-Aged Individuals without Obvious Cause. These cases of so-called idiopathic gangrene have been reported in large numbers. In very few of them was a bacteriological or pathological study carried out, and it is very probable that the majority were due to vascular obstruction or specific infection.

3. Multiple Spontaneous Gangrene with Acute Infections. Multiple patches of gangrene, not symmetrical, occur as complications of acute infections, measles, typhoid, typhus, scarlatina, diphtheria, and malaria. The skin and adjacent tissues are more frequently affected than the extremities. No previous vascular disturbances have been observed. In typhoid fever the complication of gangrene occurs most often in the male, and is found in order of its occurrence in the left leg, carotid region, mesentery, and cheek. In the majority of these cases an endarteritis is found at autopsy, while in other cases the gangrene seems to result from the toxic action of the products of the typhoid bacillus. Weakened circulation and impaired nutrition are favoring factors.

Neuropathic Gangrene.—In parts of the body affected by sensory or motor paralysis slight injury, such as long-continued pressure, very frequently produces gangrene. This occurrence has been explained as being due to the removal of trophic nerve influence, but it has not yet been conclusively proved that the complete cutting-off of the nervous supply of a part is in itself sufficient to cause gangrene. The cause is much rather to be sought in circulatory disturbances and secondary infections. Raynaud's disease and other forms of symmetrical gangrene have been regarded as neuropathic affections, but are probably dependent upon vascular disturbances.

More properly to be regarded as neuropathic are those cases of hysterical gangrene in which under mental excitement, hysterical crises, or apparently under the control of the will gangrenous areas are formed in the skin. These are usually sharply circumscribed, and are preceded by various vascular phenomena which make it evident that vaso-motor disturbances play the chief rôle in their production. In many of these cases there have been, however, undoubted evidences of fraud on the part of the patient, and it has been shown that the gangrenous areas were self-inflicted and were produced by applications of hydrochloric acid, acetic acid, Paris green, caustic potash, green soap, concentrated brine, or by methods unknown. The gangrenous areas in these cases are irregular, of varying depth of loss of tissue, and do not correspond to the course of either vessels or nerves. The existence of true hysterical gangrene cannot be regarded as an impossibility, but it is to be explained on the hypothesis of vaso-motor disturbances and not as evidence of removal of trophic influence.

Lepra mutilans, noma, acute decubitus, etc., have also been regarded as examples of neuropathic gangrene, but the majority of conditions so considered have been found to depend upon vascular and nutritive changes or specific infection. Multiple gangrene of the skin is also said to occur in excessive iodism, and it is probable that some of the supposed hysterical cases may be explained by this fact.

Traumatic Gangrene.—This is frequently produced by rupture of the inner arterial coats. Simple contusion over an artery without injury to the skin may cause rupture of the inner coat with resulting thrombosis and gangrene. Circumscribed rupture of the inner coat occurs especially in the case of fractures. The intima may be rolled up within the vessel blocking the lumen. Dislocations, especially those of the shoulder joint, through injury or compression of the vessels may cause gangrene secondary to thrombosis. In severe trauma with resulting disorganization of the tissue gangrene results from secondary infection of the dead part. In the case of open wounds without destruction of tissue primary gangrene may be caused by direct infection with specific bacteria.

Hospital Gangrene.—This form of wound gangrene, so common and so disastrous in its results during the Civil War, has practically disappeared. It represented a specific infection, the cause of which is not known.

Emphysematous Gangrene (Gangrene Foudroyante, Gaseous Cellulitis, Gas Phlegmon, Infective Emphysema, etc.). In gangrene with gas formation the Bacillus aërogenes capsulatus is the most commonly occurring specific cause. The colon and proteus bacilli are doubtful factors. Facultative anaërobic bacilli resembling colon bacilli may produce the condition, and other forms of bacteria have been described as causal agents, but their exact relation to the process is not clear. The B. aërogenes capsulatus is widely distributed in soils, dust, etc., and is present in the intestine and probably in other parts of the normal living body. Gaseous gangrene may also be produced by infection with anthrax and malignant œdema, but it is probable that some of the cases regarded as malignant œdema in the human body were in reality cases of infection by the B. aërogenes capsulatus.

The organism enters through open wounds, particularly those associated with contusion; but may follow ligation of arteries, or the avenue of infection may be through the uterus after abortion or delivery. The infection is very virulent; at the point of entrance there is a rapid necrosis with gas formation. The entire surface of the body may become emphysematous. At autopsy the internal organs have a characteristic sponge-like appearance from the formation of numerous small gas bubbles throughout the tissues. In these numerous bacilli may be found. The blood in the heart and great vessels is foamy. It is probable that some of the cases of supposed air embolism are due to infection with this organism. The presence of gas cysts or foamy blood in the cadaver several hours after death cannot be regarded as of great pathological significance, inasmuch as this organism, which is probably frequently present in the normal body, may develop under favorable conditions with great rapidity in the dead body.

Toxic Gangrene.—The most familiar form of gangrene due to poisons is that produced by ergot. The ends of the extremities are chiefly affected, the gangrene is usually of the dry form, and is caused by the action of the ergot in producing contraction of the peripheral vessels with thrombosis. Sloughing gangrene of the endometrium, bladder, and skin may also be produced by long-continued medicinal use of ergot.

Roentgen-Ray Gangrene.—Gangrenous dermatitis has followed prolonged exposure to *x*-rays. The condition develops several weeks after exposure and is slow in healing. The exact relation of these cases to the alleged cause is not yet apparent.

Carbolic-Acid Gangrene.—Dry gangrene has been produced in a number of cases by prolonged application of carbolic-acid dressings, even when weak solutions were used. The fingers and toes were the parts affected in the majority of cases; in one instance the eyelids were injured.

Gangrene of Pancreas.—Traumatic injuries of the pancreas or inflammatory conditions of this organ may lead to gangrene. Self-digestion by the pancreatic juices is probably the first step in the process, infection from the intestine the second. Fat necrosis is usually present.

Idiopathic Gangrene.—According to recent observers the so-called idiopathic gangrene occurring in children is always secondary to arterial thrombosis. In the new-born it is frequently associated with congenital syphilis. Gangrene of penis and scrotum in the new-born has been observed a number of times in connection with thrombosis of the renal and spermatic veins. The cause is unknown. In the adult gangrene of the same region occurs from primary infection, or rarely as the result of embolism or thrombosis. The gangrene of the extremities observed in cases of premature labor is probably due to thrombosis or possible primary infection.

Sequelæ.—Besides the end products of decomposition mentioned above, ptomaïns are produced in the gangrenous area. These are for the greater part diffusible and readily absorbed into the circulation, producing the systemic effects of gangrene. The intensity of the general symptoms in any case will depend upon the amount and character of the poisons produced in the gangrenous tissues, the amount and rapidity of the absorption, and the resistance of the patient. The intoxication may be so severe as to cause death, or the gangrene may progress until death is brought about by the involvement of vital parts, or the gangrenous area may become circumscribed, be cast off as a slough, or organized, calcified, or encysted. Portions of dead extremities may drop off spontaneously, or through operative procedures the gangrenous portion may be removed. *Aldred Scott Warthin.*

GANGRENE. (SURGICAL.)—The term gangrene, and its synonyms, mortification and sphacelus, are employed by the surgeon to denote the death and, in most cases, the subsequent decomposition of a circumscribed portion of tissue on some exposed part of the body. Necrosis is a term extensively used by surgeons to denote the death of a circumscribed portion of bone, whilst pathologists employ it to express the death of a portion of tissue, belonging to some internal organ, that has been cut off from its necessary blood supply. Such necrosis is unaccompanied by bacterial decomposition; it is absorbed and replaced by the formation of blood-vessels and new tissue.

ETIOLOGY AND PATHOLOGY.—A general division of the causes of gangrene into traumatic, physical, and infectious may be made, but it is evident that, whether the local death of a part is produced by mechanical violence or by other causes, the result must be the same—namely, an interference or arrest of the nutrition of the part due to obstruction of the circulation. Nutrition is interfered with, or arrested, by *obstruction in the arteries*, such as occurs in cases of gunshot wounds; by ruptures due to mechanical violence; by compression or ligature; by disease of the arterial coats; by pressure of a tumor in the adjacent tissues, or by a thrombus; by *obstruction in the capillaries*, which may produce complete anæmia of the part, and which is due to pressure upon the capillary walls by tumors, by extravasated blood or fibrin, or by superficial pressure from bandaging. The observation that tight bandaging would occasionally produce gangrene is as old as Hippocrates, who distinctly refers to it. Anything, therefore, which will produce long-continued stasis in the capillary circulation of a part,—whether it be mechanical violence, inflammatory change, the internal administration of certain drugs, the action of chemicals, or some obstruction in the veins sufficiently pronounced to prevent completely the return circulation,—must necessarily result in gangrene of that part.

Let us now examine these causative states somewhat in detail. Obstruction to the arterial circulation occurs in consequence of gunshot, lacerated, and incised wounds, whenever the artery is torn or cut, and this obstruction results in gangrene whenever the collateral circulation fails to become established. The plates accompanying this article, from the "Medical and Surgical History of the War of the Rebellion," show cases of this kind with great distinctness. Pressure upon arteries during the treatment for aneurism has also produced gangrene. Surgeon Fessenden, of the Marine Hospital Service, has reported a case* in which compression was applied to the popliteal artery, just above an aneurism of that vessel, for one hour, when pulsation ceased in the tumor; three days later, it was noticed that sensibility was lost in the foot and leg, which became very much discolored, and there occurred blebs on the foot; a day later the entire foot and leg were gangrenous, and amputation was performed.

Coagula (*thrombi*) may form in the arteries as a result of chronic endocarditis or endarteritis. Obstruction to the capillaries is a prolific source of gangrene. It is in them that the effect of diminished cardiac power is most manifest, especially in the parts remote from the heart. Chronic exhaustive diseases, senile and general debility, therefore, are important factors in the production of gangrene. Gangrene from the administration of ergot is produced by the effect of the drug on the arterioles through the vaso-motor nerves, whereby these vessels are permanently diminished in calibre. The experiments of Holmes (1870) showed the effect of ergot upon animals to be manifested in the capillaries, as witnessed in frogs, and Péton (1878) observed the contraction of the retinal vessels in man. Péton believes that this effect is produced, independently of any influence upon the vaso-motor system, by the direct action of the drug upon the muscular fibres. Nikit, however, in 1878, denied this, and his investigations have led him to confirm the usually accepted theory. In recent years we have learned to distinguish some infectious causes of gangrene, and also to recognize the fact that carbolic-acid solutions are, in certain cases, competent to induce this condition. Farther on, we will consider these matters more in detail.

Ergotism, as a cause of certain epidemics of gangrene in man, was first described by Dodard in 1676, then by Saviard in 1694, and by Noel in 1710. The disease appeared in Switzerland in 1676, according to Langius and Quassond. It also appeared in Dauphiné in 1709. Duhamel, in the "Mémoires de l'Académie Royale de Paris" for 1748, states that the disease was accompanied by very great mortality, "not more than four or five out of one hundred and twenty who had been attacked escaped with life." Péreira (1840) thinks that this affection was known at a still earlier period, and he quotes a passage from Sigebert to support his views (South): "1089, a pestilential year, especially in the western parts of Loraine, where many persons became putrid in consequence of their inward parts being consumed by St. Anthony's fire. Their limbs were rotten and became coal-black, they either perished miserably or, deprived of their hands and feet, were reserved for a more miserable life." It is stated that "the bread which was eaten at this period was remarkable for its deep violet color."

Notwithstanding the general concurrence of opinion as to the effects of ergotism on man, it has often been denied that it produced any such effect upon animals. Block, in 1811, fed nine pounds of ergot daily to twenty sheep for four weeks without any visible effect, and twenty sheep of another lot ate thirteen and a half pounds daily for two months without injury. Thirty cows took twenty-seven pounds daily for three months, and the only apparent effect was to injure the quality of the cream (Péreira). Tessier, however, in 1776, visited those countries in which the epidemic had prevailed, or was then present, and found that, although the quantity necessarily varied, yet it finally produced the gangrenous affection ("Mémoires de la Société Royale de Médecine," 1776, 1777–78). Instances are not wanting of the prevalence of gangrene as an epidemic among animals in the United States. Dr. Salmon, Chief of the Bureau of Animal Industry of the Agricultural Department, in a recent report on this subject (1885), has shown conclusively that many so-called epidemics of the "hoof-and-mouth disease" of cattle are really epidemics of ergotism. He found much ergot in the heads of "red-top" grass, in timothy, and in the chess or "cheat," as well as in rye; and in the particular epidemic in Kansas which called out the inquiry, the ergot was found in the hay fed to the diseased animals in the proportion of about one to every seventy-five pounds. In these cases there were sloughing ulcers of the mouth, ulcers in the rectum, with diarrhœa, a temperature of 101° to 104° F., and a line of demarcation above the hoof in some cases as high as the middle of the leg, and not infrequently the ends of the tails became gangrenous and dropped off. In an exhaustive review of the history of epidemics of gangrene from ergotism, Dr. Salmon cites many instances to show that nearly all the domesticated animals have suffered from the effects of this poison. As bearing upon the question of treatment, it is interesting

to note that Dr. Salmon considers that ergot in hay may be prevented by cutting the grass before the seeds have formed.

The first effect of extreme cold upon the tissues is the contraction of the capillaries to the smallest practicable degree. A certain amount of blood serum is actually frozen and the capillary is ruptured, the circulation is not resumed when the parts are thawed, and gangrene results. Gangrene thus produced is usually of the dry variety, although, when the venioles or the larger venous trunks are frozen, by reason of the failure of the return circulation, moist gangrene is produced. Direct destruction of cells by caustic chemicals may produce gangrene of distal parts, through failure of both supply and return of blood. Gangrene of the perineum may occur from extravasated urine (Green, 1884), as even normal urine is highly irritating; but in such cases there must have been local inflammation and consequent death of the adjacent cells. Urine which has undergone putrefaction, being loaded with the putrefactive bacteria, is often very speedy in its action, especially as the tissues themselves are weak in their power of resistance; while not absolutely devitalized, they are yet in a state of extreme inertia. It is well known that the power of resistance to the entrance and subsequent development of the pathogenic bacteria is variable, and that, for instance, in cases of convalescence from such exhaustive diseases as typhoid, typhus, and the severer exanthemata, fatal forms of so-called blood-poisoning are apt to make their appearance; this condition, while perhaps immediately dependent upon diminished cardiac power, is one of deficient innervation; for insufficient nutrition of the nerve centres is necessarily manifested in weakness of muscular tissues throughout the body.

Obstruction of the veins, it will be seen, is very rarely a direct cause of gangrene; pressure or occlusion of the superficial veins alone will scarcely produce it, unless there is constitutional predisposition, as above set forth, for the deep veins will still carry away a large share of the return blood current. When gangrene does result from compression or ligature of superficial veins, it is by the production of stasis in the capillaries; to this cause we must refer the cases produced by tight bandaging, and, indeed, all of similar character, except those of venous thrombi.

Moist Gangrene.—This form of gangrene, also called acute gangrene, hot gangrene, inflammatory gangrene, is always preceded by inflammation. The part is at first swollen and painful, there is almost always inflammation of the veins (phlebitis), and the moist condition depends upon the obstruction to the return circulation, by which the water is left in the tissues.

Symptoms.—There will be a history of an injury and of antecedent inflammation, and there will be an absence of pain in the part that is actually gangrenous, although the adjacent parts, where the inflammatory blush is present, will be the seat of acute pain. Characteristic changes in color will take place; the part will be at first livid, then bluish, and finally completely black. Then, again, there will be swelling of a boggy character (œdematous), sometimes accompanied by emphysematous crackling. It is sometimes said that sensation is not destroyed; but this, when seemingly present, is only the well-known phenomenon of a person's experiencing, in a wounded or severed nerve, sensations which he refers to the peripheral area of distribution of that nerve. In the beginning the odor is imperceptible, but as the putrefactive change progresses the odor becomes "sweetish," and finally stinking in the highest degree. Constitutional symptoms of toxæmia are usually present, and in advanced stages of this condition great prostration is noted, even collapse; diarrhœa may be present, and in exact proportion to the degree of fever there will be the profound rigors and profuse sweatings of pyæmia; but if the gangrene is not extensive and is well localized, there may be little general disturbance. In cases in which the disease is protracted, the septic fever pursues its usual course, and the well-known typhoid condition of the system will be present, the various symptoms of which need not be here described.

There is little difficulty in the *diagnosis* of this affection, but in the lax condition of the skin of the aged, with its enfeebled circulation and diminished vitality, there is sometimes doubt whether the blackness of the surface is due simply to ecchymosis or to gangrene. When the gangrene ceases to advance there is usually seen, encircling the part, a series of vesicles, or sometimes a mere line of redness. This redness becomes deeper, the epidermis over it falls off, the dead part begins to shrink away, and nature commences, by the rapid consolidation of the inflammatory exudate, to prevent further absorption of any septic material by the lymphatics. This line of redness (termed the "line of demarcation") is a narrow band of granulation tissue, which, like all granulation tissue, is characterized by the absence of lymphatics, and hence is incapable of absorbing septic material. The line of demarcation gradually extends entirely to the bone, in case an extremity is involved, and the dead soft part finally drops off. So long a time is required for the bones to undergo this process that they are usually seen protruding, and the case is seldom left to nature beyond this point.

Treatment.—When gangrene is threatened the treatment should be directed toward its prevention; *i.e.*, the inflammation should be combated, and the return circulation favored by massage and external heat. There is no single remedy so generally applicable and so prompt in its effects as external heat. The part, after gentle friction, may be enveloped in hot flannel, which should be changed frequently, or bottles of hot water may be applied. Another plan, which is preferred by some, is to irrigate the threatened part with hot water. But if this plan is adopted, it is necessary, if any good is to be accomplished, that the water used shall be as hot as can be borne. Thus the feeblest circulation may often be encouraged so that it once more becomes strong, and the effect of these measures in keeping alive the collateral circulation in cases in which the main artery is occluded from injury, operation, or disease is often beneficial in the highest degree. The old axiom that "heat is life, and cold is death" is nowhere more applicable than in these cases. When stasis is manifest by the presence of œdema, and by the boggy feel of the tissues, broad punctures, made deeply through the tissues, are of great service. The patient should be supported with tonic and stimulant remedies according to individual judgment. When the gangrene has become complete, local remedies are of no avail except to favor the production of sloughs, to hasten their separation, and to render the odor less offensive. Among these may be mentioned solutions of bromine, Labarraque's solution of chlorinated soda, and solution of the bichloride of mercury. The mass can be rendered quite innocuous by deep injections of the bromine solution. When the line of demarcation is fully established, operative interference is then demanded.

Dry Gangrene.—In this form of gangrene there is neither venous obstruction nor failure of the lymphatics, and the fluids of the part are carried back into the system as fast as formed. As the arterial supply is gradually cut off, a drying or mummification of the tissues results. This condition frequently occurs in those who are suffering from starvation or who are subject to gout (Chelius); it also occurs in those who have exhausted themselves by excessive debauchery. There is frequently an absence of inflammatory symptoms, and the gangrene may develop suddenly without premonition. There is usually organic disease of the heart and arteries. This is the chronic gangrene of Travers (South).

Symptoms.—Corrugation and shrinking of the soft parts, and gradually deepening color, until the whole mass is of a coal black; pains of varying severity usually precede the discoloration, sometimes lasting for several weeks. Occasionally pain is absent, and the patient simply experiences a sensation of coldness and numbness in the part. As the gangrene progresses, constitutional symptoms are manifested, there are great mental depression, unquiet sleep, palpitation of the heart, epigastric pain, and occasionally an intense internal cold (Chelius). Sometimes the distinctive characteristics between dry and moist gangrene are so obscure that it is difficult to place the case in one class or the other (Moore: "International Encyclopedia of Surgery," 1882).

The *treatment* is essentially the same as that already recommended for the moist form of the disease.

The *prognosis* is unfavorable.

SENILE GANGRENE.—This gangrene, which is usually of the dry variety, is almost wholly due to arterial obstruction, the pathology of which has already been discussed; but the obstruction is long in forming, and the progress of the disease is slow. The description which Percival Pott gave of the affection, as it occurs in the foot, was so striking that for a long time it was known as Pott's disease of the toe; but, as the disease occasionally attacks the hands, the name was manifestly inappropriate. The condition of the arteries in these cases is one of "ossification," or, rather, of calcification, which results in a complete loss of elasticity of their walls, and consequent diminution of the blood supply. The bead-like feel of the radial pulse, in the aged, gives the observer a palpable object-lesson in senile calcification. The statement has been made that certain seasons specially predispose to senile gangrene, and the winter is alleged to be the season most favorable to its production, owing to the astringent effect of the cold; but there are no statistics to bear out this assertion, and the writer considers the case by no means made out.

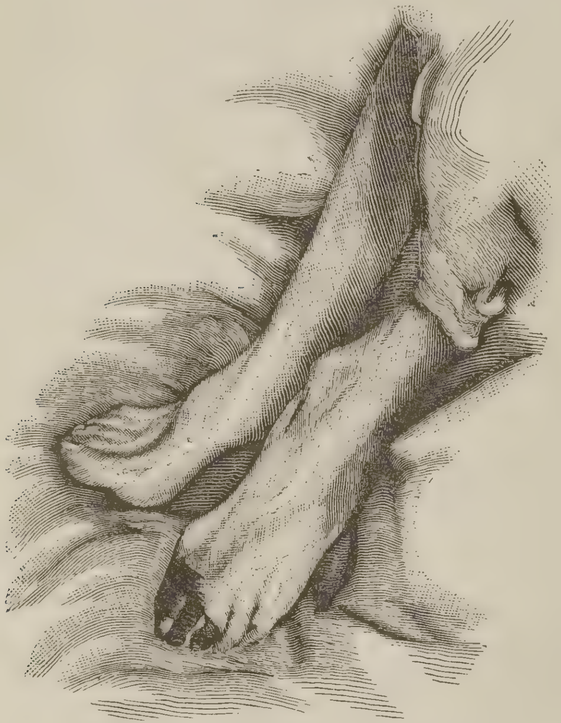

FIG. 2267.—Dr. Hamilton's Case of Senile Gangrene.

Symptoms.—After some months or weeks of pain or otherwise unpleasant sensations in the part, a small bluish spot appears on one of the toes, frequently at the root of the nail, and the spot becomes black; from this point the discoloration slowly spreads to the adjoining toes, and finally, if the patient survive long enough, the whole foot and leg become involved. Sometimes the line of demarcation is formed near the centre of the foot, but more often the patient succumbs under the combined influence of the nervous exhaustion produced by the pain and of the failure of the digestion. The pain accompanying the disease is a prominent symptom, and gives the patient more immediate concern than the fear of losing the limb, or even life itself. The accompanying figure, taken from a photograph of a patient under the care of Dr. John B. Hamilton, at the Providence Hospital, shows the stage of the disease at the time of her death. The notes are as follows: Elizabeth B——, aged eighty-five, admitted to hospital April 13th, for a contusion of the knee, which, however, had left no trace; the pain in the toes and foot had been constant and harassing. Three weeks later, a blue spot was noticed on the dorsum of the second toe. The spot gradually spread until it included the great toe, as shown in the photograph, and the patient died July 20th, 1885.

Treatment.—This has been well formulated by Van Buren. "The treatment of senile gangrene is limited to a judicious husbanding of the patient's vital resources, looking to a possible self-limitation of the disease, after which a cure may be completed by amputation." To husband the patient's resources it is necessary, along with stimulating and supporting measures, to control the pain; here there is nothing more philosophical in its action than the hydrochlorate of cocaine injected into the painful tissue. In these cases, as in the foregoing varieties of gangrene, external heat will be found advantageous.

SYMMETRICAL GANGRENE (*Relapsing Gangrene*).—This affection, probably first accurately described by Raynaud ("De l'Asphyxie locale et de la Gangrène symmétrique des Extrémities," 1862), is exceedingly rare. According to Raynaud, the disease occurs chiefly in chlorotic and nervous individuals of early adult life, patients in convalescence from typhoid fever and similar exhausting disease. Moore ("International Encyclopedia of Surgery") has seen a case presumably dependent upon this cause, and the appearance of the parts affected is shown in the plate which accompanies the doctor's article.

"The disease most frequently attacks the fingers—rarely the toes, tip of the nose, and external ear; often, for months beforehand, the affected parts suddenly become white, bloodless, without feeling, dead; the skin is strongly wrinkled and shrunken, the ends of the fingers appear thin and conical. The temperature of the parts is sunken, and the muscular movement is as though paralyzed. If this state extend over a whole extremity, the pulse becomes imperceptible. After a variable time there follows a painful reaction; itching arises, and the feeling of overfilling of blood; the skin becomes bluish-red. Severe pains precede the proper outbreak of gangrene. The extremities become bluish-white, violet, dark, livid, marbled; they are insensible but very painful, and icy cold; then small vesicles appear which fill with sero-purulent liquid, and are usually destroyed, so that the cutis becomes laid bare. Even now, the part may be restored; but for the most part, after a time the attack returns, and then the fingers show numerous small, white, depressed, and hard cicatrices on their extremities, which are found specially in front of and beneath the nails, and form conical callosities. If the ischæmia is of longer duration, there follows from the consecutive hyperæmia a true mummification, which terminates with the falling-off of the last phalanx" (Wagner).

DIABETIC GANGRENE.—The impoverished condition of the blood in cases of diabetes mellitus favors the production of gangrene, and it has been specifically named as a variety, although without any very good reason. As well might gangrene occurring in the progress of any chronic disease be separately named, and in most articles on the subject of diabetes the occurrence of gangrene is mentioned as among the complications of that disease.

"Spontaneous gangrene of the lower extremities, with obstruction of one or more arteries of the limb, is not infrequent in diabetes" (Marchal de Calvi). "Ulcerated surfaces are slow to heal, and gangrene supervenes sometimes spontaneously, but more often as the result of some trifling injury" (Tyson: "Pepper's System of Medicine," vol. ii.). The treatment of gangrene, when it occurs as a complication of diabetes, does not differ in any striking respect from that which is suitable for other types of gangrene or for diabetes when not accompanied by this complication.

Gangrene Due to Infectious Causes.

Diphtheritic Gangrene.—This form is usually named as one of the varieties, but, like the last mentioned, it has no valid claim to be considered a distinct affection. By some, indeed, it is regarded as gangrenous diphtheria, by others as a variety of hospital gangrene. Diphtheritic patches resulting in gangrene are sometimes seen in the edges of the sore resulting from the incision in tracheotomy; and when hospital gangrene is present in a hospital ward, wounds are frequently seen with the tough, fibrinous diphtheritic patch springing therefrom. In these cases the constitutional poisoning seems more severe. This form of gangrene is due to infection by the Klebs-Löffler bacillus, which is known to be the specific cause of diphtheria; and the constitutional disturbance which is referred to as a characteristic feature in these cases is, doubtless, the result of the profound toxæmia that always accompanies diphtheria.

The *treatment* of diphtheritic gangrene is the same as that of hospital gangrene, which will be mentioned in detail.

Noma.—This is a gangrene affecting the pudenda and cheeks of young children from the age of weaning to that of puberty. Nurslings seem to have an immunity from it. When confined to the cheeks and mouth, it is variously termed *gangrenous stomatitis, gangræna oris, cancrum oris, gangrenopsis-stomato-necrosis, necrosis infantilis, buccal anthrax, water canker, sloughing phagedæna* of the mouth, and by the Germans *Noma* and Wasserkrebs; by the French *gangrène de la bouche.* The disease has been known for a long period, and was first described by Carolus Battus, of Amsterdam. Van Swieten (1699) recognized the disease as grangrene. Wiseman (1676) mentions the disease as noma, which he describes as "a deep Ulcer that eats and spreads without Tumor, but hath a Rottenness and Putrefaction joined with it."

The disease is attended by great mortality, but as it usually comes on while the patient is suffering from some other affection, it is difficult to determine its relative fatality with precision. The affection, whether it appear on the cheek or on the vulva, is almost invariably unilateral. It begins as an inflammation attended by great exudation, ulceration is set up, the exudate dies, and the general appearances of circumscribed gangrene due to obstruction of the arterioles are present. In the mouth the disease usually begins at the frenum of the lip, but rarely on the outside of the cheek (Chelius), and as the œdematous inflammation extends the ulcerative process is carried down to the bone and alongside of the nose, and frequently involves the whole Schneiderian membrane. Occasionally the disease begins on the gums at the alveolar border (Cohen). At the pudenda the disease usually commences at the labial margin, and extends to the clitoris, nymphæ and hymen, and sometimes to the urethra, when the pain on micturition is acute; the inflammation is rapid, and the tissues speedily fall out by sloughing, the disease spreads to the perineum, to the anus, the thigh, and to the mons veneris, and, as is the case when the disease affects the mouth, the sloughing is deep and frequently extends quite to the bone. Sometimes the affection beginning at the mouth is later on developed at the vulva, and frequently the noma is ushered in with general constitutional symptoms, such as rigors with fever; but more commonly its onset is masked by the particular affection from which the child has been suffering; but always, in the later stage of the affection, there is great prostration, with feeble pulse and chlorotic countenance. When the affection is on the pudenda, there is great pain in all movements of the lower extremities, and the child usually assumes of its own accord the dorsal decubitus, and the legs are widely separated. There are retention of urine, owing to the severity of the urethritis, and constipation. There is rapid emaciation, and the patient sinks under the "typhoid condition" so constantly present in the later stages of the other forms of gangrene. Cohen remarks that in noma of the mouth pulmonary gangrene is often observed as a complication, as is also enterocolitis. When noma affects the mouth alone, there is great variability in the degree of constitutional sympathy, some patients being able to sit up and play, while others are hopelessly comatose from the outset. Hemorrhage from the facial or from the pudendal branches of the pubic may occur; but in this variety, as in other forms of gangrene, the arteries are plugged by septic thrombi long in advance of the loss of tissue. The disease in most cases is more than likely due to a long thread-like organism of the leptothrix type which has so far resisted cultivation on ordinary media.

The *treatment* of noma is both local and constitutional. For the local treatment such measures should be adopted as are likely to arrest the advance of the disease into sound tissue, and to this end nothing suffices but the application of the most decisive escharotics like the Paquelin cautery or fuming nitric acid. Quinine and iron, stimulants in the form of milk punch and liquid food are always indicated; when the stomach becomes irritable, nutritive enemata should be employed.

Hospital Gangrene.—This form of gangrene, known also under the various names of *hospital phagedæna, gangræna nosocomialis, and pourriture des hôpitaux,* was the scourge of military hospitals in the pre-antiseptic era. To-day it is absolutely unknown, the vast majority of living surgeons having had no clinical experience with it. Whether its spread was due to the agency of a specific micro-organism, or to an acquired virulence of the well-known pathogenic microbes in victims rendered specially susceptible by lowered vital resistance, remains a matter for speculation. Because of its great rarity we must turn to the writings of the older authors for a clinical picture of the disease. Mr. Guthrie graphically describes it as follows: "A wound attacked by hospital gangrene in its most concentrated and active form presents a horrible aspect after the first forty-eight hours. The whole surface has become of a dark-red color, of a ragged appearance, with blood partly coagulated, and apparently half putrid, adhering at every point. The edges are everted, the cuticle separating from half to three-fourths of an inch around, with a concentric circle of inflammation extending an inch or two beyond it; the limb is usually swollen for some distance, of a white, shining color, not peculiarly sensible except in spots, the whole of it being œdematous and pasty. The pain is burning and unbearable in the part itself, while the extension of the disease, generally in a circular direction, may be marked from hour to hour; so that in from another twenty-four to forty-eight hours nearly the whole of a calf of a leg, or the muscle of a buttock, or even the wall of the abdomen may disappear, leaving a deep great hollow or hiatus of the most destructive character, exhaling a peculiar stench which can never be mistaken, and spreading with a rapidity quite awful to contemplate. The great nerves and arteries appear to resist its influence longer than the muscular structures, but these at last yield; the largest nerves are destroyed, and the arteries give way, frequently closing the scene, after repeated hemorrhages, by one which proves the last solace of the unfortunate sufferer. . . . The joints offer little resistance; the capsular and synovial membranes are soon invaded, and the ends of the bones laid bare. The extension of this disease is in the first instance through the cellular structures. The skin is undermined and falls in, or a painful red and soon black patch is perceived at some distance from the original mischief, preparatory to the whole becoming one mass of putridity, while the sufferings of the patient are extreme."

The surface of the wound soon becomes a sticky, pulpy mass of a grayish color. This substance cannot be wiped off, and it resists the usual washings. If, at this stage, the further progress of the disease be not arrested, the patient succumbs, as from a fatal form of septicæmia. The disease was very prevalent in the military hospitals of our Civil War; an extended account of it may be found in the surgical volumes of the "Medical and Surgical History of the War of the Rebellion," by Otis (see Plate XXIX., Figs. 1 and 3).

Treatment.—The treatment should be prophylactic, constitutional, and local. The first of these should have reference to the rules of antiseptic and aseptic wound treatment and to the rules of hygiene that bear on the subject of overcrowding; and when the disease first appears in the wards containing other wounded, it is important promptly to isolate those who are affected. The constitutional treatment should be directed to the free use of stimulants and good nutritious food. The local treatment directed to the gangrene when it invades the wounds should be of the most radical kind. The sloughing tissues should be removed by means of the curette and scissors, and the actual cautery should be applied freely. Bromine, fuming nitric acid, and subnitrate of mercury were extensively and successfully used by the older surgeons.

Malignant Œdema is one of the forms of gangrenous inflammation due to the invasion of a wound by the bacillus of malignant œdema. The organism morphologically resembles the Bacillus anthracis, though it differs from it in being motile, and in that it is strictly anaërobic. It is mostly found in rich garden soil, from which it is isolated by inoculation into animals. It is apt to invade all kinds of wounds—incised, lacerated, punctured. Instances are given of the disease following the sting of insects and penetration from a hypodermic needle. Malignant œdema is regarded as one of the most fatal forms of gangrene. The changes in the tissues are very rapid, a circumstance that led French writers to adopt the name gangrène foudroyante. The changes in the tissues are marked by an abundant exudate and by the formation of gas, both of which exert pressure upon the surrounding blood-vessels, and thus favor the development of gangrene. The clinical picture is best described by Park as follows: "Malignant œdema is known by the brownish discoloration of the overlying skin, which is streaked with blue where the overfilled veins show through it, while the underlying tissues are sodden with fluid and more or less blown up by the gaseous products of decomposition, so that the finger detects a firm crepitus, as is common in subcutaneous emphysema. From the wound, if one there be, flows a thin, foul-smelling secretion, which may also be expressed from the deeper layers. That the neighboring lymph spaces and nodes are actively involved is evident from the enormous swelling of the latter, as well as from the general condition of the patient. The rapid elevation of temperature with but trifling remissions remains constant until shortly before death. The tongue early becomes dry and cleaves to the palate, its surface being covered with a thick, foul fur. Patients early become apathetic, complaining only of pain and burning thirst. Delirium and coma usually precede death, which may occur in even so short a time as from fifteen to thirty hours. After death the cadaver bloats quickly and putrefaction goes on with amazing rapidity."

Treatment.—The treatment of this decisive form of gangrene should be of the most radical character. When the disease is recognized in a wound on a limb, the member should be amputated at once well above the limits of the disease. In situations where amputation cannot be practised, excision of the affected tissues should be practised at once and the wound dressed with antiseptics. The strength of the patient should be maintained by stimulants, nutritious diet, and supporting treatment.

Spreading Traumatic Gangrene.—The last of the infectious forms of gangrene to be noted is known under the names of spreading traumatic gangrene, fulminating gangrene, or gangrenous emphysema. It results most generally in cases of rupture of the principal vessels supplying a part of a limb, with sudden arrest of the blood supply; or in those cases of traumatism in which intense, rapidly spreading inflammation appears. In either condition the rapid death of the part and the spread of the disease process to contiguous healthy structures are due to the sudden development of a mixed infection by micrococci and bacilli. The putrefaction set up by these micro-organisms is often accompanied by the liberation of gas, the presence of which is noted by emphysematous crackling in the subcutaneous tissues as the process spreads beyond the diseased area. As a result of the sudden development of bacterial decomposition, poisoning by ptomaïns, with constitutional symptoms of profound toxæmia, is early noticed. The treatment in such cases demands prompt amputation of the limb implicated, at a safe distance within the sound tissues; or rapid and thorough destruction of all gangrenous parts with the curette and actual cautery, in those situations which do not admit of amputation. (See Plate XXIX., Fig. 2, and Plate XXX.)

Ainhum.—This is a form of gangrene of unknown origin, more frequently seen in men than in women. It has been met with in the East and West Indies, but it is more frequently observed among negroes on the west coast of Africa. The affection is usually limited to the little toe, although it has occasionally been observed in the little finger. It begins by the occurrence, on the plantar surface, of a fissure which encircles the toe near the web. As the fissure deepens, gangrene of the soft parts occurs, with a rarefying osteitis of the bones. The disease is very gradual, the process lasting as much as ten years in some instances. It usually ends in spontaneous amputation.

Carbolic-Acid Gangrene.—The watery solutions of this antiseptic drug used in surgical practice have been known to cause gangrene when persistently applied, especially to fingers and toes. The evaporation of the water, in the solution, which takes place during the prolonged application of compresses so saturated, tends to concentrate the agent in the dressings; hence the well-known effects of the strong solutions, such as blanching, numbing, etc., which lead ultimately to gangrene. So many cases of gangrene from this source have been reported in recent medical literature that topical applications of the drug to the parts mentioned should be practised with extreme caution. *John B. Hamilton.*

GARLIC.—Allium. "The bulb of *Allium sativum* L., fam. *Liliaceæ*" (U. S. P.).

Garlic is a compound bulb, globose-ovoid, an inch or two in diameter, of a white or red-brown color and a very strong alliaceous odor and taste. The drug proceeds wholly from cultivated plants.

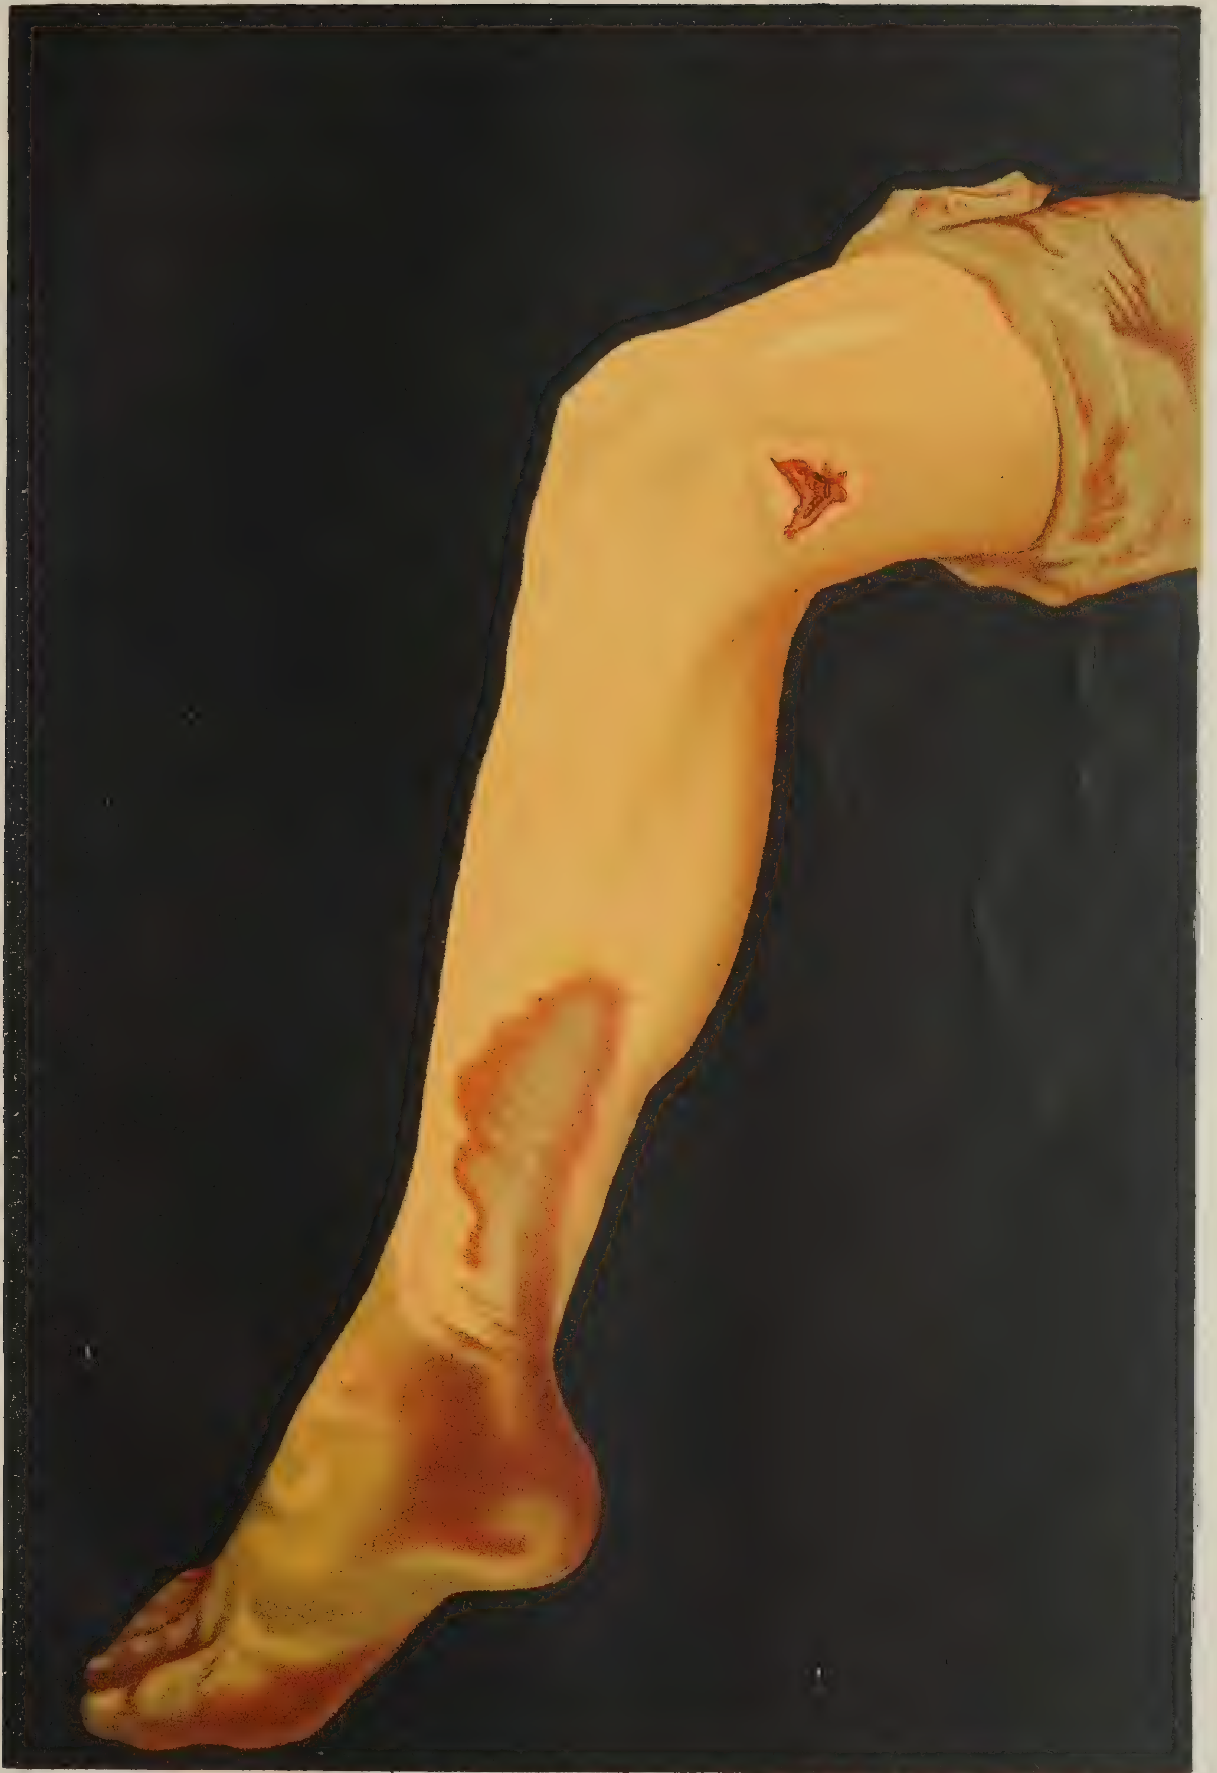
Garlic contains as its active principle—either already formed or produced, as in mustard, etc., by the addition of water—a very irritating, pungent, and volatile oil, *sulphide of allyl,* similar to that of the onion and others of the genus and belonging to the same group with the oils of mustard and other *Cruciferæ.*

It is now and then given with some advantage, as an antispasmodic, and sometimes as an expectorant in chronic bronchitis and pharyngeal or laryngeal catarrh. Internally taken, garlic, like the onion, etc., is an aromatic and carminative, and scents the breath with sulphur compounds during elimination.

There is an official syrup, of twenty-per-cent. strength, which is to be made from the fresh bulbs. Of this the dose is a half-ounce. The fresh juice is also often given in half-drachm doses. The fresh bulb is sometimes crushed and applied to the chest as a rubefacient.

Garlic is likely to be dropped from the next edition of the Pharmacopœia. *Henry H. Rusby.*

GASSERIAN GANGLION, OPERATIVE REMOVAL OF THE.—The Gasserian ganglion is associated with the large sensory root of the fifth cranial nerve. It is situated in a depression near the apex of the petrous portion of the temporal bone. The sensory root of the fifth nerve enters it from behind, while the smaller motor root of the nerve passes under it, without having any connection with it, to join the inferior maxillary nerve.



GANGRENE FOLLOWING A SHOT LACERATION OF THE FEMORAL ARTERY.

(FROM THE MEDICAL AND SURGICAL HISTORY OF THE WAR OF THE REBELLION.)

LIBRARY
OF THE
UNIVERSITY of ILLINOIS

Three branches proceed from the anterior border of the ganglion: the ophthalmic, the superior maxillary, and the inferior maxillary. They leave the skull through the sphenoidal fissure, the foramen rotundum, and the foramen ovale respectively. All three branches are nerves of sensation; the inferior maxillary is in addition a nerve of motion since it receives the motor root of the fifth nerve as stated above. It supplies with motor fibres the masseter, deep temporal, buccal, and internal and external pterygoid muscles.

The distribution of the sensory branches of the ganglion is as follows: The ophthalmic branch supplies the eyeball, the lachrymal gland, the conjunctival mucous membrane and that of the nasal fossa, and the integument and muscles of the eyebrow, forehead, and nose. The superior maxillary supplies the integument of the temple and part of the cheek, and the gums and teeth of the upper jaw. The inferior maxillary supplies the integument of the temple, external ear, lower part of the face, and lower lip, the teeth and gums of the lower jaw, and a part of the tongue. It also has a motor function as above mentioned.

The Gasserian ganglion has been of anatomical importance ever since its nature was recognized by Hirsch in 1765. The very great surgical interest which is now felt in this structure, and which is less than ten years old, is due to three facts. The fifth or trigeminal nerve is affected in neuralgia more often than any other nerve. The attacks of pain recur after operations upon the three divisions of the nerve, whether the operation be a simple nerve-stretching, or a division of the nerve, or a resection of a portion of the nerve, or a tearing out of as much of the affected nerve as possible, as advised by Thiersch. The removal of the Gasserian ganglion, first performed by Rose in 1890, affords the patient permanent relief from his neuralgia. It seems like a wanton act to open the skull, burrow in at the base of the brain, and tear out this great ganglion, but desperate conditions demand desperate remedies. Rose removed the superior maxilla and trephined the skull, putting the pin of the trephine in the foramen ovale. His patient recovered with the subsequent loss of an eye, and counted herself happy to be free from the neuralgia even at that price.

Other surgeons soon improved the technique of the operation. Hartley in America, and Krause in Germany, working independently, showed that the skull can be opened, and the ganglion removed by turning downward a flap of skin and bone from the temporal region. In a recent article upon this subject, Krause thus details the steps of the operation as performed by himself:

The patient is in a half-reclining position, with the head held exactly forward or turned a little toward the affected side, so that the blood may flow from the wound. Chloroform is used, if the patient's condition permits. Only dry sponges are employed. A flap of skin, fascia, muscle, periosteum, and bone is cut from the temporal region, and reflected downward. The base of this flap is about 1.5 inches wide and overlies the zygomatic process. Its height is 2.5 inches, and its greatest breadth is 2 inches. The dura mater is not opened. When all bleeding has been stopped by compression and ligature, and the flap, wrapped with gauze, has been reflected downward on the cheek, well out of the way, the dura is separated from the skull down to the bottom of the middle fossa, and the middle meningeal artery is exposed and ligated in two places and then divided. There is usually considerable venous hemorrhage due to the separation of the dura from the base of the skull. This can be controlled by pressure. The next step in the operation is the lifting up of the brain by means of a long retractor, and the dissection of the second and third branches of the fifth nerve from their origin in the Gasserian ganglion to their exit from the skull through the foramen rotundum and the foramen ovale. Then the ganglion itself is freed, at least above and below and backward, until the fifth nerve comes into view. The first division of the fifth nerve, the ophthalmic nerve, is then cut off close to the ganglion, no attempt being made to dissect it free, on account of the danger of injury to the third and fourth cranial nerves, which are intimately associated with it. As these nerves supply the muscles of the eye their injury would be a serious calamity. The fifth nerve is next seized with a pair of clamps close behind the Gasserian ganglion. The second and third divisions are cut off close to their foramina of exit. The ganglion and as much of the root of the fifth nerve as can be twisted out with it, is torn from the brain. The stumps of the second and third divisions are pushed outward through the foramina so as to prevent any union of divided nerve fibres. Inspection of the cavity occupied by the ganglion should prove to the operator that the removal has been a complete one. All bleeding is then to be controlled, and the flap of bone and soft parts replaced. The operation lasts usually from one and one-half to three hours. In a favorable case the patient can get up in one or two weeks and be discharged from the hospital in three weeks.

The two chief dangers of the operation are hemorrhage and prolonged pressure of the brain. The mortality of the operation is variously reckoned at from ten to twenty per cent. The patient awakes from his narcosis absolutely free from neuralgia. This is in striking contrast to the recovery after operations upon the peripheral nerves, since after these operations the attacks of pain recur for a few days in gradually diminishing intensity.

So far as is known removal of the Gasserian ganglion invariably gives permanent relief from the neuralgic attacks, although as the operation has been performed only in the last few years, one must not speak too positively. The numbness and partial paralysis of the muscles of mastication of the side operated upon are a small price to pay for relief from the fearful attacks of pain which these patients have been compelled to endure.

Edward Milton Foote.

GASTEIN.—A picturesque valley in the Duchy of Salzburg, Austria, famous for its mineral springs. It is an arm of the Salzbach Valley, and is about twenty-five miles long by a little more than a mile wide. Its sides are formed by two ranges of mountains which extend to the right and left from the two peaks, Nassfeld-Tauern, 7,820 feet high, and the Ankogel, of 10,700 feet. The situation is romantic, near the region of the glaciers, and at an elevation of about 3,000 feet. In the midst of the valley flows the dashing little river Ache, which forms two beautiful waterfalls near the village of Wildbad-Gastein, now the principal resort. The climate is mild and uniform, the variations in temperature being slight. It is claimed that the thermometer has never risen above 86° F. in summer and seldom above 70°. The barometric changes are also slight, averaging 29.50 inches pressure for the year. Rainy days are, however, rather numerous in the summer.

The thermal springs are eighteen or twenty in number, and are said to have been known as early as the seventh century. Many of them are designated by such names as the Fürstenquelle, the Hauptquelle, the Doctor's-Quelle, and the Spitalquelle. Seven of the springs issue from the solid granite rock or from artificial clefts; the others flow from stratified beds of feldspar, gneiss, and mica. Their deep origin is probably in the heart of the great Ankogel. The temperature of the springs ranges from 87° to 160° F., with but slight variation at any season. The waters are rich in the variety of their mineral salts, but they are very dilute. Of sodium sulphate, the most abundant ingredient, there is but 1.51 grains in a pint, while of calcium carbonate and sodium chloride, the next most abundant ingredients, there is only 0.36 grain each. Oxygen is found in 30.89 per cent. and nitrogen in 69.11 per cent.

The waters are employed almost entirely for bathing, for which purpose many public and private institutions have been erected. Their fame is said to have originated from the cure of Duke Frederick, of Austria, in 1436. Much of the efficacy attributed to them belongs no doubt to the bracing mountain atmosphere.

The baths are recommended chiefly for nervous disorders, especially in cases not amenable to more vigorous treatment. Their beneficial effects in senile marasmus have given them the name of "baths of the aged." Hysteria, hypochondriasis, spinal irritation, impotence, tabes dorsalis, paralysis, neuralgia, rheumatism, disorders of nutrition or of the blood-making functions, as well as pelvic exudations and wasting diseases, are in the category of especial indications. Gastein is also recommended as an after-treatment to a course at Carlsbad, Marienbad, and other springs. *James M. French.*

GASTRECTOMY, ETC. See *Stomach, Surgery of the.*

GASTRIC JUICE.—Nothing was known about the gastric juice until the middle of the last century. By some physiologists gastric digestion was supposed to be merely a mechanical process, the food being triturated by the contraction of the muscular walls of the stomach, as had been observed in the gizzards of fowls. By others the food was supposed to be reduced to a fluid state by maceration under the influence of the warmth of the stomach. By still others the vague and indefinite term fermentation was used to describe the unknown process going on within the stomach. Réaumur (1752) demonstrated satisfactorily by his experiments on a tame buzzard that meat was dissolved in the stomach under the influence of an acid fluid possessing antiseptic qualities. Stevens (1777) came to essentially the same conclusions by experimenting on a human being who possessed the power of regurgitation; and he was the first to carry on digestion outside the body by means of the gastric juice of a dog. Spallanzani (1777–83) deserves credit for having established beyond reasonable doubt that digestion is performed by a fluid in the stomach, and to this fluid, whose acidity and antiseptic properties he likewise recognized, he gave the name gastric juice. At the beginning of the present century this view was accepted and taught by nearly all physiologists.

The next great addition to our knowledge was made by Beaumont (1833), and his contribution may justly be called the most important one ever made to the science of gastric digestion. His observations were made upon a Canadian, Alexis St. Martin, in whom a permanent gastric fistula remained after a gunshot wound. As a result of these observations he described the gastric juice "as a clear, transparent fluid, inodorous, a little saltish, and very perceptibly acid. Its taste when applied to the tongue is similar to thin mucilaginous water slightly acidulated with muriatic acid." He further described it as powerfully antiseptic, and an effectual solvent of food.

In the winter of 1832–33 he submitted a sample of gastric juice contaminated with a little mucus to Professor Dunglison for examination. Dr. Dunglison reported that, in collaboration with Professor Emmet of the Virginia University, he had found the gastric juice to contain "free muriatic and acetic acid, phosphates and muriates, with bases of potassa, soda, magnesia, and lime, and an animal matter soluble in cold water, but insoluble in hot." He expressed astonishment at the large amount of free muriatic acid present.

Prout in 1824 had already declared that the acidity of the gastric juice was due to free hydrochloric acid.

In 1836 Schwann concluded that the digestive power of the gastric juice was due to some unknown active principle which he called pepsin, though he could not isolate it as a distinct chemical substance. This was done by Wassmann (1839) who prepared an impure pepsin as a yellowish powder soluble in water.

Lab ferment was discovered and isolated (also in an impure state) by Hammarsten in 1872.

During the past two decades experiments on animals and direct observations of the gastric juice of man, by means of gastric fistulæ and the stomach tube, have enabled us to gain more accurate information concerning the physical and chemical properties of gastric juice. It is probable that the chemical composition of the gastric juice varies somewhat under different conditions, and that the secretion adapts itself in a measure to the physiological task to be performed. The gastric juice secreted reflexly as a result of the *sight* or *smell* of savory food seems to differ slightly from that secreted after the *ingestion* of food; and it is probable that different foods call forth variations in the chemical composition of the secreted fluid. Beaumont had noticed that the gastric juice was by no means always the same. He noted that exercise leading to perspiration increased the secretion from the gastric cavity; that the fluid poured out under these conditions was only slightly acid, and that it had inferior solvent properties. The ingestion of alcohol in strong solution is known to cause a transudation from the gastric mucosa, the resulting fluid having but little resemblance to gastric juice. Our knowledge, however, of these physiological and pathological variations from the normal is as yet very fragmentary. The quantity of gastric juice secreted in twenty-four hours has never been even approximately determined and estimates range from 180 gm. to 6.5 kgm. The gastric contents as usually removed are made up of food, swallowed saliva, mucus, and gastric juice. As this mixture is being propelled constantly in small quantities into the duodenum throughout the whole process of digestion, any estimate of the total quantity of gastric juice must be subject to very great inaccuracies and no reliable data are at hand.

Human gastric juice contains about five per cent. of solids. Its specific gravity varies from 1.001 to 1.010; the average in the human being is between 1.002 and 1.003.

The mineral salts are chiefly the chlorides of sodium, potassium, and calcium, and the phosphates of magnesium, calcium, and iron. Together they constitute only two per cent. of the gastric juice.

The gastric juice is not rendered turbid by boiling, and is lævo-rotatory. It contains a trace of proteid (probably a peptone) and some mucin. Lactic acid, which until recently was considered a component part of normal gastric juice, is not present in the pure secretion, but occurs as a result of the fermentation of ingested carbohydrates. The active elements of the gastric juice are hydrochloric acid, pepsin, and lab ferment.

Neither the pepsin nor the lab ferment has ever been isolated in a chemically pure state.

Hammarsten separated lab ferment (rennin) from pepsin by fractional precipitation with lead acetate. Gamgee has summarized the qualities of an approximately pure solution of rennin as follows: It is not coagulated by heat; it is not precipitated by alcohol, nitric acid, tannin, iodine, nor by sugar of lead, but by basic lead acetate.

Lab ferment is not diffusible. It is destroyed by 0.5 to 1 per cent. Na_2CO_3.

Its chief characteristic is its power to clot solutions of casein. This it accomplishes by splitting up the casein into two forms of proteid, one of which remains in solution, while the other coagulates in the presence of lime salts.

Pepsin is probably not a proteid. It is soluble in water and glycerin. It is non-diffusible. In the presence of free mineral acid (especially hydrochloric) it has the property of changing albumin into peptone. It is rendered inert by alkalies.

The hydrochloric acid in the gastric juice exists partly in the free state and partly combined with some of the organic and inorganic constituents of the juice. In man the free acid constitutes from 1 to 2 pro mille of the pure gastric juice. In dogs the acidity is higher; in herbivorous animals it is less. When food is ingested the gastric mucous membrane secretes hydrochloric acid until the chemical affinity of the food for hydrochloric is satisfied, and then it continues to secrete acid until the amount of free acid present has reached a certain norm for that individual, usually 0.12 to 0.18 per cent. After the norm has been reached the secretion of acid comes to a standstill, and by this reflex mechanism the overproduction of hydrochloric acid is prevented in the healthy stomach. *Henry Wald Bettmann.*

GASTRULA.—(Dim. of L. *gaster* from the Greek γαστήρ, belly, stomach.) The *gastrula* is a stage in the embryonic development of at least one representative of nearly every great group of animals above the Protozoa. Moreover, those forms which do not possess a typical gastrula stage are found on careful examination to exhibit, with few exceptions, structures or modes of development which may be interpreted as vestiges of this stage.

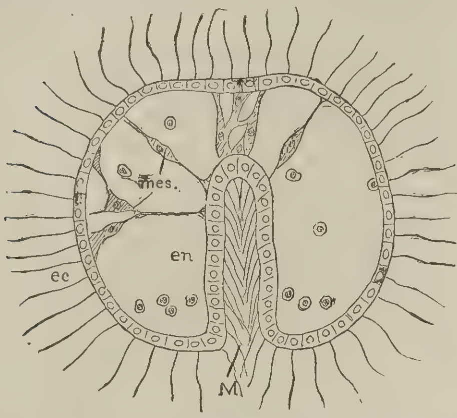


FIG. 2268.—Section of a Gastrula of a Sea-Urchin, *Toxopneustes lividus.* (After Selenka.) Highly magnified. *ec*, Ectoderm; *en*, endoderm; *mes*, mesoderm; *M*, blastopore.

In holoblastic eggs with equal cleavage (see article *Segmentation of the Ovum*) the cleavage results in the formation of a typical *blastula*. This is a rounded body composed of cells, the *blastomeres*, forming a continuous membrane, the *blastoderm*, which encloses a cavity, the *blastocœl*.

The next stage is the *gastrula*, which is formed from the blastula usually by the invagination of its wall on one side. By this process the blastoderm becomes differentiated into the two primary germ layers. The part which remains on the outside is the *ectoderm*, and the part which is invaginated is the *endoderm*. (See *Germ Layers*.) In most animals the cells of the blastula are not all alike, those on one side, the animal pole, being smaller and containing less deutoplasm (yolk granules) than those on the other side, the vegetative pole, which are in many cases very large and heavily laden with deutoplasm. When such differentiation obtains it is always the cells of the vegetative pole that are invaginated to form the endoderm.

The nearly typical gastrula of a sea-urchin is represented in longitudinal section in Fig. 2268. This embryo contains two cavities,—one a closed cavity, the blastocœl, lying between the ectoderm (*ec*) and the endoderm (*en*), and the other, the primitive stomach, or *archenteron*, a cavity entirely surrounded by endoderm, except at one side, where it opens to the exterior by the primitive mouth, or *blastopore* (*M*). At the lips of the blastopore the ectoderm and endoderm are continuous. This embryo is not quite a typical gastrula on account of the presence in the blastocœl of mesenchyme cells (*mes*), which in most animals appear at a somewhat later stage.

Gastrulas of this same general type are to be met with in the sponges, cœlenterates, echinoderms, nemertians, annelids (Eupomatus), sipunculids, chætognaths, crustacea (Lucifer), mollusks, and chordata (tunicates and Amphioxus).

Of these various forms, the one of most interest to us is the gastrula of Amphioxus. If one were to draw a diagram to show the essential structures of a vertebrate reduced to their simplest forms, the drawing with slight alterations could be made to represent an amphioxus. This is a little fish-like animal an inch or two in length, that lives in the sand in shallow arms of the sea in various parts of the world. It is found in the Chesapeake Bay, in the lagoons of the Bahamas, and the writer has gathered hundreds of specimens on the sand flats by the railroad wharf at Port Tampa, Florida. The Amphioxus, having little more than a notochord by way of skeleton, has left no fossil remains, but its habitat is exactly similar to that in which countless generations of Lingula have dwelt with practically no change of structure, so far as we can see, since lower Silurian times. So it is not impossible that we may be right if we infer from its structure that Amphioxus is also of a very ancient type, and is a living representative of our ancestors, that lived before the appearance of the earliest fishes. For this reason the embryology of this form is of special interest. This proves to be just as diagrammatically primitive as the structure and confirms our inference from comparative anatomy.

The gastrula of Amphioxus (Fig. 2269) is a typical one of the *embolic* type. That is, the archenteron is formed, as in the sea-urchin, by the invagination of the endoderm. This is contrasted with the *epibolic* type of gastrula in which, owing to the large size of the slowly dividing endodermal cells, heavily laden with yolk, an invagination is impossible, and the smaller and more active ectodermal cells form the gastrula by growing over and around the large and less active endodermal cells. These types of gastrula grade into one another, so that in some cases it is difficult to tell to which type the gastrula belongs.

Fig. 2269 represents a vertical longitudinal section of a gastrula of Amphioxus. The archenteron is large and the endoderm is so closely pressed against the ectoderm that the blastocœl is obliterated except in a small space near each lip of the blastopore, which at this stage is widely open. The development of the gastrula of this species is represented in Fig. 2270.

The eggs of Amphioxus are laid, according to Wilson, as a rule, between five and six in the afternoon. Cleavage results in the formation of a globular blastula; and about midnight, according to Morgan, gastrulation begins by the flattening of one side of the blastula. This side may be distinguished from the other by the presence of larger cells more completely filled with yolk granules. About two hours later the flattened side has pushed inward until the endoderm nearly touches the ectoderm and the embryo has become saucer-shaped (Fig. 2270, *a*).

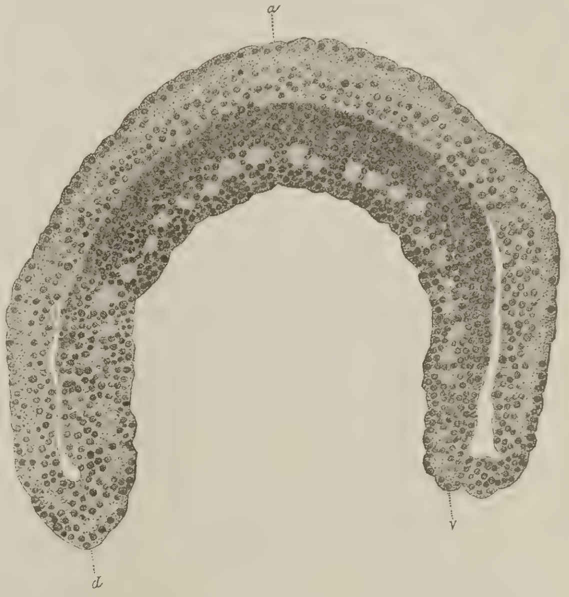

FIG. 2269.—Sagittal Section of a Gastrula of Amphioxus at 4 A.M. *a*, Anterior pole; *d*, dorsal lip of the blastopore; *v*, ventral lip. Reduced from camera drawing made with Zeiss 4, oil immersion 2 mm. (After Morgan and Hazen.)

From this time on there is a gradual closing of the blastopore accompanied by the growth of its lips, until, when the blastopore is nearly closed, the embryo has the shape of a football (Fig. 2270, *d*), the small opening being a slight distance from the posterior end of the long axis of the embryo and on the dorsal side of it. The end of the gastrula stage is marked by the closure of the blastopore from direct communication with the exterior. But for a long time the inner part of it forms a passageway from the archenteron into the developing neural tube, it is then called the *neurenteric* canal.

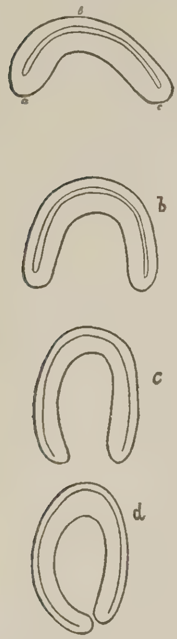

FIG. 2270.—Four Stages in the Development of the Gastrula and Closure of Blastopore of Amphioxus. Sagittal sections. *a*, Ventral lip of blastopore; *b*, anterior pole; *c*, dorsal lip. (After Morgan and Hazen.)

The simplest form of gastrula to be found in the true vertebrates is of the type observed in the cyclostomes, ganoids (Fig. 2271), and amphibians (Figs. 2272 and 2273). In the eggs of these forms the cleavage is always unequal and may be holoblastic as in the frog or meroblastic as in the gar-pike. In either case it results in the formation of a blastula in which the blastocœl is excentric, lying near the upper pole. In either case the roof of the blastocœl is composed of one or more layers of small cells, while its floor is composed of large cells or imperfectly divided yolk. The formation of the gastrula begins by the development of a slight groove on one side near the edge of the area of small cells. The upper edge of this groove is the dorsal lip of the blastopore. The ends of the groove extend in a circle until they meet, completing the blastopore at its ventral lip. Within the blastopore there is a mass of large endodermal cells, the so-called *yolk-plug*. The formation of the blastopore has been observed in living eggs of a number of amphibians by several investigators. The observations of H. V. Wilson upon a tree frog (*Chorophilus feriarum*) are of special interest because by the skilful use of an inverted microscope he was able to watch the changes in uninjured eggs in their normal position. He finds that all parts of the edge of the blastopore, as soon as they are formed, begin to grow over the yolk cells. During this process, not only the yolk cells disappear under the advancing edge of the blastopore, but cells outside of the blastopore are seen to move to the edge and then to roll over and disappear beneath it, so that there is here a combination of overgrowth (*epiboly*) and invagination (*emboly*). The dorsal lip being the first to form, Wilson finds that it grows over an angular distance of 25° before the ventral lip starts, at which time the width of the blastopore is 95°. After that the rate of closure is equal on all sides.

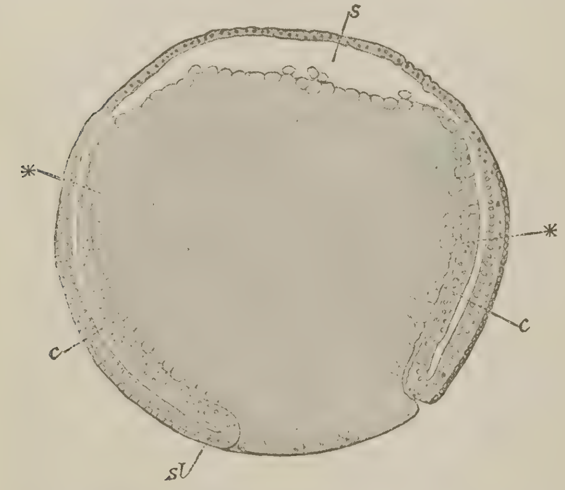

FIG. 2271.—Sagittal Section of a Gastrula of Forty Hours of the Gar-pike, Lepidosteus. *c*, Endoderm; *sl*, dorsal lip of blastopore; *s*, blastocœl; * *, innermost limit of archenteron. (After Dean.) × 30.

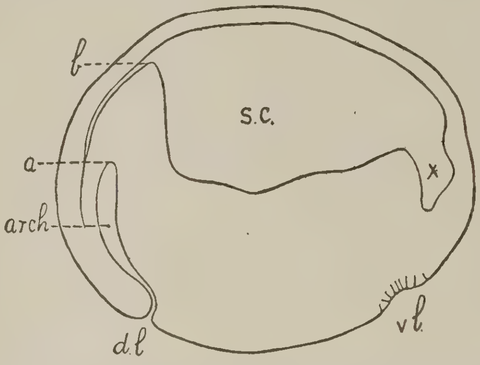

FIG. 2272.—Sagittal Section of the Gastrula of a Tree-toad, Chorophilus. *arch*, Archenteron; *a–b*, "tongue" of uncleft yolk in front of archenteron; *d.l.*, dorsal lip; *v.l*, ventral lip, *s.c.*, blastocœl; *x*, space produced artificially. (After H. V. Wilson.) Camera drawing, Zeiss A, 2.

When the blastopore has been reduced to a very small opening, the overgrowth stops at the dorsal and ventral sides, but continues laterally, so that the blastopore finally becomes a mere slit and at length the lips fuse in the middle, leaving a minute opening at each end. The dorsal one is the neuropore, or neurenteric canal, and the ventral one may or may not persist as the permanent anus.

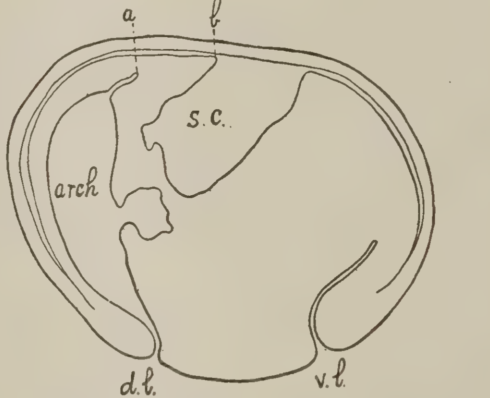

FIG. 2273.—Sagittal Section of the Gastrula of a Tree-toad, Chorophilus. Later stage than that shown in Fig. 2272. Reference letters the same. (After H. V. Wilson). Zeiss A, 2.

Figs. 2271, 2272, and 2273 represent sagittal sections of gastrulas of the gar-pike and the tree frog. Comparing these with Fig. 2269 we see that they are similar to the gastrula of Amphioxus, except that in these forms the endoderm forming the ventral and anterior wall of the archenteron is greatly thickened so as nearly to fill the cavity of the archenteron and to protrude through the blastopore.

In the Sauropsida, reptiles and birds, we find an enormous increase in the proportion of yolk in the egg.

Nevertheless, there is a stage in the development of these forms that may be regarded as a gastrula. The hen's egg may be taken as the type of this class. Cleavage begins and the egg passes through the blastula stage while in the oviduct. The germinal area in the blastula stage consists of two layers of cells. The outer layer forms a membrane of completely divided cells and is separated by a shallow cavity, the blastocœl, from the lower layer of cells, in which the cell boundaries are incomplete, so that the cells are not separated from the white yolk below. At the margin of the germinal area the two layers are united and all the cell boundaries are incomplete below.

At about the time that the egg is laid the posterior border of the germinal disc becomes sharply defined by the appearance of a crescentic groove, which gradually extends around toward the anterior side. Inside of the groove the disc becomes thicker and more opaque. The gastrula stage begins with the formation of this groove and ends with the completion of the primitive streak.

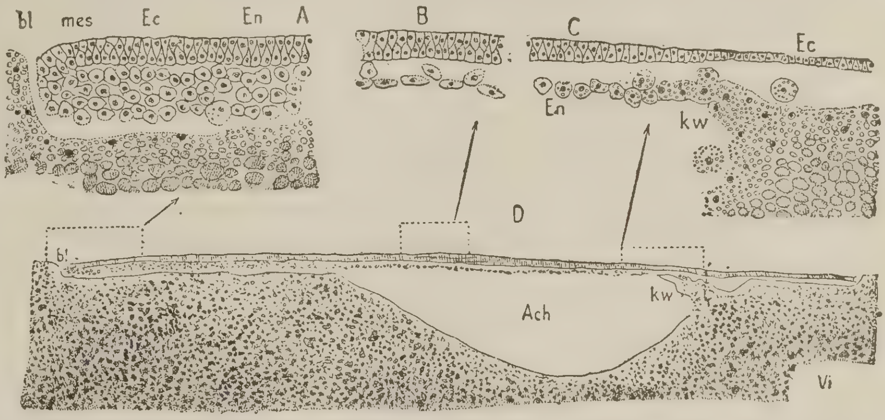

Fig. 2274.—Sagittal Section through the Blastoderm of a Hen's Egg Incubated Six Hours. *Ach*, Archenteron; *bl*, dorsal lip of blastopore; *Ec*, ectoderm; *En*, endoderm; *kw*, germinal wall; *mes*, marginal rim; *Vi*, Yolk. (After Duval, from Minot.) *D*, × about 40; *A*, *B*, *C*, details of *D* more highly magnified.

The blastocœl quickly disappears and the groove opens into a new cavity lying between the germinal disc and the yolk, the subgerminal cavity or archenteron. Fig. 2274 represents a sagittal section through a late gastrula stage of the hen's egg and may be compared with the dorsal half of the gastrula of the frog, Fig. 2273. At the anterior end of the section the ectoderm is seen to be growing over the yolk while the endoderm below is continuous with the yolk (*kw*), while at the posterior end the endoderm and ectoderm are continuous with one another and separated from the yolk by a slit (*bl*), which connects with the archenteron and may be regarded as homologous with the blastopore of the frog. As in the frog the blastopore begins as a crescentic groove and the dorsal lip proceeds to grow backward over the yolk. But, unlike the frog's egg, the egg of the hen contains so much yolk that the ends of the crescent are unable to meet around the yolk-plug. So the closure of the blastopore is effected in another way,—by the progressive separation of the ectoderm from the endoderm, beginning at the ends of the crescent, and the growth of the ectoderm as a distinct layer over the yolk, as described in the article on the *Area embryonalis* (see Vol. i., pp. 441, 442).

In the mammalia, although the egg is minute and undergoes a holoblastic cleavage, the development of the embryo is a very complex process, to be explained probably by the supposition that the ancestors of the mammals had eggs with a large amount of yolk. In this group the gastrula stage has almost entirely disappeared, the stage figured by Haeckel as such not being a gastrula at all. Hubrecht, however, described structures in the primitive streak of the shrew (Sorex) that resemble what is found at the lip of the blastopore of the frog, and he finds there a minute canal that he regards as a vestige of the neurenteric canal.

The gastrula has been a stage of more than ordinary interest to embryologists because of the importance attributed to it in the *Gastræa Theory* of Haeckel. This theory is based primarily upon the discovery made by Huxley in 1849: "That a Medusa consists essentially of two membranes enclosing a variously-shaped cavity, inasmuch as its various organs are so composed"; and that "a complete identity of structure connects the foundation membranes of the Medusa with corresponding organs in the rest of the series; and it is curious to remark, that throughout the outer and inner membranes appear to bear the same physiological relation to one another as do the serous and mucous layers of the germ; the outer becoming developed into the muscular system and giving rise to the organs of offence and defence; the inner, on the other hand, appearing to be more closely subservient to the purposes of nutrition and generation." To these two layers Allman in 1853 gave the names ectoderm and endoderm, respectively. Later, Alexander Kowalevsky, beginning in 1866, made a brilliant series of observations upon the embryonic development of a large number of invertebrates, corals, hydromedusæ, scyphomedusæ, ctenophores, worms, Phoronis, brachiopods, echinoderms, mollusks, and insects, and also upon various lower chordata, including tunicates, Amphioxus, and fishes. He concluded that in all the invertebrates that he had studied, two germ layers are formed at the beginning of development, and that in most cases there is formed at first a vesicle of cells, one side of which becomes invaginated, forming a double cup with a central cavity opening to the exterior. He found a similar condition in tunicates and Amphioxus and by comparison of their subsequent stages of development demonstrated the affinity of the tunicates with Amphioxus and, through that form, with the true vertebrates.

In 1872 Haeckel published a description of the two-layered, cup-shaped larva of the calcareous sponges, and asserted that this stage, to which he gave the name *Gastrula*, is a fundamental one for all metazoa.

In 1874 and 1875 he elaborated more fully the theory that the gastrula represents the type of the most primitive metazoan, the common ancestor of the whole great group of animals above the protozoa. To this hypothetical ancestor he gave the name *Gastræa*. As already indicated, this generalization of Haeckel has been, in the main, confirmed by subsequent investigations.

GAYLORD AND GULICK MINERAL SPRINGS.—(Formerly Blossburg Mineral Springs.) Tioga County, Pennsylvania.

POST-OFFICE.—Blossburg. Hotels in the village.

ACCESS.—Viâ Tioga branch of Erie Railroad to Blossburg; also viâ Northern Central Railroad to Roaring Branch, and thence by stage line over the mountains.

These springs are located in a picturesque mountain region 1,500 feet above the sea-level. They are surrounded by a charming tract of woodland containing 213 acres, from which a fine view of the valley of the Tioga may be obtained. The place offers many attractions as a summer resort, but is not fully developed as yet. The springs are two in number, and flow about 1,800 gallons of water per hour. The following analysis was made by Prof. F. A. Genth in 1879:

SULPHATED ACID CHALYBEATE.

ONE UNITED STATES GALLON CONTAINS:

Solids.	Grains.
Magnesium sulphate	13.10
Calcium sulphate	23.13
Lithium sulphate	.12
Sodium sulphate	.27
Potassium sulphate	.24
Sodium chloride	.10
Manganese sulphate	1.83
Cobalt sulphate	.03
Nickel sulphate	.36
Aluminum sulphate	6.58
Iron sulphate	31.31
Iron phosphate	.32
Sulphuric acid	5.64
Silicic acid	2.15
Total	85.18

This analysis shows a sulphated acid chalybeate water of great potency. It is remarkably rich in ferruginous ingredients, and contains a considerable proportion of the sulphate of magnesia or Epsom salt. The analysis also shows appreciable quantities of the rare ingredients manganese, nickel, and cobalt. The water possesses excellent properties as a tonic and reconstructive, and has been found very useful in conditions characterized by anæmia and general debility. It is also used in dyspepsia and intestinal disorders. Locally it has decided astringent and stimulant effects, and as such is recommended as a douche, spray, gargle, or lotion. The water is used commercially. A mineral water of this strength should always be taken under the direction of a physician. *James K. Crook.*

GEISSOSPERMUM.—*Pao Pereira Bark.* The bark of one or more species of *Geissospermum* (fam. *Apocynaceæ*), *G. læve* Miers being the important one, used in Brazil as a febrifuge. Three alkaloids have been reported, *geissospermine, pereirine* (this is not the only alkaloid of this name), and *vellosine* (from *G. Vellosii* Allem.). The drug and its alkaloids have been used experimentally, especially in Europe, but have found no accepted position in medicine. *Henry H. Rusby.*

GELATIN.—GELATINUM. *Gelatin* has been defined by the British Pharmacopœia as "the air-dried product of the action of boiling water upon such animal tissues as skin, tendons, ligaments, and bones." It appears in a variety of forms. That which has not been purified, made usually from animal matter which has partly decomposed, is *glue.* When purified by special processes it becomes *sparkling.* It usually occurs in sheets which have been dried upon coarse matting, but frequently in narrow strips cut from such sheets (*shredded gelatin*). Gelatin should be almost or quite colorless and transparent, without odor, and nearly tasteless. Dissolved in 50 parts of hot water, it should yield a firm jelly on cooling. The aqueous solution is precipitated by tannin, but not by alum, subacetate of lead, or ferric chloride T. S. Gelatin is soluble in acetic acid, but not in strong alcohol or ether. It has no medicinal activity, but is a nutrient of the albuminoid class, used in the diet of invalids and in the kitchen generally. Its chief use in medicine is, strictly speaking, pharmaceutical, for the manufacture of the well-known soft and hard gelatin capsules and for the coating of pills.

Gelatose is gelatin which, as a result of certain changes, especially those of bacterial causation, can no longer be gelatinized. *Henry H. Rusby.*

GELSEMIUM.—YELLOW JASMINE, YELLOW JESSAMINE. "The dried rhizome and roots of *Gelsemium sempervirens* (L.) Ait. f. (fam. *Loganiaceæ*)," U. S. P. The yellow jessamine of the Southern States is a pretty climbing shrub, with a large woody rhizome, and numerous fine roots, and slender, smooth, twining, purplish stems. It has dark green, glossy, lanceolate, entire, evergreen leaves, growing opposite to each other, and bearing in their axils solitary or clustered flowers. The latter are large, sweet-scented, bright yellow, and slightly irregular. Calyx small, of five-pointed sepals; corolla funnel-shaped, with a slightly oblique, five-lobed border; stamens five, perigynous. Fruit an oblong, flattened, drooping pod; seeds margined. This is one of the most attractive flowers in the Southern States. It grows abundantly from Virginia southward, in woods, and mounts to the tops of tall trees. The flowers, which appear in the spring, load the air with their sweet odor.

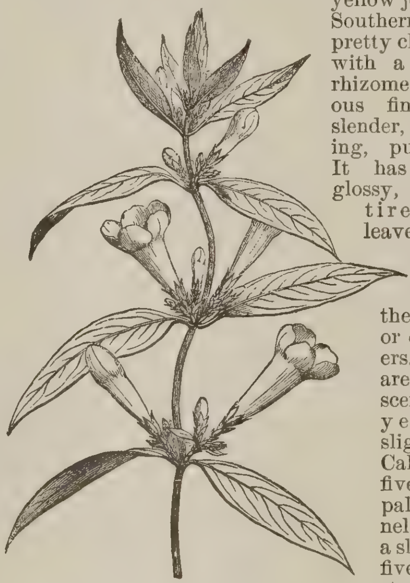

FIG. 2275.—Yellow Jasmine.

Of course, so conspicuous a plant was early noticed; in fact, it was carried to England as an ornament in the first half of the seventeenth century. Its poisonous properties were also early known, but its medicinal employment is of rather recent date.

DESCRIPTION.—Rhizome cylindrical, short-flexuous, elongated or cut in sections of variable length, mostly from 0.5 to 1.5 cm. ($\frac{1}{5}$ to $\frac{3}{5}$ in.) and occasionally 3 cm. (a little more than an inch) in diameter, the roots much thinner, a few elongated, unbranched, coarsely hair-like tough rootlets usually attached; externally of a light yellowish-brown, commonly with some purple or purplish-brown longitudinal lines or patches, or occasionally deep purple-brown with yellowish-brown, fine ridges; heavy, hard, and tough; internally yellowish-white; fracture of the rhizome splintery, the roots breaking with half the fracture transverse, the other oblique or short-splintery; bark thin, closely adhering, that of the rhizome with fine, silky bast fibres, the wood porous, with numerous fine medullary rays; odor peculiar; taste slightly aromatic, bitter.

COMPOSITION.—It contains two alkaloids, *Gelsemine* ($C_{49}H_{63}N_5O_{17}$), crystalline, but inert upon the human subject, and *Gelseminine* ($C_{12}H_{14}NO_2$), which, like its salts, is amorphous, occurring as a white powder, soluble in alcohol, not in water, and which is the active constituent. Gelseminic acid is a saponin-like substance. A little resin and volatile oil, with starch, are also present.

ACTION AND USE.—Gelsemium is an active paralyzing poison, capable of killing both animals and man in small doses, expending its action upon the nervous system. It does not affect consciousness until near the end of fatal cases; sometimes, but not always, it produces convulsions, due apparently to respiratory interference. Reflex excitability is increased at first, afterward diminished, while its paralyzing effect upon the motor columns steadily increases to the end. Death takes place by asphyxia, proceeding from central paralysis. It depresses or paralyzes the nerve endings to a less extent, and less promptly than the centres. Locally, and to a less extent systematically, it dilates the pupil and paralyzes the power of accommodation precisely like atropine. The following symptoms are observed in man after moderate doses: languor, debility, dizziness, disturbances of vision, dilatation of the pupils, paresis, especially of the flexors of the arm, and drowsiness. The poison appears to be quickly absorbed and promptly eliminated. This root, whose medicinal value is said to have been discovered by accident, has been considerably used in the South and West in the treatment of malarial and other fevers. It is occasionally employed in pneumonia and pleurisy as a depressant; in asthma, whooping-cough, etc., it is also indicated, but is not, in the East at least, very frequently given. In neuralgias it holds, perhaps, its place most firmly. It has also been useful when dilatation of the pupil is desirable, differing from atropine in the transientness of its effects.

ADMINISTRATION.—From 25 to 30 cgm. (0.25 to 0.30 gm. = gr. iv. ad gr. v.) of the powder, or the same measures of the fluid extract (*Extractum Gelsemii Fluidum*, U. S. P.) are suitable doses. The official 15-per-cent. tincture is given in doses of 1–4 c.c. (fl. ʒ ¼–i.).

It has been observed quickly to counteract mild disturbances due to overdoses of strychnine, and might be found efficacious as an antidote to that poison.

W. P. Bolles.

GELSEMIUM, POISONING BY.—In Gelsemium sempervirens are found an acid and two alkaloids. The alkaloids are gelsemine and gelseminine. Gelsemine has a tetanizing action, and causes in the frog violent spinal excitement with increased reflexes followed by paralysis due to the action upon the nerve endings. Gelseminine is the more active of the two, producing a paralysis by direct action upon the spinal centres, and having a curare-like paralytic influence upon the nerve trunks. The acid, gelseminic acid, was by Robbins regarded as identical with æsculin, the glucoside of the horse chestnut; Dragendorf and Schwartz arrived at similar results, but Professor Wormley in re-investigating the subject proved that gelseminic acid is not identical with aesculin. According to Kunkel, the acid is of no toxicological importance. Nottage says that commercially the alkaloids are found as a crystalline alkaloid and an amorphous alkaloid of which the former has about ten times the potency of the latter. From the amorphous alkaloid the dosimetric granules are commonly made. The paralyzing alkaloid is the more potent and causes the characteristic symptoms in poisoning from preparations of the whole plant, such as the tincture or fluid extract. The symptoms come on usually within a half-hour, but in some cases the action is immediate. A full dose gives rise to languor, muscular relaxation, and weakness, drooping of the eyelids, double vision, and dilated pupils. When a poisonous dose is taken the muscular relaxation is more pronounced, the jaw usually drops, the skin becomes cold and cyanotic, the respiration shallow and weak, the heart is weakened, and at times the patient has such paroxysms of dyspnœa as to clutch at the throat for air. Sensation is not so early impaired as motion, and intellection is preserved in most instances until the impaired respiration poisons the brain.

The fatal dose is difficult to determine. Twelve minims of the fluid extract have proved fatal to a boy of three years; thirty-five drops of the tincture of the bark have resulted fatally in an hour and a half. In one instance known to the writer a drachm of the tincture taken by mistake proved fatal to a young lady in one-half hour. Dr. Hartwell has known twelve grains of the resenoid to result fatally. Recoveries have occurred after the ingestion of considerable-sized doses. Dr. Main recovered in somewhat over an hour after taking by mistake a drachm of the fluid extract. Blake's patient recovered after taking two drachms of the tincture, although the depression was most profound, and there was intense cyanosis with fearful paroxysms of dyspnœa. In my own case of fatal poisoning the patient, who had taken small doses of the tincture at intervals after a debauch without any marked effect, took probably a half ounce of the fluid extract, and when found a half-hour later was intensely cyanosed, pupils dilated, jaw dropped, lids drooped, muscles completely relaxed, with weak heart and shallow and weak respiration. The patient was somnolent, but could be aroused. Despite all efforts death resulted in seven and one-half hours. The poison seems to be a spinal depressant, as is shown by its late involvement of the higher intellectual centres, and the fact that the poison acts upon the pithed frog and when the main artery of an extremity is tied. It seems to be particularly a respiratory poison. After death no distinctive pathological changes are found. There are no true chemical or physiological antidotes. Morphine, which has been extolled as an antidote and which appeared in Blake's and Courtwright's cases to have rendered excellent service, has been shown by Rehfuss in his experiments to be in no sense an antidote, only slightly retarding the effects of gelsemium and not acting in this way as efficiently as atropine.

The treatment of gelsemium poisoning must be conducted upon general principles. The stomach should be evacuated, and the respiration maintained by strychnine, atropine, artificial respiration, and faradism of the respiratory muscles. The heart suffers secondarily, and nitroglycerin and digitalis will be of service in maintaining its action. Rehfuss, as a result of his experimental studies, recommends emetics, ammonium carbonate, brandy, and the early and repeated use of small doses of atropine to sustain respiration; in addition sinapisms, faradic current, and artificial respiration. Jepson used hypodermics of strychnine successfully in one case. In my own fatal case there was very marked improvement following the administration of atropine and nitroglycerin combined with artificial respiration and faradism of the respiratory muscles. The pulse, which had been very feeble, increased in strength, the cyanosis disappeared; the respirations, which had been shallow, feeble, and irregular, became full and deep, so that the lips previously blue became rosy. The patient was lying upon a blanket before an open fire in a rapidly chilling room. The improvement was so marked that we felt the worst had been averted, and we then attempted to move him nearer the fire by lifting him by the corners of the blanket. By this his diaphragm was cramped, and he died instantly —a warning regarding the care which should be used in moving patients under these circumstances. Were the writer to be again confronted with a case of gelsemium poisoning he would rely upon repeated hypodermics of atropine and strychnine, and would, if the Fells apparatus, which has proved so successful in opium poisoning, were at hand, maintain artificial respiration by the aid of this instrument. Faradism of the respiratory muscles is a powerful adjuvant, but that its application to the hands should have had the result of banishing all symptoms "instantaneously and permanently" in Dr. Main's own case seems remarkable.

GENEVA LITHIA SPRINGS.—Ontario County, New York.

Post-Office.—Geneva.

Location.—Geneva.

The well-known Geneva lithia water is obtained from an artesian well over eight hundred feet deep, which was bored in 1886. Issuing from a stratum of pervious rock defined by a layer of mediæval sandstone sixty feet thick and a deep substratum of hard slate, the water is forced up by an internal pressure of one hundred and twenty pounds to the square inch, and, if unimpeded at the surface, would form a fountain eighty feet high. The water is bright, clear, and sparkling, being agreeable to the palate and excellently adapted for table use. The following analysis was made by Prof. A. Auchie Cunningham, F.C.S.:

One United States Gallon Contains:

Solids.	Grains.
Magnesium sulphate	83.13
Magnesium carbonate	16.00
Potassium chloride	13.40
Sodium chloride	24.54
Sodium sulphate	17.64
Aluminum sulphate	8.75
Lithium bicarbonate	10.03
Lithium sulphate	4.10
Iron carbonate	2.15
Calcium sulphate	18.75
Calcium carbonate	35.84
Phosphoric acid	Trace.
Total	234.33

There is an entire absence of organic matter. The analysis shows a valuable lithia water, which possesses many excellent qualities. It may be classed as belonging to the lithiated-saline chalybeate variety. Aside from its strong impregnation with the bicarbonate and sulphate of lithia, it possesses enough of the sulphates of magnesium and sodium to give it laxative properties, and enough iron to make it a valuable ferruginous tonic when taken continuously. The water is used commercially, and has an extensive sale. It has the indorsement of many prominent physicians of the great Eastern cities. The water resembles that of a spring at Rippoldsau, in the Duchy of Baden, but is more heavily charged with iron and free phosphoric acid. It is extensively employed in anæmic states and general debility, and in many of the conditions resulting from the uric-acid diathesis, viz., gout, dyspepsia, rheumatism, renal and vesical calculus, Bright's disease, etc. *James K. Crook.*

GENITAL ORGANS, FEMALE. See *Sexual Organs, Female.*

GENITAL ORGANS, MALE.—Embryology of the Genital Organs.—In order to have a proper knowledge of the normal and at times abnormal anatomy of the human male genital organs, it is essential that a brief review of the main facts of their embryology should be presented.

That the higher types of vertebrates, during their development, pass through stages the essentials of which are permanent in some of the forms below them, is particularly well exemplified by a study of the embryology of the genital organs.

In the light of the theory of development many cases of anomaly of the genital organs will furnish striking evidence of either *atavism* or *arrested development.* In the growth of the embryo there is at first a period during which there is no indication of any provision either for a urinary or a generative function. A little later the rudiments of a urogenital apparatus are developed, but as yet there is no evidence of sexual differentiation.

In the course of embryological changes it will be observed that certain of the structures concerned appear and assume their permanent characters. Gradually and without modification of plan other structures, at first employed for purposes unrelated to the urogenital apparatus, become adapted, secondarily, for special purposes in this system; others, though belonging to this system from the first and attaining to a condition of functional activity in one direction, are later adapted to altogether different activities in another direction; lastly, other rudiments, according to the sex developed, either become elaborated into efficient and important parts of the reproductive organs, or dwindle into useless vestiges that never take any part in the normal work of the body.

In order that the reader may appreciate, to some extent, the significance of references to the lower animals, it may be well to state here that Tunicates are the lowest vertebrates known. Then, according to the grade of organization and from the simpler to the higher, come, in order, the Acrania (Amphioxus), Cyclostomes, Fishes, Amphibians, Reptiles and Birds, and, highest of all, the Mammals. The Mammals are further subdivided, according to grade of organization, into the Monotremes, Marsupials, and Placentals.

The common embryonic foundations of the sexual organs, male and female, are as follows, viz.: for the internal organs of generation they are the *germinal gland, the Wolffian duct,* the *mesonephros,* the *Müllerian duct,* a part of the *intra-embryonic allantois,* a part of the *cloaca,* and a part of the *proctodeum* (Figs. 2277 and 2278).

For the external organs of generation they are the *genital eminence, genital groove, genital folds,* and *genital ridges* (Figs. 2281 and 2282).

In intimate relation with the Wolffian duct arise, in orderly sequence, three important structures—viz., the *pronephros* or head kidney, *mesonephros* or Wolffian body (midkidney), and the *metanephros* or hind (permanent) kidney (Fig. 2277).

These nephric structures all lie in the dorsal wall of the embryo's abdominal cavity (cœlom) near the point where the somatic and splanchnic layers join (Fig. 2276); they extend, on either side of the notochord (primitive vertebral column), from the neighborhood of the heart to the tail end of the embryo, one behind the other in the order indicated by their names.

The intestinal, urinary, and reproductive organs are not only intimately related in the adult, but they are still more intimately related in the embryo (Fig. 2277), and therefore they must be referred to, in varying degrees, in describing the development of the male sexual apparatus.

At an early stage of the embryo an evagination occurs from the ventral surface of the hind gut near its caudal end to form the *allantois* (Fig. 2277, *A*). The part of the hind gut caudad of the allantois is the *cloaca* (*Cl*). The cloaca is present permanently in all vertebrates from Fishes to Monotremes.

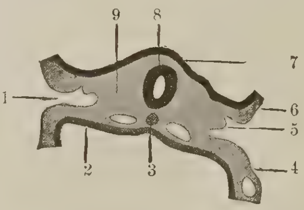

Fig. 2276.—Transverse Section of a Seventeen-Day Sheep Embryo. Diagrammatic. 1, Cœlom (pleuroperitoneal cavity); 2, entoderm; 3, notochord; 4, splanchnic mesoderm or mesoblast; 5, middle plate; 6, somatic mesoderm or mesoblast; 7, ectoderm; 8, neural canal; 9, paraxial mesoblast.

Development of the Internal Genital Organs.—The pronephros and Wolffian duct are evolved as follows: the mesothelial cells of the *somatic mesoderm* (Fig. 2276, No. 6) near the *middle plate* (No. 5) evaginate on both sides, and form a cord of cells parallel with the notochord; at several points along the cephalic extremity of this longitudinal cord of cells it retains its connection with the lining cells of the cœlom (abdominal cavity) by short transverse cords of cells. Soon the cell cords are hollowed out, and thus are formed the segmental or Wolffian duct (Fig. 2277, *W*), which passes caudad and empties into the *cloaca* (*Cl*), and several short transverse *tubules* (Nos. 1, 1, 1), opening at one end into the cœlom and at the other extremity into the Wolffian duct. The transverse tubules in the immediate neighborhood of their cœlomic extremities are evaginated by a tuft of capillary blood-vessels from a branch of the adjacent axial blood-vessel (aorta), so that a series of *glomeruli* are formed. Through the physiological activity of the cells of the glomeruli the urinary constituents are eliminated in the Anamnia from the blood and passed along the transverse tubules into the Wolffian duct and cloaca and thence evacuated from the body. It is thus seen that the transverse tubules and their glomeruli constitute a segmental primitive kidney (pronephros). This pronephros (Fig. 2277, Nos. 1, 1, 1), though functional in Cyclostomes, Teleosts, and larval Amphibians, is vestigial in Selachians, Reptiles, Birds, and Mammals, and never functionates as a urinary organ; it soon gives place to the more important *mesonephros* (Fig. 2277, Nos. 2, 2, 2, 2).

Simultaneously with the segmentation of the paraxial mesoderm (Fig. 2276, No. 9) into the somites, the *middle plate* undergoes segmentation, and each segment is called a *nephrotome*. In the lower vertebrates each nephrotome is hollow and is formed by evagination of the cœlomic mesothelium; but in Reptiles, Birds, and Mammals the nephrotomes are at first solid cords of cells which subsequently become hollowed out and converted into a series of transverse, short canals situated behind, caudad of, the pronephros. They soon acquire connection with the previously formed Wolffian duct. Collectively they constitute the Wolffian body or *mesonephros*. At the cephalic end of the Wolffian duct, the now atrophied transverse tubules and glomeruli of the pronephros are still in connection with it. Embryologists usually compare the mesonephros with its Wolffian duct to a comb, the duct corresponding to the back of the comb, and the short transverse tubules representing the teeth.

In the further development of the mesonephros each transverse tubule becomes somewhat saccular midway between its two extremities, and then the sacculated portion is invaginated by a tuft of capillary blood-vessels derived from an arterial branch of the aorta. The invaginating tuft of capillaries is known as a Malpighian tuft, while the invaginated portion of the transverse tubule is called the Malpighian capsule; the two together constitute a primitive Malpighian body, analogous with the Malpighian bodies of the permanent kidney or metanephros. By the development of secondary tubules and Malpighian bodies the complexity of the mesonephros is greatly increased.

In those vertebrates in which the pronephros attains to a temporary functional activity, as in Cyclostomes, Teleosts, and Amphibians, the mesonephros appears relatively late; on the contrary, in those animals in which the pronephros remains rudimentary, as in Sharks, Reptiles, Birds, and Mammals, the mesonephros is developed early.

In the Anamnia (Fishes and Amphibians) the mesonephros not only acquires relations with the sexual apparatus, but also functionates as a urinary organ. Hence in these animals there is no metanephros. In the Amnia (Reptiles, Birds, and Mammals) the mesonephros functionates as a urinary organ only a short period during embryonic life; it undergoes profound retrograde and adaptive changes soon after its formation and enters into the exclusive service of the sexual apparatus, serving as channels to conduct the sexual cells from the germinal glands in the male, and becoming entirely vestigial in the female (parovarium and paroöphoron).

The transverse tubules of the mesonephros are divisible, in man, into an anterior or cephalic series and a posterior or caudal set. The former are the *sexual* set, and the latter become vestigial as the paradidymis and vas aberrans (homologous with the paroöphoron of woman) (Fig. 2279).

In the Amnia the permanent urinary organ is the metanephros. While the mesonephros and its Wolffian duct are temporarily functionating as a kidney, an evagination occurs from the caudal extremity of the duct.

This evagination soon lengthens into a tube (Fig. 2277, *Met*), which extends cephalad, toward the caudal part of the mesonephros. The cephalic end of the rudimentary metanephros branches freely to form a number of smaller tubes. The surrounding undifferentiated mesodermic cells form enveloping connective and vascular tissue. The blind end of each little tube becomes dilated and then invaginated by a tuft of capillary blood-vessels so that Malpighian bodies are formed analogous to those in the pro- and mesonephros. The tubules, owing to excessive growth in length, become tortuous and convoluted. The stalk of the diverticulum becomes the *ureter*, while the dilated part from which the branches are given off differentiates into the pelvis of the kidney with its infundibula and calyces.

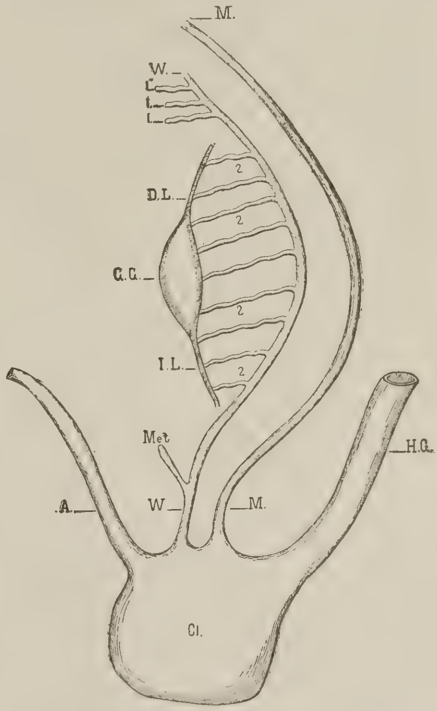

FIG. 2277.—Early Embryonic Condition of the Urogenital System. Diagrammatic. Sex undifferentiated. *A.*, Allantois; *Cl.*, cloaca; *H. G.*, hind gut; *W.*, Wolffian duct; *M.*, Müllerian duct; 1, 1, 1, pronephros; 2, 2, 2, 2, mesonephros (Wolffian body); *Met.*, metanephros (rudimentary permanent kidney); *G. G.*, germinal gland; *D. L.*, diaphragmatic ligament; *I. L.*, inguinal ligament.

Shortly after the formation of the mesonephros another tube (*Müllerian duct*) appears (Fig. 2277, *M.*). It lies close to the outer side of the Wolffian duct and parallel with it. It arises by evagination of the mesothelium of the cœlom in the form of a solid cord of cells and later acquires a lumen. The cephalic end of the duct, near the pronephros, maintains a communication with the cœlom by means of an expanded funnel-shaped mouth, while the caudal part empties into the cloaca. Its lower segment becomes closely associated with its fellow of the opposite side and with the two Wolffian ducts, thus forming the *genital cord*. The cloacal segments of the Müllerian ducts fuse early into a common tube, except in the Monotremes, where they remain permanently separate and empty into the urogenital sinus (Fig. 2278, *M.*). In all other Mammals they fuse to a greater and greater degree in the ascending mammalian scale. Varying degrees of reversion to the more primitive types occur as instructive anomalies in human anatomy.

In the ascending vertebrate scale, the Wolffian duct first appears in Cyclostomes, the Müllerian duct in Elasmobranchs, and the metanephric ureter in Reptiles.

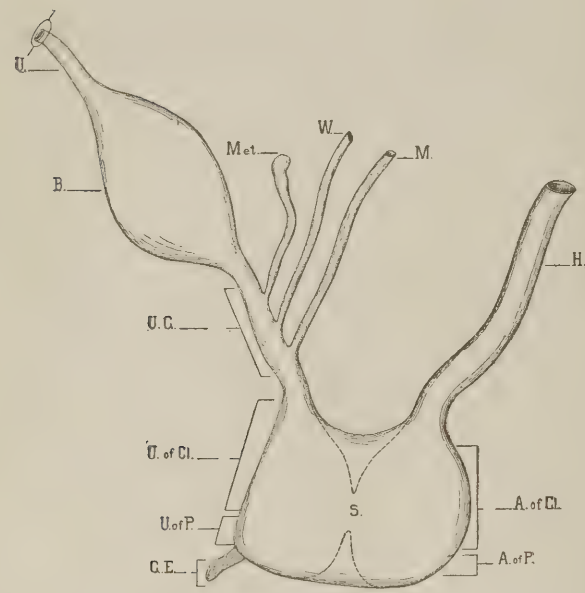

FIG. 2278.—Embryonic Condition of the Urogenital System Later than that Represented in Fig. 2277. Diagrammatic. The allantois has differentiated into the urachus (*U.*), bladder (*B.*), and urogenital sinus (*U. G.*). The proctodeum has appeared and, with the cloaca, is undergoing subdivision by the formation of the perineum (*S.*). *U. of Cl.*, Urogenital part of the cloaca; *U. of P.*, urogenital part of the proctodeum; *A. of P.*, anal part of the proctodeum; *A. of Cl.*, anal part of the cloaca; *H. G.*, hind gut; *G. E.*, genital eminence; *Met.*, metanephros (permanent kidney); *W.*, caudal part of the Wolffian duct; *M.*, caudal part of the Müllerian duct.

This is a convenient place to state that the intra-embryonic portion of the allantois—in other words, that portion extending from the umbilicus to the cloaca—becomes differentiated into three segments as follows: The middle part dilates to form the *bladder* (Fig. 2278, *B.*), the umbilical portion becomes the *urachus* (*U.*), and the cloacal segment differentiates into the *urogenital sinus* (*U. G.*).

Through unequal growth of the parts the Wolffian and Müllerian ducts shift their positions from the cloaca to the urogenital sinus (Figs. 2277 and 2278), and also the duct (ureter) of the metanephros (permanent kidney) shifts its position from the Wolffian duct, first, to the urogenital sinus (Fig. 2278, *Met.*), and, finally, to the base of the bladder (Fig. 2279, *Met.*). Only in the Monotremes, among Mammals, do the ureters open permanently into the urogenital sinus.

In the twelfth week of the embryo the urogenital sinus acquires thick muscular walls, and the lining epithelial tube evaginates into the muscular tissue in the form of little sacs, the lining cells of which differentiate into secreting epithelium. Thus is formed the *prostate gland* enveloping the urogenital sinus or, as it is now designated, the *prostatic urethra.* The prostatic urethra is homologous with the *urethra* and the proximal part of the *internymphal space* of the adult female (Fig. 2280). The musculo-glandular part of the prostate is possibly homologous with the musculo-glandular part of the uterus. In this connection it is interesting to note that castration leads to atrophy of the prostate and removal of the ovaries induces atrophy of the uterus.

While the Müllerian duct is developing, a thickening of the mesothelial cells of the cœlom occurs close to the ventromesial portion of the mesonephros, thus forming an elongated swelling (*germinal ridge*) on the wall of the cœlom. By the proliferation of the mesoblastic tissue beneath the mesothelial cells the germinal ridge is still further enlarged, ultimately forming the *germinal gland* (Fig. 2277, *G.G.*). The gland becomes gradually pinched off from the mesonephros as the embryo grows, though still maintaining a connection with the vestige of this body by a fold of peritoneum (mesorchium or mesovarium).

In the differentiation of the male from the abovementioned indifferent fundiments the following changes take place, viz.: columns of mesothelial cells of the germinal gland are evaginated into the mesoblastic tissue as *sperm tubes,* or sexual cords. By growths of the mesoblastic tissue the sexual cords are divided into roundish, follicle-like masses, which become hollowed out to constitute the *seminal ampullæ.* These, by further growth, are transformed into *seminiferous tubules* (Fig. 2288, No. 6), containing, among many smaller cells, a less number of large *sperm cells* (spermatogones) which develop into spermatozoa. By further transformations the characteristics of the adult testicle proper, or *didymis* (Fig. 2287, *Tunica vag. Vis.*), are developed. At the same time marked changes occur in the *mesonephros,* for from the sexual series of the transverse tubules of this organ cords of cells *penetrate* the germinal glands and fuse with the seminiferous tubules. The conversion of the cell cords into tubes produces the *coni vasculosi* of the *head* or globus major (Fig. 2288, No. 2; Fig. 2279, No. 8; Fig. 2287) of the epididymis, which are homologous with the parovarium of the female; the *vasa efferentia* (Fig. 2288, No. 3); the *rete testis* (No. 9); and the *vasa recta* (No. 7). The cephalic part of the Wolffian duct (from the mesonephros, Fig. 2277) develops into the *body* (Fig. 2288, No. 10) and *tail* or globus minor (Fig. 2288, No. 10; Fig. 2279, Nos. 4, 4, 4, 4) of the epididymis, while the caudal portion becomes the *vas deferens* (Fig. 2288, No. 12; Fig. 2279, W.) (homologous with the duct of Gärtner of the female). Near the extreme caudal portion of the Wolffian duct an evaginated pouch appears which develops into the *seminal bladder* (Fig. 2279, *V.*) and its duct. Caudad of this evagination the Wolffian duct becomes the *ejaculatory duct.*

The pronephros degenerates in both sexes into a vestige, *the stalked hydatid,* or hydatid of Morgagni, a little pedunculated sac attached to the upper part of the epididymis in the male (Fig. 2279, No. 7; Fig. 2287). The non-sexual, caudal series of mesonephric tubules likewise give rise to a vestigial structure, the paradidymis (Fig. 2279, Nos. 3, 3, 3), or organ of Giraldès, homologous with the paroöphoron in the female, lying among the convolutions of the tail of the adult epididymis. Primitively the germinal glands were arranged segmentally and extended along a greater number of somites as in Amphioxus at present. Each segment discharged its germ cells into an atrium and thence by an atriopore to the external water where impregnation took place; or, as in the higher Cyclostomes, the spermatozoa were discharged into the cœlom and made their way through the urogenital pores into the urogenital sinus and thence to the water. Then in Elasmobranchs the advance took place by which the spermatozoa are discharged along the Wolffian duct, a condition which persists in all the higher vertebrates.

In the male the Müllerian duct becomes vestigial throughout nearly its whole extent. Its cephalic extremity persists as the sessile or unstalked hydatid (Fig. 2279, No. 6), and is homologous with the fimbriated extremity of the Fallopian tube in the female. It is a small vesicle attached to the cephalic part of the testicle. The caudal part of the duct becomes the *uterus masculinus* (Fig. 2279, *M.*), and is homologous with the vagina and uterus. Should the intervening part of the duct persist in a patulous condition it is known as the *duct of Rathke* and is homologous with the oviduct of the female.

Testes. The testes in some Mammals, as in *Manis* among the Edentates, are subintegumental and lie in the inguinal canal. They remain normally in the abdomen in many Mammals, as in Monotremes, most Edentates, and the Elephant.

During ontogeny the testes arise in the same relative position as the ovaries in Mammals. Whereas normally, in man, the ovary never passes further caudad than the pelvis, the testis usually passes out of the abdomen through the *inguinal canal* into an evagination of the abdominal wall (*scrotal sac*) lined by evaginated peritoneum (*tunica vaginalis*). In some of the lower Mammals the two scrotal sacs continue separate, but in man they unite by a median raphe into a single scrotum. In man and most Mammals the testes remain permanently in the scrotum by reason of the great reduction in size of the inguinal canal. Through arrest of development man's testicles may present all degrees of reversion in position to that of more primitive types.

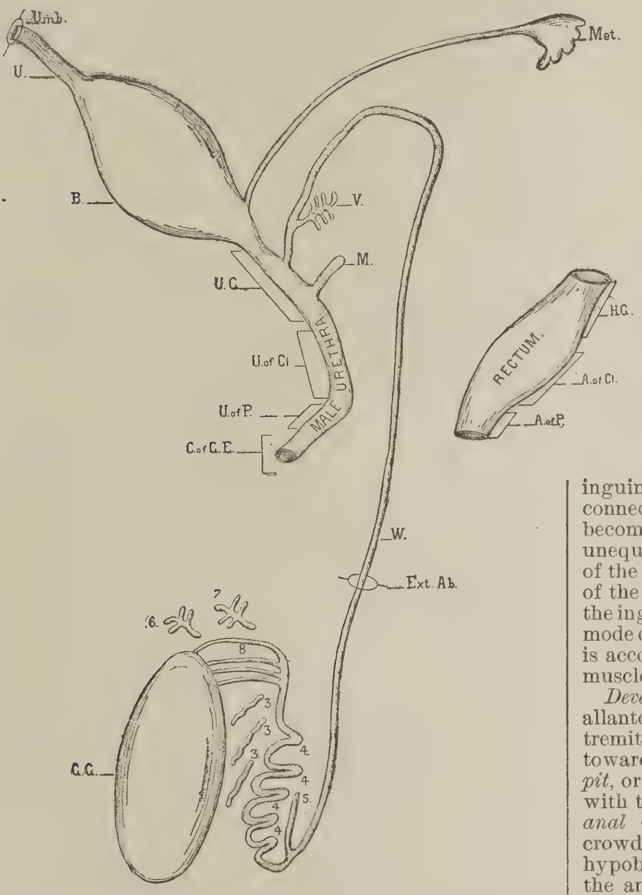

FIG. 2279.—Diagrammatic Representation of the Adult Male Urogenital System. Illustrating especially the embryonic elements that enter into the formation of the male urethra, the epididymis, and the rectum. The testicle (*G. G.*) and its related but much modified mesonephros (3, 3, 3, 4, 4, 4, 4, 5, 8) have descended from the abdominal cavity into the scrotum. *Umb.*, Umbilicus; *U.*, urachus; *B.*, bladder; *U. G.*, prostatic urethra (urogenital sinus); *U. of Cl.*, together with *U. of P.*, form the membranous urethra (*U. of Cl.* is the urogenital part of the cloaca, and *U. of P.* is the urogenital part of the proctodeum); *C. of G. E.*, spongy urethra (canal of the genital eminence); *Met.*, permanent kidney (metanephros) and ureter; *V.*, vesicula seminalis; *M.*, uterus masculinus (distal vestige of Müllerian duct); *W.*, vas deferens (Wolffian duct); *Ext. Ab.*, external abdominal ring; 6, sessile hydatid (proximal vestige of Müllerian duct); 7, stalked hydatid (vestige of pronephros); 8, globus major of the epididymis; 4, 4, 4, 4, body and globus minor of the epididymis continued into the vas deferens (*W.*); 8, 4, 4, 4, 4, sexual adaptations of the mesonephros; 5, vas aberrans (vestige of mesonephros); 3, 3, 3, paradidymis (non-sexual vestige of mesonephros); *G. G.*, testicle or didymis (germinal gland); *A. of P.*, anal part of proctodeum; *A. of Cl.*, anal part of cloaca; *H. G.*, hind gut.

Compare the male urethra with the female urethro-internymphal channel (Fig. 2280, 1, 2, 4, 5, 6).

The descent of the testes is a late development peculiar to Mammals. Primitively it was a periodic phenomenon occurring in the adult. At present, in the hedgehog, the testes retain their primitive cœlomic position up to the rutting period; but as the rut approaches they come to lie in evaginable portions of the abdominal wall in the inguinal region. After the rutting season they return to their abdominal position.

In their descent the testicles necessarily drag after them their attached structures, such as the spermatic artery and veins, the vas deferens, lymphatics, and nerves, all bound together by connective tissue, and thus constituting the *spermatic cord* (Fig. 2287, *Funiculus Sperm.*).

Mode of descent of the testicle. The descent of the testicle is a striking feature of its development. From the mode of development of the mesonephros and its ventro-median genital gland, they both are situated behind the peritoneal sac. Increasing in size they invaginate the sac and apparently project into the abdominal cavity, being held in position by peritoneum (mesorchium). Since the mid-kidney is the most conspicuous part of the projecting mass, the portion of the mesorchium extending to the diaphragm is called the *diaphragmatic ligament* (Fig. 2277, *D. L.*) of the kidney and the segment extending to the inguinal region is designated its *inguinal ligament* (Fig. 2277, *I. L.*). When the primitive kidney has become incorporated with the testicle as a part of its excretory apparatus, the inguinal ligament connects exclusively the testicle with the inguinal region. The inguinal ligament contains between its peritoneal folds connective tissue and unstriped muscular fibres, which become the *gubernaculum testis.* It is through processes of unequal growth of the body of the fœtus and the tissues of the ligament that the testicle is displaced from the side of the lumbar spine to the false pelvis and thence through the inguinal canal into the scrotum. The most primitive mode of descent is that observed in Insectivores, where it is accomplished through the agency of the cremasteric muscle.

Development of the External Genital Organs.—While the allantois is growing there is formed, near the caudal extremity of the embryo, a *surface depression* extending toward the cloaca. This depression is known as the *anal pit,* or *proctodeum.* The anal pit, though communicating with the surface, is partitioned off from the cloaca by the *anal membrane.* This membrane has its mesoblast crowded aside by the anal epiblast and the cloacal hypoblast growing together. By the breaking down of the anal membrane the cloaca is enlarged and communicates with the surface. Should the membrane fail of normal absorption a child would be born with *imperforate anus.*

In Fishes, Amphibians, Reptiles, Birds, and the lowest Mammals (*Monotremes*), the cloaca is a permanent structure through which the intestinal, urinary, and testicular secretions are voided. Man evolves first to and then beyond the cloacal state. In all mammals above Monotremes, and therefore in man, the *enlarged cloaca* (cloaca-proctodeum) undergoes division about the eighth week into a dorsal or *anorectal* cloaca (rectum and canal of the anus) and a ventral or *urogenital* cloaca (Fig. 2278, *U. of Cl.*, *A. of Cl.*, *U. of P.*, *A. of P.*). This division is accomplished by the growth and fusion of three ridges, one of which appears at the point of union of the gut and the urogenital sinus, while the other two extend, one from each lateral wall of the cloaca. The septum formed by the growth and fusion of the three ridges continues to thicken, especially near the surface, until it forms a pyramidal mass of tissue, called the perineum, or, preferably, *perineal body* (Fig. 2278, *S.*), since the urogenital portion of the outlet of the pelvis has been designated as the perineum. The urogenital portion of the cloaca-proctodeum develops into the *membranous urethra* of the adult male.

Just ventral to the aperture of the cloaca (cloaca-proctodeum), about the sixth week, appears the *genital eminence* (Fig. 2278, *G. E.*, Figs. 2281 and 2282), and soon both cloacal aperture and the eminence are surrounded by the *genital ridges.* About the eighth week a groove (*genital groove*) appears on the under or cloacal surface of the genital eminence in *continuity with* the urogenital cloaca-proctodeum, and therefore with the urogenital sinus (Figs. 2279, 2281, and 2282). The groove becoming deeper is bounded laterally by projecting folds (Figs. 2281 and 2282) of skin (*genital folds*). For descriptive purposes, later, the genital folds may be divided into intra- and extraperineal portions. It is due to the growth of the perineal body that the anus is pushed entirely out of the field of the developed genital ridges (scrotum). The external genital organs of the male represent a further stage of development than the corresponding female parts. The genital eminence early acquires a knob-like extremity which develops into the *glans penis* (homologous with glans clitoridis) and its enveloping *prepuce* The rest of the genital eminence, exclusive of the genital groove and genital folds, becomes developed into the corpora cavernosa of the clitoris or penis, and their enveloping tissues. The penis has well-marked intra- and extraperineal segments.

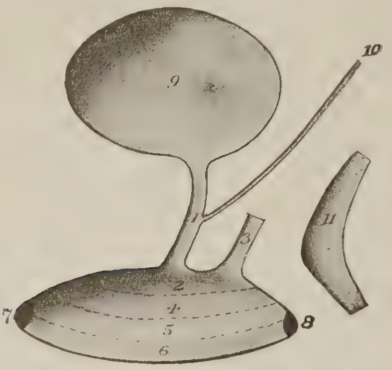

FIG. 2280.—Sagittal Section through the Adult Vulva, Vagina, Urethra, etc. Medial surface. Diagrammatic. 1, Urethra (proximal part of the urogenital sinus); 2, distal part of the urogenital sinus or proximal part of the internymphal cleft; 4, stratum of the internymphal cleft corresponding to the urogenital cloaca; 5, stratum of the cleft corresponding to the urogenital proctodeum; 6, stratum corresponding to the genital groove of the genital eminence; 2, 4, 5, 6, mesial surface of the right boundary of the internymphal cleft; 7, glans clitoridis; 8, fourchette; 9, bladder; 10, duct of Gärtner (persistent Wolffian duct): 3, vagina (enlarged Müllerian duct); 11, rectum; 1, 2, 4, 5, 6, urethro-internymphal channel and homologous with the entire male urethra. Compare with Fig. 2279.

In both sexes, by further growth, the genital folds are extended along the sides of the outlet of the urogenital portion of the proctodeum dorsad toward the perineal body, so that a large part of the groove is caudad from, but continuous with, the outlet of the proctodeum (Fig. 2282). This portion of the genital folds may be spoken of as the *intraperineal* parts By ventrad extension of the genital eminence and its glans penis, the *extraperineal* parts of the penis are formed. The extraperineal development of the genital eminence in the female is so slight that it scarcely exists,—in her the eminence is essentially intraperineal. In the female, through lack of fusion of the segments, the intraperineal parts form the *nymphæ* with their contained *bulbi vestibuli* and *pars intermedia* as the lateral boundaries of the genital groove, the *fourchette* as the dorsal boundary, and the *glans clitoridis* as the ventral boundary of the *genital groove.* The genital groove, caudad from the proctodeum, becomes in the adult the most caudal morphological element of the internymphal cleft (Figs 2280, 2282). In the male development proceeds further than the stage represented in Fig. 2282. The genital folds bordering the outlet of the proctodeum fuse at their free margins and form the *intraperineal* portions of the corpus spongiosum (bulb and portion of the body), the intraperineal urethra, and the enveloping skin. This intraperineal portion of the corpus spongiosum is homologous with the bulbi vestibuli and pars intermedia of the female. By ventrad extension of the genital eminence and its genital folds and groove, and fusion of the fold margins, the extraperineal (pendulous) portion of the corpus spongiosum and its urethra are formed. The distal opening of the urethra is the *meatus urinarius.* It is generally stated in works on embryology, to the confusion of students of homology, that the urogenital sinus of the sexually undifferentiated embryo is homologous with the prostatic and membranous urethra of the male and with the vestibule of the female. But this certainly is incorrect. It seems to us far more in conformity with the facts to say that the *embryonic urogenital sinus* (Figs. 2278 and 2279, *U. G.*), plus the *urogenital cloaca* (*U. of Cl.*), plus the *urogenital proctodeum* (*U. of P.*), and plus the *genital groove* (*G. E.*, or *C. of G. E.*), differentiate into the *male urethra* from the neck of the bladder to the meatus urinarius on the one hand, or into the *female urethra and internymphal cleft* on the other hand (Fig. 2280). So that the male urethra is homologous with the urethro-internymphal space of the female.

The *vestibule* in human anatomy is described as the space extending from the glans clitoridis to the ostium vaginæ and between the nymphæ. The vestibule as thus defined is useless for studying homologies. The *whole space* between the nymphæ extending from the glans clitoridis (Fig. 2280, No. 7) to the fourchette (Fig. 2280, No. 8) must be considered. This internymphal space of the female is formed from several (four) distinct morphological elements, as follows—viz., a *part* of the urogenital sinus of the embryo (Fig. 2280, No. 2), urogenital cloaca (4), urogenital proctodeum (5), and genital groove (6).

That the most caudal part of the internymphal space corresponds to the spongy urethra is illustrated, among other things, by the fact that the ducts of Bartholin's glands open on the mesial surfaces of the nymphæ external to the hymen, just as the ducts of Cowper's glands open into the spongy urethra. The genital ridge differentiates into the mons veneris, and into two prominent pouches on either side of the penis, which become fused, by a median *raphe,* into the scrotum (homologous with labia majora of female).

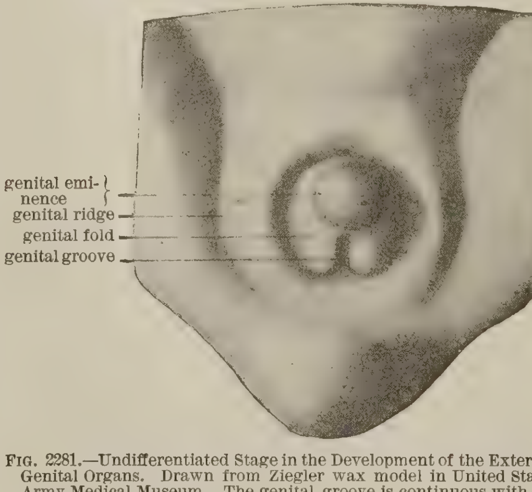

FIG. 2281.—Undifferentiated Stage in the Development of the External Genital Organs. Drawn from Ziegler wax model in United States Army Medical Museum. The genital groove is continuous with the undivided cloaca-proctodeal cavity.

By consequence of evaginations from the genital groove there are formed the glands of Cowper (homologous with the glands of Bartholin).

The differentiation of the genital ridges in the female into the *labia majora* enlarges the internymphal space into the interlabial space. In adult human anatomy the *vulval cleft* usually means the whole interlabial space. From the fact that the external fundiments of the sexual organs are exactly alike in both sexes, it is evident why, through abnormal ontogeny, forms come under observation occasionally which make it very difficult to decide whether they are male or female. These are the so-called cases of *hermaphroditism*. They arise either from the excessive development of certain fundiments or the interrupted development of other parts, in both the male and female. The male is most subject to those malformations which have led to the supposition that there may be hermaphroditism in man. They are due to the fact that the normal processes of fusion are interrupted in association with the interrupted development of other parts. For example, the genital ridges (Fig. 2282) may fail to unite into a scrotum and will simulate the labia majora of the female; the resemblance may be heightened by the failure of the testes to leave the abdominal cavity; and, further, the penis may be so rudimentary as closely to resemble a clitoris. Again, as I have seen, there may be a very noticeable depression between what seem to be incompletely fused genital folds (Fig. 2282) and every suggestion of a rudimentary *vagina*. The individual, though an adult, may be lacking in a growth of hair on the face; and, lastly, the mammary glands, as I have seen, may be as well developed as a woman's. But in spite of all these misleading features, the presence of *testes* in the abdominal cavity would stamp the individual as a man. In a case of this kind, unless a microscopic examination should reveal a seminal discharge, it would require an autopsy to ascertain whether testes or ovaries were in the abdomen.

Lack of fusion of the genital folds leads to various degrees of a pathological condition known as *hypospadias*.

Copulatory organs of various forms occur amongst the vertebrates, often morphologically distinct from one another.

A specially modified portion of each pelvic fin (clasper) occurs in male Sharks. Amongst the Teleosts the male Girardinus has the terminal portion of the anal fin modified for holding the female, and in many Cyprinoids the anal fin has modifications for a similar function. A marked swelling of the lips of the cloaca occurs in certain Amphibians, as the Urodeles, during the breeding season, by which internal impregnation may take place, but only in male Gymnophiona is a definite copulatory organ present in the form of an eversible cloaca, which is regulated by a well-developed musculature. Among Reptiles two kinds of copulatory organs exist, the one being seen in Crocodiles and Chelonians, and the other in Snakes and Lizards. In the former the organ is single and is a thickened portion of the ventral wall of the cloaca which is regulated by muscles and is protrusible. It consists of erectile tissue and has its dorsal surface grooved for the reception of the seminal fluid from the seminal ducts.

In Snakes and Lizards two copulatory sacs lie under the skin at the root of the tail and outside of the cloaca, which are regulated by a well-developed musculature and can be protruded through the cloacal opening and withdrawn. A spiral groove, for the transmission of semen, extends along each everted sac.

In most Birds the semen is expelled through a noneversible cloaca, but in many, copulatory organs are present similar to those of Crocodiles and Chelonians.

In the males of all Mammals except the Monotremes, Marsupials, and some Edentates the *penis* consists of two *corpora cavernosa* attached proximally to the *ischia*, and a central portion, the *corpus spongiosum*, perforated by the urethral canal and expanded at the extremity to form the glans. The penis of Monotremes, decidedly reptilian, is situated in the cloaca and is indirectly in relation with the seminal ducts through the urogenital sinus. It consists of an unpaired corpus cavernosum (there is no corpus spongiosum) perforated with a canal in continuity with the urogenital sinus and the seminal ducts. It is only loosely surrounded by the mucous membrane of the cloaca, has a well-developed musculature, and can be protruded through the cloacal aperture.

The penis sheath, in Marsupials, opens directly on the surface of the body ventral to the anus, on account of the growth of the perineum. The two openings are surrounded by a common sphincter muscle. The erectile tissue is paired (two corpora cavernosa), but unconnected with the ischia.

The penis of Insectivores and Rodents, among Placental Mammals, approaches nearest that of Marsupials. In the ascending scale of Mammals the opening of the penis sheath is separated more and more from the anus and the penis comes more and more to a ventral position, attaining a horizontal and fixed position along the abdomen. In the Apes the organ becomes more or less free from the body wall at its distal end, while in Man the whole of the distal end is free and the penis sheath forms a double integumentary tube-like investment (prepuce) over the glans.

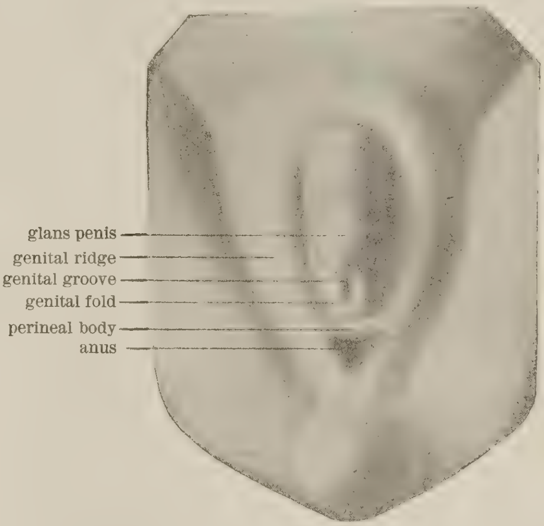

FIG. 2282.—Early Embryonic Stage of Male External Genital Organs. Drawn from Ziegler wax model in United States Army Medical Museum. Genital eminence projects so far dorsad and caudad as to conceal the genital folds and genital groove, which are continued to the under surface of the glans penis. The perineal body has formed and separates the cloaca-proctodeal cavity into a dorsal part having its outlet at the anus, and a ventral part having outlet at the genital groove, in virtue of the fact that the genital folds have extended dorsad and united to form the fourchette just ventrad of the perineal body. It will thus be observed that the genital folds and genital groove are practically divisible, even at this early stage, into intraperineal (root of penis) and extraperineal (pendulous part of penis) segments.

During ontogeny, in Marsupials and Placental Mammals, the penis passes through stages that resemble successively those which are permanent in Crocodiles and Monotremes.

CHRONOLOGY OF UROGENITAL DEVELOPMENT.—*Third Week.*—About this time the Wolffian duct and pronephros are recognizable, the nephrotomes begin to develop and also the allantoic stalk appears.

Fifth Week.—The germinal ridges and the Müllerian duct appear and the fœtus is two-fifths of an inch (1 cm.) long.

Sixth Week.—The genital eminence, folds, groove, and ridge appear.

Seventh Week.—The mesonephros reaches its maximum development.

Eighth Week.—The caudal portions of the Müllerian ducts fuse, and the allantois presents a spindle-shaped dilatation in its middle forming the bladder.

Ninth Week.—The cloaca is divided into two parts. The permanent kidney has characteristic features. The testes are distinguishable from ovaries. The fundiments of the external genitals begin to show distinctions of sex.

The fœtus is one inch long (25 mm.) and weighs about 16 gm. (half ounce).

Third Month.—Prostate gland begins to develop. The union of the testes with the canals of the Wolffian body is complete. The testes are in the false pelvis. Fœtus is 2¾ inches long (7 cm.) and weighs 125 gm. (four ounces).

Fourth Month.—Sexual distinctions in external genitals are well marked. The genital groove is closed. The scrotum is formed, as also the prepuce. The prostate is well formed. Fœtus is 5 inches (13 cm.) long and weighs 240 gm., or 7¾ ounces.

Seventh Month.—The testes are at the internal abdominal ring. Fœtus 14 inches (36 cm.) long and weighs 3 pounds (about 1.5 kgm.).

Eighth Month.—The testes are in the inguinal canal. Fœtus 16 inches (41 cm.) long. Weighs 4 to 5 pounds (about 2 to 2.5 kgm.).

Ninth Month.—The testes are in the scrotum. Fœtus 20 inches (50 cm.) long. Weighs 6 to 7 pounds (about 3 to 3.5 kgm.).

ADULT GENITAL ORGANS.—The *male urethra* is the urogenital canal extending from the bladder to the extremity of the penis (Figs. 2279 and 2283). In the flaccid state it forms a double curve, but when erect it presents a single curve with the concavity ventrad. It is about 7 inches (19 cm.) in length when flaccid, but during erections greatly elongated. It is divided in a prostatic portion (1¼ in. or 32 mm. long), membranous part (three-quarters of an inch or 20 mm. long), and a spongy portion (5 in. or 14 cm. long). The urethra, except during the passage of urine or semen, has the ventral and dorsal surfaces in contact. The prostatic portion (Fig. 2283, No. 3) is spindle shaped and is the most dilatable and widest part of the canal. A narrow longitudinal ridge (*verumontanum*), three-quarters of an inch (20 mm.) in length, exists upon the dorsal wall. It is formed by the projecting mucous membrane and contains muscular and erectile tissue. It serves, when distended, to prevent the semen passing back into the bladder. There is a slightly depressed fossa (*prostatic sinus*) on either side of the verumontanum. A depression (*uterus masculinus*) exists at its distal part (Fig. 2279, *M*). It is a *cul-de-sac* about a quarter of an inch (6 mm.) in length extending dorsocephalad in the substance of an organ (*prostate gland*), which envelops the prostatic urethra (Fig. 2283, No. 3). Its walls are composed of mucous, connective, and muscular tissue, and the ducts of numerous small glands open upon its mucous surface. The uterus masculinus is homologous with the vagina and uterus of the female. The membranous urethra (Fig. 2283, No. 2) is the narrowest part of the canal except at its termination in the penis. Its ventral surface is concave and is placed about an inch dorso-caudad from the subpubic arch. Its dorsal surface is separated from the rectum by the perineal body (Fig. 2283, No. 5).

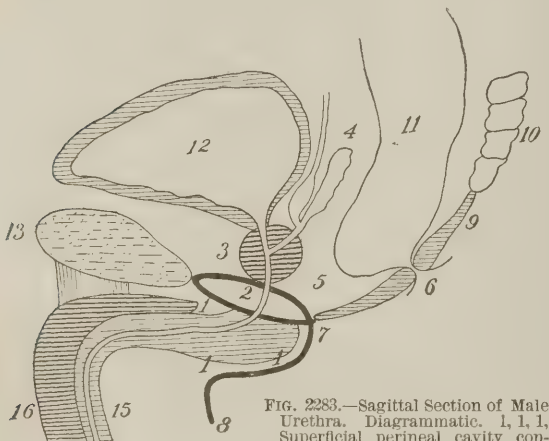

FIG. 2283.—Sagittal Section of Male Urethra. Diagrammatic. 1, 1, 1, Superficial perineal cavity containing the intraperineal segments of the corpora cavernosa, corpus spongiosum, etc. ; 2, deep perineal cavity containing the membranous urethra and bounded by the two layers of the deep perineal fascia (triangular ligament of the urethra) ; 3, prostate gland transmitting the prostatic urethra ; 4, vesicula seminalis and vas deferens emptying through the ejaculatory duct into prostatic urethra; 5, site of perineal body ; 6, anal portion of rectum (11) passing through the sphincter ani muscle (9) ; 7, central tendon of perineum whence starts Colles' fascia to continue into the dartos (8) of the scrotum ; 10, coccyx ; 12, bladder ; 13, symphysis pubis ; 15, extraperineal portion of corpus spongiosum ; the spongy urethra is seen traversing the corpus spongiosum and terminating at the meatus urinarius in the glans penis (14) ; the bulb of the corpus spongiosum is seen in the superficial perineal cavity, resting against the perineal layer of triangular ligament ; the prostate is in the pelvic cavity, resting against the pelvic layer of triangular ligament ; 16, extraperineal portion of corpus cavernosum ; extending between the symphysis and corpus cavernosum is seen the suspensory ligament of the penis.

The spongy urethra (Fig. 2283, No. 15) is the longest. Its calibre is intermediate between the other segments, and uniform except at either extremity. For half an inch (13 mm.) behind the terminal opening it is dilated and forms the *fossa navicularis*, while behind, for an inch (25 mm.), it widens in every direction and is called the *pars bulbosa.*

The urethra is composed of three coats: mucous, areolar, and muscular. The inner, or mucous, coat is continuous at its proximal end with the mucous coat of the bladder and at its distal end with the integument of the penis. It is also continuous with the ducts of the several glands opening into it. Its epithelial lining consists of columnar cells, except at the distal opening, where the cells are squamous. The mucous coat is arranged in longitudinal folds in the membranous and spongy portions when the urethra is empty. The orifices of numerous mucous glands occur on the surface of the mucous coat, especially on the spongy portion, while the glands themselves (glands of Littré) are situated in the submucous connective tissue. The orifices are directed distally and vary in size, and some may easily intercept the point of a small instrument. One of these orifices, much larger than the rest (*lacuna magna*), is situated in the fossa navicularis on its dorsal surface, about half an inch (13 mm.) or so from the outlet.

The areolar coat is rich in elastic fibres, and its interstices are plentifully supplied with convoluted vessels which serve the purpose of erectile tissue. The outer or muscular coat consists of two layers of unstriped muscular fibres, the outer being longitudinal and the inner circular.

The Perineum and Penis.—The male perineum (Fig. 2284), or urogenital region of the outlet of the pelvis, is bounded by the subpubic arch (Nos. 1, 1), the pubo-ischiatic rami (No. 4), the ischial tuberosities (No. 7), and the transversus perinei muscles. The arch and rami present two lips and an intermediate space. The transversus perinei muscles, one on either side, arise laterally from the ischial tuberosities and are inserted medianly into the central tendinous point (No. 6) of the perineum. Each is innervated by the perineal branch of the internal pudic nerve. Their action is to fix the central tendinous point of the perineum.

Extending from fixed attachments—viz., from the dorsal (posterior) border of the muscles and the central tendon, along their deep (pelvic) surfaces, and thence along the deep (pelvic) lips of the pubo-ischiatic rami, and subpubic arch—is a triangular-shaped fascia (Fig. 2284, No. 5). At the points of attachment the fascia is single, but across the triangular interval which it occupies it divides into two layers, a superficial or perineal layer and a deep or pelvic one. Between the two layers, therefore, exists a space called the *deep perineal cavity* (Fig. 2283, No. 2), which contains a number of structures, viz., the membranous portion of the urethra (whence the name of triangular ligament of urethra for the double-layered fascia), Cowper's glands, the compressor urethræ muscle, subpubic ligament, the internal pudic vessels, the dorsal nerve and vein of the penis, the artery and nerve of the bulb, and a plexus of veins, all bound together by very delicate connective tissue.

The deep or pelvic layer of the triangular ligament is continuous with the pelvic fascia. The superficial layer is the *deep floor* of a second perineal cavity, *the superficial perineal cavity* (Fig. 2283, Nos. 1, 1, 1). The perineum has another important fascia (superficial perineal fascia) which, like the triangular ligament or deep perineal fascia, is divisible into two layers. The deeper layer is the *fascia of Colles.* It is continuous, at the posterior border of the transversus perinei muscles, with the triangular ligament (Fig. 2283, No. 7). It passes superficial to the muscles and is attached firmly to the superficial lips of the pubo-ischiatic rami and the adjacent ischial tuberosities, but is *not attached* to the superficial lip of the subpubic arch, for the corpora cavernosa and the corpus spongiosum intervene (Fig. 2284, Nos. 1, 1). Colles' fascia, in this region, is continuous with the dartos of the scrotum (Fig. 2283, Nos. 7, 8).

This *superficial perineal cavity* is bounded thus on the pelvic side by the triangular ligament (Fig. 2283, No. 2), on the cutaneous side with the fascia of Colles (Nos. 7, 8), laterally by the intermediate surface of each pubo-ischiatic ramus (Fig. 2284, No. 4), and dorsally (posteriorly) by the line of junction of Colles' fascia and the triangular ligament (Fig. 2283, No. 7). The superficial perineal space is continuous ventrally with the *sub-dartos* space of the scrotum and penis (Fig 2283, No. 8; Fig. 2284, Nos. 1, 1).

It is in the superficial perineal cavity that extravasation of urine most frequently takes place in cases of rupture of the urethra. From the nature of the fascial attachments, it is clear that the only direction in which the fluid can make its way is ventrad along the scrotum and penis and thence on the ventral part of the abdomen.

This superficial perineal space contains the following *intraperineal* segments of the penis, viz.: the crura penis (Fig. 2284, No. 2; Fig. 2283) partly covered by the erector penis muscle, the bulb and part of the body of the corpus spongiosum (Fig. 2283, Nos. 1, 1, 1; Fig. 2284, No. 3) hidden by the accelerator urinæ muscle, the transversus perinei muscles, and the superficial perineal blood-vessels and nerves.

The crura penis (homologous with the crura clitoridis of the female) are the intraperineal and diverging parts of two fibrous cylindrical tubes called the corpora cavernosa. The latter are placed side by side and intimately connected by the septum pectiniforme along the median plane for their anterior (extraperineal) three-fourths (Figs. 2284 and 2285); the posterior (intraperineal) fourth of each corpus cavernosum diverges from its fellow to form a strong tapering fibrous process firmly connected to the pubo-ischiatic ramus. In many mammals (*e.g.*, lemurs and apes), a bone, the *os penis*, is developed in the septum between the corpora cavernosa.

The corpus spongiosum, a single, bilaterally symmetrical structure, is composed also of two parts, an intra- and an extraperineal portion.

The intraperineal portion commences between the diverging crura penis, where it forms an enlargement, the *bulb*, and then narrowing forms a part of the body (Fig. 2283, Nos. 1, 1, 1; Fig. 2284, No. 3). The extraperineal part is composed of two segments, the remaining portion of the body (Fig. 2283, No. 15) and the *glans penis* (No. 14). The body is cylindrical and situated in a groove on the ventral surface of the corpora cavernosa (Fig. 2285, No. 10). The glans penis overlaps the rounded extremities of the corpora cavernosa and presents the form of an obtuse cone flattened dorso-ventrally (Fig. 2283, No. 14). At its summit is a vertical opening, the meatus urinarius. The base forms a projecting rounded border (corona), behind which is a constriction (neck). Both these parts have numerous sebaceous glands secreting a cheesy matter of peculiar odor.

The three fibro-elastic tubes (viz., the corpus spongiosum and the corpora cavernosa) enclose a fibrous trabecular structure whose meshes lodge the erectile tissue. The trabeculæ are more delicate and the meshes smaller in the corpus spongiosum. The meshes or areolæ of the corpus spongiosum freely communicate with one another. The areolæ of the corpora cavernosa freely communicate with one another on each side, and also with those of the opposite side through fissures in the fibrous septum between them. The areolæ are lined with epithelial cells and are comparable to widely dilated capillaries. At several points in their walls arteries communicate with them; they give origin to the veins. Blood rushing into, and being retained in the, areolæ causes erection of the penis.

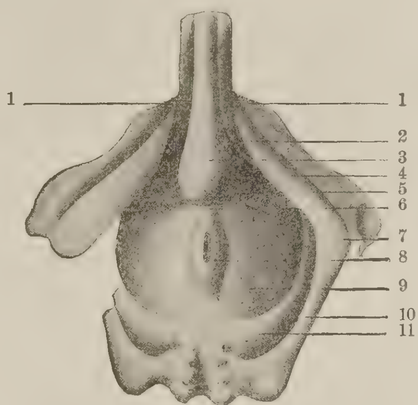

FIG. 2284.—Male Perineum, Showing Triangular Ligament and the Intra- and Extraperineal Portions of the Penis. Colles' fascia and the superjacent parts have been removed. 1, 1, Region of subpubic arch hidden by penis; 4, rami of pubes and ischium (pubo-ischiatic rami); 7, tuberosity of ischium (drawn much too far dorsad); 6, central tendon of the perineum, between which and the tuberosities of the ischium extend the transversus perinei muscles (omitted in the drawing); 5, triangular ligament or deep perineal fascia, on the superficial or perineal layer of which are shown the following structures, viz.: 3, the bulb of the corpus spongiosum from which the enveloping accelerator urinæ muscle has been removed; 2, crus penis of the corpus cavernosum, from which on either side the enveloping erector penis muscle has been removed. 8, Sphincter ani; 9, levator ani. The dorsal boundary of the triangular ligament is seen in the figure to extend as far back as the central tendon, where it is continuous with Colles' fascia. The triangular ligament is shown to be attached to the deep or pelvic lip of the pubo-ischiatic rami and subpubic arch; Colles' fascia has been removed from the superficial lip of the rami. The portions of the penis dorsad from the subpubic arch are intraperineal portions, while the parts ventrad of the arch are extraperineal.

The corpus spongiosum and the corpora cavernosa, with their envelopes, constitute the penis. The intraperineal segments of the penis converge at the apex (ventral part) of the superficial perineal cavity and, passing out of the cavity beneath the symphysis pubis (Figs. 2283 and 2284, Nos. 1, 1), form the pendulous body (extraperineal portion) of the penis. A strong band of fibrous tissue (the suspensory ligament of the penis) passes downward from the symphysis and blends with the fibrous cylinders of the corpora cavernosa (Fig. 2283).

The urethra (spongy portion) extends throughout the length of the corpus spongiosum and terminates at the meatus urinarius.

The erector penis muscle (homologous with the erector clitoridis) embraces the crus penis and arises from the intermediate space of the pubo-ischiatic ramus and the ischial tuberosity. It is inserted into the sides and ventral surface of the crus. By compressing the crus it assists in causing and maintaining erection. The accelerator urinæ muscle is bilaterally symmetrical. It is also called the ejaculator seminis. It is homologous with the sphincter vaginæ or bulbo-cavernosus of the female. It arises from the central tendinous point and from the median raphe in front. From these points its fibres diverge like the plumes of a feather. The greater number course around the sides and are inserted into the dorsum of the intraperineal part of the corpus spongiosum, while the foremost fibres extend around the lateral part of each corpus cavernosum and are inserted into the midline of the dorsum of the two bodies, covering the dorsal vessels. By compressing the latter it helps to cause and maintain erection. The superficial layer of the superficial perineal fascia acquires no bony attachments and is continuous with the corresponding fasciæ of the secrotum, thighs, and ischio-rectal fossæ.

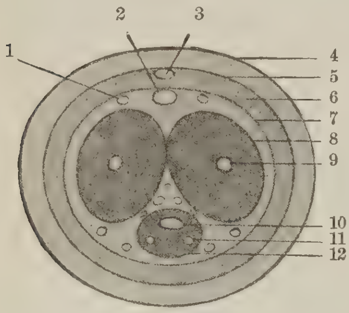

Fig. 2285.—Transverse Section of the Penis. Diagrammatic. 1, Dorsal artery; 2, deep dorsal vein; 3, superficial dorsal vein; 4, skin; 5, dartos (superficial layer of superficial fascia); 6, deep layer (areolar tissue) of the superficial fascia; 7, deep fascia; 8, cylindrical membrane containing erectile tissue of corpus cavernosum; 9, artery of corpus cavernosum; 10, spongy urethra in corpus spongiosum; 11, branch of artery of bulb supplying corpus cavernosum; 12, cylindrical membrane containing erectile tissue of corpus spongiosum; surrounding the latter are several blood-vessels.

The common envelopes of the extraperineal penis are the skin, superficial fascia (containing the dartos), and deep fascia. The dartos is the superficial layer of the superficial fascia and contains unstriped muscular fibres, and is continuous with the dartos of the scrotum. When contracted, it compresses the veins of the penis and favors erection. The skin is remarkably thin, is loosely connected with the deeper parts, is dark in color, and free from adipose tissue.

The erectile structures receive sympathetic nerves from the pelvic plexus and spinal nerves from the superficial perineal and the dorsal nerve of the penis. The coverings of the penis receive nerves from the inferior perineal of the internal pudic and from the genital branch of the genito-crural nerve. They receive *blood* from the external pubic artery, and from the superficial perineal and dorsal artery of the penis, branches of the internal pudic. The bulb and body of the corpus spongiosum are supplied by a branch (artery of the bulb) of the internal pudic. Each corpus cavernosum receives the cavernous branch of the internal pudic. The glans is mostly supplied by the dorsal artery of the penis (Fig. 2285).

The *veins* from the envelopes of the penis converge to the dorsum of the organ and empty into the superficial dorsal vein, lying in the areolar tissue beneath the dartos along the median line and emptying into the obturator and external pudic veins. The veins from the glans emerge at its neck and form the deep dorsal vein which runs in the median groove on the cavernous bodies beneath the deep fascia (Fig. 2285). It perforates the triangular ligament and empties into the prostatic plexus. Those from the body and bulb enter the same plexus or the internal pudic vein. Small veins emerge from the ventral and dorsal surfaces of the corpora cavernosa. They empty into the deep dorsal vein, the former circling around the sides of the bodies. The principal vein comes from the posterior part of each cavernous body, and, perforating the triangular ligament, enters the prostatic plexus.

The superficial lymphatics of the penis empty into the superficial inguinal glands, while the deep lymphatics empty into the pelvic glands about the internal iliac artery.

The Testicle, Spermatic Cord, and their Envelopes.—The testicle is the gland that secretes the male germ cells or spermatozoa (Figs. 2286 and 2287). It is supplied with arteries, veins, lymphatics, nerves, and an excretory duct (vas deferens). In migrating, during development, from the abdomen it evaginates a portion of the peritoneum (visceral and parietal layers, which subsequently become pinched off and form the *tunica vaginalis*) and all the layers of the abdominal wall in the inguinal region. It pushes in front of it, hernia-like, the following layers in addition to the peritoneum—viz., first, the *subperitoneal connective tissue,* and then, in order, the *infundibuliform fascia* (portion of transversalis fascia), some of the lower fibres of the internal oblique muscle thus forming the *cremasteric fascia,* the *intercolumnar fascia,* the *dartos* (superficial fascia rich in unstriped muscular fibres), and, finally, the *skin* (Fig. 2286). The path of the testicle through the abdominal wall is the *inguinal canal;* the evaginated, many-layered pouch is the *scrotal sac,* one on either side. By fusion the skin forms a common covering for both testicles, the line of fusion being indicated by the raphe; but the remaining layers meet in the median plane to form the *septum scroti.* All the envelopes of the two glands together form the *scrotum.* The deep "opening" of the inguinal canal is the *internal abdominal ring;* the superficial or subcutaneous end is the *external abdominal ring* (Fig. 2279, *Ext. Ab.*).

The inguinal canal is oblique and runs parallel with Poupart's ligament. It is about an inch and a half in length. It commences near the middle of Poupart's ligament and half an inch cephalad from it, and extends to the spine of the pubis. Its cephalic boundary is the arched fibres of the internal oblique and transversalis muscles; its caudal boundary is formed by the union of Poupart's ligament with the transversalis fascia; the ventral boundary is the skin, superficial fascia, aponeurosis of the external oblique, and partly by the internal oblique; the dorsal boundary is the triangular fascia, the conjoined tendon of the internal oblique and transversalis muscles, the subperitoneal connective tissue, and peritoneum.

The testicle, in migrating from the abdomen into the distal part of the scrotum, carries with it its tributary structures, such as the vas deferens, arteries, veins, lymphatics, and nerves, all bound together with connective tissue into a *spermatic cord* (Fig. 2287). The spermatic cord extends from the testicle to the internal abdominal ring, and is therefore divisible into a scrotal and an inguinal portion.

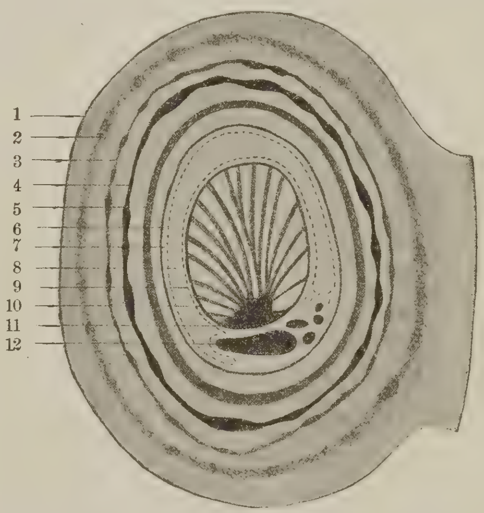

Fig. 2286.—Transverse Section of the Testicle and its Scrotum. Diagrammatic. For the sake of clearness the individual layers of the scrotum are represented as widely separated. 1, Skin; 2, dartos (superficial fascia); 3, intercolumnar fascia; 4, cremasteric fascia; 5, infundibuliform fascia; 6, subperitoneal fascia; 7, parietal layer of the tunica vaginalis; 8, cavity of the tunica vaginalis; 9, visceral layer of the tunica vaginalis connected by subserous areolar tissue to the tunica albuginea (10); 11, the mediastinum giving off trabeculæ to the tunica albuginea; 12, epididymis.

The Testicles. Each testicle consists of two separate but closely related parts, viz., the testicle proper, or didymis (Fig. 2287, *Tunica vag. Vis*), and an epididymis (*globus major, globus minor*). Each didymis is compressed laterally and is oval in form. It is one and a half

Genital Organs.

to two inches long (38 to 50 mm.), an inch and a quarter (30 mm.) dorso-ventrally, and one inch (25 mm.) in breadth. It weighs about six drachms (24 gm.). It has a lateral, convex surface looking outward and a little backward; a median, flat surface looking inward and a little forward. The dorsal border, nearly straight, is directed backward and upward and has attached upon its entire length, nearer its lateral than its median part, a structure composed of convoluted tubules and called the *epididymis.* The ventral border of the testicle looks forward and slightly downward. The inferior or caudal extremity is pointed and occupies a plane postero-internal to the more rounded upper or cephalic extremity. The epididymis consists of an enlarged cephalic *head* (*globus major*), a central portion or *body*, and a caudal, pointed *tail* (*globus minor*). The tubules of the globus major are continuous directly with those of the testicle (Fig. 2288, No. 3), but the body and globus minor are connected to the testicle by the tunica vaginalis and its subserous connective tissue. In horizontal section the body resembles a comma, and therefore it shows it to possess a ventral and dorsal surface, as well as lateral and median borders. The dorsal surface is convex, the ventral is concave. Between the concave surface and the testicle is a blind depression (*digital fossa*) opening laterally. The median border corresponds to the tail of the comma.

There are found connected with the globus major and neighboring part of the testicle two small bodies (*hydatids of Morgagni*), one of which is sessile and the other pedunculated (Fig. 2287). The former, one-eighth to one-third of an inch (3 to 8 mm.) in length, is flattened or rounded, and situated ventrally either on the globus major, the adjacent part of the testicle, or between the two; the latter, about the same size, is attached to the globus major. The hydatids are fœtal vestiges.

The testicle proper (didymis), as distinguished from its epididymis, is a fibro-glandular structure (Fig. 2288). The outermost part (*tunica albuginea*) is a dense connective-tissue membrane, which at the dorsal border is reflected ventrally into the gland and forms an incomplete vertical septum (*mediastinum*). From the sides and front of the mediastinum numerous connective-tissue cords and laminæ (*trabeculæ*) radiate to the inner surface of the tunica albuginea. Thus the interior of the gland is divided into a number (about two hundred) of incomplete cone-shaped spaces (*loculi*), which have their bases at the inner surface of the tunica albuginea and their apices at the mediastinum. In the cone-shaped loculi and lining the tunica albuginea and trabeculæ is a vascular layer (*tunica vasculosa*) consisting of a network of minute blood-vessels held together by delicate connective tissue. The true glandular tissue (seminiferous tubules) occupies the loculi. Each loculus contains two or three seminiferous tubules (*tubuli seminiferi*), commencing at the base of the space by blind extremities and taking a very convoluted course to the apex of the loculus. In their course toward the mediastinum they give off two or three blind pouches, and not only make anastomoses with one another, but also with the tubules in adjacent loculi. The tubules of each loculus, near its apex, unite together and form a single, straight, excretory tube (*tubulus rectus*) which enters the mediastinum. The tubules of a single loculus are bound together by a delicate interstitial connective tissue, rich in minute blood-vessels, and make a cone-shaped body (*lobule*) with the apex at the mediastinum. Each little tube in a lobule is about $\frac{1}{120}$ in. ($\frac{1}{5}$ mm.) in diameter, and when uncoiled its length is increased about thirty times (about 2 ft. or 62 cm.). The tubuli recti, formed as already described at the apices of the lobules, are smaller in diameter than the convoluted tubules of the lobules. They enter the mediastinum and form throughout that structure a network of anastomosing tubules (*rete testis*) of varying diameter, but always larger than the tubuli recti or convoluted tubules of a lobule. They have no proper wall, but are excavations in the mediastinum lined by epithelium of varying character. At the dorso-cephalic part of the testicle these channels finally unite to form about twelve tubes (*vasa efferentia*), which escape almost immediately through the tunica albuginea and enter into the globus major of the epididymis. The vasa efferentia, shortly after piercing the tunica albuginea, become greatly convoluted and form about twelve cone-shaped bodies (*coni vasculosi*) with their bases turned away from the tunica albuginea. They are each about one-third of an inch (or 8 mm.) long and enter a common duct and together constitute the globus major. This common duct extends downward, as the *tube of the epididymis*, and, greatly convoluted, forms the body and globus minor. The coils are held together by connective tissue. The length of the tube when uncoiled is about 15 ft., or 4.5 metres. Its diameter above is about $\frac{1}{60}$ in., or $\frac{2}{5}$ mm., but gradually decreases toward the globus minor and then enlarges beyond that structure. The tube consists of an inner mucous coat lined with ciliated columnar cells, and an outer coat of unstriped muscular fibres. The tube of the epididymis emerges from the globus minor as a constituent (*vas deferens*) of the spermatic cord (Figs. 2279 and 2288).

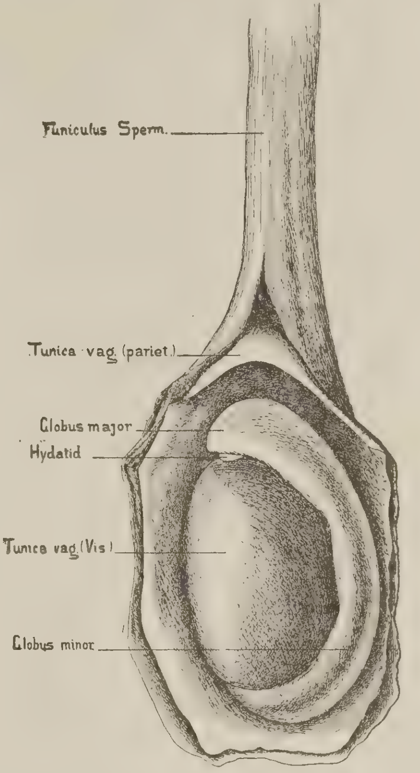

FIG. 2287.—Lateral Surface of the Left Testicle. (Modified from Gegenbaur.) All the layers of the scrotum down to and including the parietal layer of the tunica vaginalis, cut through and turned aside, thus exposing the cavity and the visceral layer of the tunica vaginalis; the latter enveloping the didymis (*Tunica vag. Vis.*), the epididymis (*Globus major*, *Globus minor*), and the hydatid.

Spermatogenesis.—The male germ cells are formed only in the convoluted tubes of the lobules of the testis. The process is homologous with oögenesis (maturation of the ovum) in the female. If a section of a seminiferous tubule be examined, the following arrangement will be observed: Each tubule presents several layers of cells. The layer furthest from the lumen of the tube is formed principally by a number of cells called *spermatogones.* Each of these, from time to time, divides into two daughter cells, one of which persists as a spermatogone, while the other differentiates into a *primary spermatocyte,* thus forming a layer nearer the lumen. This latter cell divides into two cells, the *secondary spermatocytes,* thus forming a layer still nearer the lumen. These undergoing division present a layer of *spermatids*, each one of which develops into a *spermatozoon*. In addition to the preceding cells there are others, found in all the layers, which serve the purposes of supporting and nourishing cells (Sertoli cells). The spermatozoa form the layer of cells next to the lumen. Each spermatid, in differentiating into a spermatozoon, gradually elongates; its nucleus becomes the head of the spermatozoon enveloped by a very thin film of protoplasm; the centrosome lies behind the nucleus in the middle piece or neck; the tail develops behind the neck; an axial filament runs through the neck and tail extending beyond the sheath of the latter as the end-piece. The head is from 2 to 3 μ in breadth and from 3 to 5 μ in length; the neck is 6 μ long and 1 μ ($\frac{1}{25000}$ inch) in breadth; the tail is from 40 to 60 μ long; the end-piece is 6 μ long. In profile view the head is narrow and pointed at its free end, but on surface view it appears oval in shape.

The rate of progression of a spermatozoon is about 0.05 mm. per second.

Spermatozoa possess remarkable vitality. When mounted on a slide and protected from evaporation they have exhibited motility for nine days. They have been found alive in the male genital tract four days after death. They may retain their activity in the female genital tract for several weeks.

Weak acid solutions kill them.

Structure of the Spermatic Cord. The *vas deferens* forms the axis of the cord and is about eighteen inches (46 cm.) in length. It is in the dorsal part of the cord and is recognizable from its cord-like resistance to pressure.

The *spermatic artery* is ventral to the vas, and near the testicle becomes tortuous and divides into several branches, two or three of which accompany the vas and supply the epididymis; others pierce the tunica albuginea and supply the testicle proper (*didymis*). The *deferential artery* is a long, slender vessel accompanying and supplying the vas on its dorsal side and anastomosing with the spermatic near the testis. The *cremasteric artery* courses along the cord supplying the cremasteric and other coverings. Seven or eight *spermatic veins* emerge from the dorsal surface of the testis median to the epididymis, and unite to form the *pampiniform plexus* passing mostly along the ventral plane of the vas and constituting the bulk of the cord. Farther up the cord they are reduced to two or three in number; at the internal abdominal ring they have united into one or two spermatic veins. *Lymphatic vessels* accompany the veins. Plexuses of *sympathetic nerves* accompany the arteries.

Except for a short distance above the testicle, the scrotal portion of the spermatic cord is lacking in the serous envelope; otherwise the coverings are identical with those of the testis. The inguinal part of the cord has only the following coverings, viz., the subserous connective tissue, the infundibuliform fascia, and cremasteric fascia.

At the internal abdominal ring the constituents of the spermatic cord separate and course in different directions. The vas deferens, after winding around the outer side of the deep epigastric artery, and crossing the external iliac vessels, descends at the side of the bladder into the pelvis. It arches downward and backward to its base, crossing the vestigial hypogastric artery to reach the median side of the ureter. At this point it is sacculated and enlarged, forming the *ampulla*, which extends to the base of the prostate gland (Fig. 2283, No. 3). The ampullæ are median from the vesiculæ seminales, and are between the bladder and the second part of the rectum. They constitute the lateral boundaries of the external trigone of the bladder. At the base of the prostate gland the vas deferens becomes narrowed and, uniting here with the duct from the seminal bladder, forms the *ejaculatory duct* (Fig. 2283). The vas deferens is about two feet (61 cm.) in length and about a line and a quarter (3 mm.) in diameter. The spermatic artery can be traced crossing obliquely the external iliac artery and ureter to the aorta a little below the renal artery. It rests on the psoas magnus muscle behind the peritoneum. The right one passes across the inferior vena cava.

On either side two spermatic veins generally accompany each spermatic artery for a distance and then fuse into a single vein. The right one opens obliquely into the inferior vena cava, the left one into the left renal vein at a right angle. The left spermatic veins pass behind the sigmoid colon with their artery. The deferential artery can be traced to the superior vesical artery at the side of the bladder. The cremasteric is a branch of the deep epigastric artery. The lymphatic vessels terminate in the lumbar glands. The sympathetic nerves are the spermatic plexus derived mostly from the renal, but partly from the aortic plexus. The plexus is re-enforced through the deferential from the pelvic plexus.

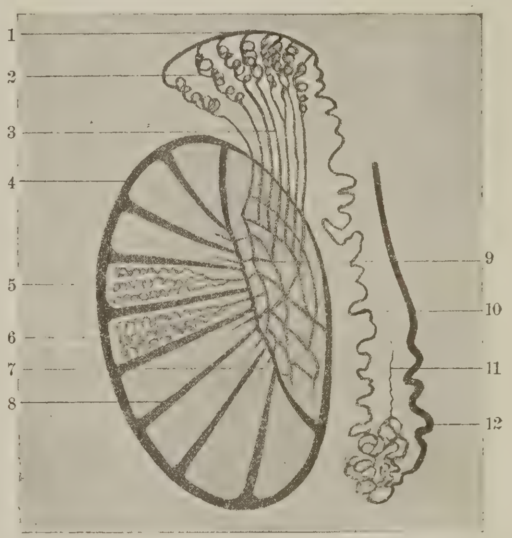

FIG. 2288.—Diagram of testicular tubules. 1, Collecting tube of the epididymis; 2, coni vasculosi; 3, vasa efferentia; 1, 2, and 3 form the globus major; 4, tunica albuginea; 5, loculus containing a lobule; 6, lobule; 7, one of the vasa recta; 8, trabecula; 9, rete testis in the mediastinum; 10, tube of the epididymis forming the body and globus minor; 11, vas aberrans; 12, vas deferens.

Dorsal to the spermatic cord is the internal branch of the genito-crural nerve from the lumbar plexus. It innervates the cremaster muscle. The ilio-inguinal nerve from the lumbar plexus enters the inguinal canal at varying points and appears at the external abdominal ring ventral to the cord. It gives sensibility to the scrotum.

Tunica Vaginalis (Fig. 2287). As already stated, the tunica vaginalis is the innermost of the scrotal coats of the testis, derived from the peritoneum during the descent of the testis. At birth the cavity of the tunica is directly continuous with that of the peritoneum, so that the tunica consists of inguinal, scrotal, and testicular segments. But, usually, a short time after birth, the inguinal and upper scrotal parts are reduced to a fibrocellular thread lying in the loose connective tissue around the spermatic cord; so that the tunica vaginalis is reduced to a testicular portion. There are all grades of variation between a tunica vaginalis whose cavity is freely continuous with the cavity of the abdominal peritoneum and one whose cavity is absolutely shut off from that of the abdomen, and without even the presence of a vestigial connective-tissue thread.

The *visceral layer* of the tunica is closely adherent to the testicle proper, and to the globus major and lateral part of the body of the epididymis, and is prolonged upward upon the spermatic cord for half an inch (12 mm.). It extends into the digital fossa between the epididymis and testicle. It leaves uncovered nearly all the postero-internal part of the body and the globus minor of the epididymis. It is in those uncovered parts that extensive vascular communication is established between the testicle and its coverings and the cord. The *parietal layer* is continuous with the visceral layer at the point of reflection from the spermatic cord, and at the postero-inferior parts of the testicle. It is loosely connected with the infundibuliform fascia by the subserous connective tissue. The two layers are in contact normally except for a very thin film of serous fluid secreted by the endothelial cells of the tunica.

The Seminal Vesicles (Fig. 2283, No. 4). These reservoirs for the semen, to which they add their own secretion, are situated between the bladder and the rectum. They are lobulated pouches of pyramidal shape placed one on either side external to the ampullæ of the vasa deferentia, and are two inches (50 mm.) long and a half-inch (12 mm.) wide at the base. They present rectal and bladder surfaces, median and lateral borders, a base and an apex. The ventral surface is attached to the base of the bladder overlapping the ureter. The rectal surface is covered above by the recto-vesical pouch of the peritoneum, but below is separated from the rectum only by the recto-vesical fascia. The bases are widely separated, but the apices converge and narrowing into straight ducts unite, near the base of the prostate gland, with the corresponding vasa deferentia to form the ejaculatory ducts.

Each vesicle consists of a single tube coiled upon itself and giving off many blind diverticula, all bound together firmly by fibrous tissue. When uncoiled the main tube is about five inches (125 mm.) in length and of the diameter of a quill.

Each ejaculatory duct is about three-quarters of an inch (19 mm.) long, and commencing at the base of the prostate it runs downward and forward between the lateral and middle lobes to empty into the urethra, near or through the uterus masculinus. The seminal vesicles and ejaculatory ducts have three coats: an inner or mucous one, a middle or muscular one, and an outer or areolar one.

The nerves of the vesicles and ducts are derived from the pelvic plexus. The middle hemorrhoidal and the vesical arteries supply the vesicles and the extraprostatic portion of the duct. The intraprostatic portion receives its nutriment from the prostatic vessels. Veins and lymphatics accompany the arteries, emptying into the vesico-prostatic plexus.

Prostate Gland (Fig. 2283, No. 3). The prostate is a musculo-glandular body surrounding the proximal urethra and the neck of the bladder. It is in the pelvic cavity behind the lower part of the symphysis pubis. It is cephalad from the deep layer of the triangular ligament of the urethra (deep perineal fascia). It is about the shape and size of a large chestnut. It develops at puberty and atrophies after castration. It presents a base, an apex, a ventral, a dorsal, and two lateral surfaces. The base is situated immediately below the bladder; the apex rests upon the pelvic side of the triangular ligament; the dorsal surface rests on the rectum, distant about one inch and a half (37 mm.) from the anus; the ventral surface, about three-quarters of an inch (19 mm.) behind the symphysis, has some loose fat and a plexus of veins in front of it, and is connected on either side to the pubic bone by the pubo-prostatic ligaments; the lateral surfaces are in relation with the anterior portions of the levator ani muscles, the vesico-prostatic plexus of veins intervening. The prostate consists of a median and two lateral lobes. The lateral lobes are separated by a deep notch at the base and by a slight furrow on the ventral and dorsal surfaces. The middle lobe, variable in shape, is a small transverse band, placed between the two lobes at the posterior part of the gland, behind the proximal urethra. The ejaculatory ducts pass between the middle and lateral lobes. The prostate is enveloped by a thin but firm fibrous capsule continuous with the pelvic layer of the triangular ligament and the recto-vesical fascia. It consists of stroma (mostly muscular) and glandular tissue. Immediately beneath the fibrous capsule is a thick muscular layer, and around the prostatic urethra is another strong, circular, muscular layer; extending between the two are a series of decussating muscular trabeculæ, forming interstices that contain the glandular tissue. The tubular glands are arranged around the urethra in a radiating manner, and their ducts (about thirty in number) communicate by minute orifices with the prostatic sinus on either side. They are lined with columnar epithelium and secrete a milky fluid, which is added to the seminal fluid at the moment of ejaculation.

The prostate is supplied by the internal pudic, vesical, and hemorrhoidal arteries. The veins empty into the vesico-prostatic plexus surrounding the organ, and thence into the internal iliac vein. The nerves are derived from the pelvic plexus.

Cowper's Glands. These glands are two firm lobulated bodies about the size of peas and situated, one on either side of the membranous urethra, between the two layers of the triangular ligament (Fig. 2283, No. 2). They lie close above the bulb among the fibres of the compressor urethræ muscle. Each body is a compound racemose gland, and its duct, lined by columnar epithelium, pierces the perineal layer of the triangular ligament and runs forward for about an inch (25 mm.) under the mucous membrane, finally emptying into the spongy urethra. The viscid, albuminoid, transparent secretion of these glands is mixed with the seminal fluid at the moment of ejaculation.

Daniel Kerfoot Shute.

GENTIAN.—Gentiana. "The dried rhizome and root of *Gentiana lutea* L. (fam. *Gentianaceæ*)," U. S. P. This, the yellow gentian, is one of the largest and showiest species of the genus. It is a tall, sturdy, mountain perennial, arising from a thick, fleshy, slightly branching or simple, and sometimes very long (from half a metre to one metre or more), yellowish-brown root, and is a yard or more high. It grows abundantly in the elevated and mountainous parts of Southern and Middle Europe, Asia Minor, etc. In Switzerland, Southern France, and the hilly parts of Germany, it is collected for use. Although sometimes cultivated for ornament, it does not thrive well, and rarely flowers except in its native pastures.

Description.—In cylindraceous, usually slightly flattened, curved or crooked pieces of indefinite length, and from 0.5 to 3.5 cm. (¼ to nearly 1½ in.) thick, or in longitudinal slices of the same thickness; externally yellowish-brown to dark brown, strongly and crookedly longitudinally wrinkled, and marked with lighter-colored circular root scars, the rhizome finely or heavily annulate; somewhat tough and flexible when damp, rather brittle when dry, the fracture short but uneven, the bark thick, reddish-brown, separated by a dark brown line from the yellowish or reddish-yellow inner portion; free from starch; odor strong, characteristic; taste very bitter, slightly sweetish. The roots of other species are distinguished by their smaller size and tendency to divide into numerous branches at the top. Their introduction is to be regarded as only technically an adulteration, as their properties are identical with those of the official root.

Composition.—The principal constituent of this and other gentians is the peculiar, intensely bitter, crystalline glucoside, *gentiopicrin*, first obtained in a state of purity in 1868, by Kromeyer, from fresh gentian root. It cannot, so it is said, be made to crystallize from that which has been dried. It forms clear, radiate, or clustered needles; is soluble in water and diluted alcohol, but not in ether; and by means of diluted acids it is separated into sugar and *gentiogenin*, a yellow, bitter, neutral powder. The yield is about one and two-thirds *per mille*. *Gentisic acid* is more abundant. It is in large needle-shaped crystals, tasteless, and almost insoluble in water and ether, but slightly soluble in alcohol. It is not an active substance. The root also contains a good deal of pectic matters, sugar (gentianose), etc., but no starch, and probably no tannic acid, unless the gentisic acid be considered a form of tannin.

Action and Use.—Gentian is the most perfect type at our command of the class of medicines called "simple bitters." In the purity of its bitter taste, the promptness of its action upon the assimilating organs, and the absence of other qualities even in considerably larger than medicinal doses, it has no equal. Concerning its physiological action in a definite way—that is, as shown by experiments in laboratories—we know but little, the more striking effects of active poisons having greater fascination for physiologists. *Gentisic acid*, when taken even to the extent of several grams, has no special action. *Gentiopicrin* has not been tested, to the writer's knowledge, in a pure state; but the older *gentianins*, etc., consisting of mixtures of the above two substances, have never shown themselves poisonous. In excessive quantities gentian and its preparations disturb the stomach and bowels, and may occasion nausea and vomiting. Sometimes it appears to be slightly laxative. Gentian is employed in medicine almost exclusively for the purpose of obtaining its stimulating effect upon the appetite, gastric secretion, and assimilating functions. Under its influence the appetite improves, the feeling of weight or discomfort felt in the stomach or bowels after eating—if due to debility of those organs—disappears, more food is taken, and probably more of what is taken is assimilated. It must be borne in mind that it probably, like other bitters, has a slight inhibitory action upon the digestive process by its presence in the mass of food. The secondary effect—viz., the improved nutrition of all the organs, and their consequently better performance of their various functions—is what is known as a tonic effect. Strength, weight, color, firmness of tissue, are all improved, and better health results. This drug is, then, indicated in debility, with poor appetite, of a more or less chronic character. Of course, acute and sudden depression, such as collapse or shock, or the weakness of fevers during the stage of high temperatures, are to be treated by stimulants, and are not suitable ones for tonics alone; but, on the other hand, during the recovery from all severe illnesses gentian may be of great value. It is often of service in dyspepsia, and, in combination with iron, in simple anæmia. As an antiperiodic it has been completely superseded by quinine; as a substitute for tobacco and opium in the treatment of those habits it has no special value.

ADMINISTRATION.—Gentian, in the form of the whole root, is sometimes chewed, and the salivary extract swallowed; the method, although troublesome, is an excellent one. The dose is not particularly important, but 2 or 3 gm. will probably do as much good as a larger quantity. There are several widely used preparations, all good. The extract (*Extractum Gentianæ*, U. S. P.), an infusion evaporated to a pillular consistence, is a nearly black, pleasant-smelling, but very bitter, soft solid, scarcely firm enough to make permanent pills. Dose, a gram or less. The fluid extract (*Extractum Gentianæ Fluidum*, U. S. P.), made with diluted alcohol, is less used than the other preparations, but represents the root well. The compound infusion (*Infusum Gentianæ Compositum*, B. P.), although not now officinal here, is considerably used; its strength is 12.5 gm. to 1,000 c.c. with orange and lemon peel. Dose, a wineglassful or two. But the most commonly used of all, and probably the most perfect bitter tonic ever made, is the compound tincture (*Tinctura Gentianæ Composita*, U. S. P.), which has the following composition: Gentian, 10 parts; bitter orange peel, 4 parts; cardamom, 1 part; percolated with diluted alcohol until 100 parts of tincture are obtained. The addition of aromatics in the last two preparations greatly enhances their value. *W. P. Bolles.*

GENTIANACEÆ.—(*The Gentian Family.*) The great size and wide distribution of this family, and the singular uniformity of its species in agreeing with the general composition and properties of the drug last discussed, render it of great importance that army surgeons and travellers generally should be able to recognize them when seen. There are no poisonous plants among them. A very few are slightly or not at all bitter and their roots or leaves are edible. Several *Coutoubeas* are used as anthelmintics. With these exceptions, all the others in use, to the number of a hundred or more, have the properties of the official *Gentian* and *Chiretta.* Among these are a large number in the genera *Gentiana, Swertia, Lisianthus, Pleurogyne, Erythræa* (the "Centaurys"), *Sabattia, Axacum*, etc. All show a distinct tendency toward laxative properties, and in some this tendency is marked. The family contains upward of sixty genera and nearly a thousand species, Gentiana being the largest genus, with about three hundred species. The family is represented mostly in the temperate zones and in tropical mountains with a temperate climate. They may be known by the following family characteristics: They are mostly herbs, smooth, with opposite, entire, extipulate leaves, these usually nerved or ribbed. The flowers are solitary or cymose in the axils, or at the summit, the cymes often panicled. The flowers are regular, rarely a little oblique, perfect, 4–5-merous, the corolla gamopetalous. The stamens are of the same number as the corolla lobes, alternate with them and affixed to the corolla tube or throat. The disc, if any, is inconspicuous. The ovary is superior, one-celled, or rarely two-celled by the union of the two parietal placentæ. The ovules are numerous, anatropous or amphitropous. The fruit is usually a two-valved, dehiscent capsule, rarely indehiscent, still more rarely fleshy. The embryo is small, in copious albumen, the radicle, if its direction is distinct, ascending.

Henry H. Rusby.

GEOFORM, or gaiaform, prepared by the action of formaldehyde on guaiacol, is a yellow, non-irritant powder, without odor or taste. It is soluble in alcohol, ether, hot benzol, and solutions of soda or potassa, and is insoluble in water, petroleum ether, and benzin. Heated for several days it acquires an odor of vanilla. Used by Brissonet and others, it is claimed to be non-toxic, as much as 15 gm. (℥ ss.) a day having been administered, without inconvenience, to a dog weighing 16 kgm. (35 pounds). It is given in capsule in tuberculosis, the dose being that of guaiacol.

Tanno-geoform, its compound with tannin, is preferred for intestinal tuberculosis and night sweats, and for other sweating processes, such as hyperidrosis.

W. A. Bastedo.

GERANIUM.—CRANESBILL. *Wild Geranium.* "The dried rhizome of *Geranium maculatum* L. (fam. *Geraniaceæ*)," U. S. P. This plant is exceedingly abundant in woodlands about New York, and elsewhere in eastern and central North America, and is represented farther west by other species, with similar properties. It is a perennial slender herb, a foot or two high, with palmately lobed, roundish leaves, from two to six inches in diameter, and numerous lilac-purple flowers, something over an inch in breadth. The rhizome is of horizontal growth, 5 to 10 cm. (2 to 4 in.) long and 0.5 to 1.5 cm. ($\frac{1}{5}$ to $\frac{3}{5}$ in.) thick, more or less crooked, cylindraceous but somewhat vertically flattened, brown; roughly and shortly wrinkled and strongly, rather sharply tuberculate; fracture short, purple, the bark thin, a few short and broad yellowish wood-wedges scattered near the dark cambium; inodorous; taste strongly astringent.

Besides inert *mucilage, resin, coloring matters*, etc., geranium contains from ten to twenty-five per cent. or more of tannin, to which its medicinal value is owing. It is a mild, rather pleasant, vegetable astringent, and considerably employed in diarrhœa, chronic dysentery, etc., and as a wash, gargle, or injection, in catarrhs of the pharynx, vagina, or urethra. A fluid extract is official and represents it well for internal use. Dose, 1 to 2 c.c. (♏ xv. ad xxx.). For washes and gargles a ten-per-cent. decoction may be made in the usual way. Cranesbill is often selected, when an astringent is needed for a child, on account of its comparatively easy administration.

Geranium will probably be dropped from the next edition of the Pharmacopœia. *Henry H. Rusby.*

GERMANDER. See *Labiatæ.*

GERMAN MEASLES. See *Roetheln.*

GERMICIDES.—Modern science having established the fact that certain infectious diseases of man and of the lower animals are due to minute micro-organisms, popularly spoken of as "germs," the term *germicides* has been introduced to designate those agents which have the power of destroying the vital activity of such organisms.

Strictly speaking, a germ is the primitive reproductive element of an animal or vegetable organism. But medical authors, in advance of exact knowledge, have long been in the habit of speaking of the "germs of disease"; and since it has been shown that in certain instances these disease germs are minute vegetable organisms, belonging to the *bacteria,* a more definite idea is attached to the word germ, and the term germicide is understood as referring to an agent which has the power to destroy organisms of this class—micrococci, bacilli, and spirilla.

It is evident that an exact knowledge of the germicidal power of various substances is desirable with a view to therapeutic possibilities, and especially with reference to the destruction of disease germs external to the bodies of infected individuals—*disinfection.* As methods have been perfected by which organisms of this class—pathogenic or non-pathogenic—may be isolated and cultivated through successive generations in sterilized media—"pure cultures"—it has become possible to determine in an exact manner the germicidal power of a given agent as regards a particular germ; and in a general way to classify chemical agents with reference to their power to destroy bacterial organisms. Already much work has been done in this direction, and it is the object of the present article to place upon record the results of the determinations which have been made up to the present date.

But before referring in detail to the experimental data, it will be desirable to give an account of the methods of research, and to call attention to the various circumstances which influence the result, and which must be taken into consideration if we attempt to compare the data obtained by different experimenters.

In the case of pathogenic organisms *two methods of determination* are available: (*a*) the inoculation of germs which have been exposed to the action of a supposed germicide into a susceptible animal; (*b*) the attempt to cultivate germs exposed in the same way in suitable culture media. In the one case failure to multiply in the body of the test animal, and in the other failure to multiply under favorable conditions in a culture medium is taken as evidence of the germicidal power of the agent tested.

Extended experiments by the method of inoculation have been made upon the anthrax bacillus (Davaine, Koch), upon the tubercle bacillus (Schill and Fischer), and upon the micrococcus of rabbit septicæmia (Davaine, Sternberg). Experiments have also been made upon the virus of glanders (Reynal, Peuch, Vallin), upon that of symptomatic anthrax (Arloing, Cornevin, and Thomas), and upon the micrococcus of fowl cholera (Salmon).

This method is very definite and satisfactory so far as the negative results are concerned—that is to say, when the agent under trial fails to exercise any germicidal power. In this case the death of the test animal, and the fact that the pathogenic organism to which this result is due is found in its blood or tissues, is sufficient evidence of the failure of the agent under trial to destroy the vitality of the germ. But the survival of the test animal cannot be taken as positive proof that the agent to the action of which the test organism was submitted has completely destroyed the vitality of this organism. This for two reasons: *first,* the inoculated animal may suffer from a modified and non-fatal attack of the infectious disease, the germ of which is used in the test; *second,* in the case of a chemical agent which has been mixed in a given amount with a pure culture of the test organism, or with blood from an infected animal containing this organism, the agent is necessarily injected into the test animal along with the germs which have been subjected to its action, and may exercise a restraining influence upon the development of these germs without destroying their vitality. This would give time for their destruction in the body of the animal by those means which have been provided by nature. The writer has elsewhere suggested that this is probably one of the functions of the white blood corpuscles, and that, when the developing power of pathogenic organisms is restrained in any way, before or after their introduction into the body of a susceptible animal, this provision of nature may suffice to prevent an attack of the disease, or at least to modify its severity.

The *second method* permits of a more accurate determination when the experiments are conducted with a due regard to the possible restraining influence of the germicide agent, which by preventing growth might lead to the mistaken inference that the vitality of the test organisms had been destroyed. This error is to be avoided by diluting the germicide agent so largely with the sterilized culture fluid into which it is introduced, along with the test organisms which have been exposed to its action, that its restraining influence is rendered *nil.* Suppose, for example, that we mix with a culture of the anthrax bacillus containing spores an equal quantity of a solution of mercuric chloride of the strength of 1 to 1,000, making the proportion of the salt in the mixture 1 to 2,000. Now, if we take one part of this mixture and add it to ten parts of sterilized *bouillon,* we shall have the mercuric chloride present in the proportion of 1 to 20,000. Experiments upon the restraining power of this salt show that anthrax spores will not grow in culture solutions containing 1 to 300,000, and that their development is retarded by solutions of 1 to 600,000. Failure to develop in this case would therefore be no proof that the growing power of the anthrax spores had been destroyed. This proof is only to be attained by adding sufficient culture fluid to dilute the mercuric chloride beyond its restraining power. The use of a comparatively large amount of the culture fluid, and of an extremely small quantity of the material containing the test organisms, permits us to exclude this source of error, for a few germs serve as well for the test as a large number. Or we may wash the test organisms in a solution which has no germicidal action but which is capable of neutralizing chemically the agent which is being tested as to its germicidal power—*e.g.*, a solution of ammonium sulphide for corrosive sublimate.

For the reason stated fluid culture media are more suitable for experiments of this nature than solids. If we bring a little of our material containing mercuric chloride in the proportion of 1 to 2,000 upon the surface of a cooked potato, or introduce it with a needle into a gelatin culture medium, the salt will not be diluted, and would exercise its restraining influence upon the germs if they had not already been destroyed by its action. On the other hand, if we add 1 part of the material to 100 parts of *bouillon* and mix thoroughly by shaking, the mercuric chloride will be diluted to 1 to 200,000; this being still within the limits of its restraining action, we may take one part of the mixture and add it to 10 parts of the sterile *bouillon.* The mercuric chloride will now be diluted to 1 to 2,000,000, a proportion quite beyond the limits of restraining action. But there will be a sufficient number of anthrax spores in the culture medium to test the question as to whether the growing power of these particular "germs" is destroyed by mercuric chloride in the proportion named.

This source of error has not been kept sufficiently in view in some of the experiments heretofore made. Again, it often happens that no development occurs for a time, but that after several days the germs which have been exposed to the action of a chemical agent commence to grow, and finally produce an abundant and vigorous progeny. In this case mistakes are likely to arise from terminating the experiment too soon. Anthrax spores, for example, develop, in a suitable culture medium, at a temperature of 80° to 100° F., within twenty-four hours, and give rise to numerous characteristic flocculi, made up of long filaments, which are readily distinguished by the naked eye. But after exposure to a germicide agent in less amount than is necessary completely to destroy their vitality, they may fail to develop under the same circumstances in forty-eight or seventy-two hours, and yet finally produce an abundant crop of filaments.

Bearing in mind these sources of error, the germicidal value of a given agent may be determined approximately by a series of experiments, in which the quantity of the agent under trial is increased or diminished according as it fails or is successful in destroying the vitality of the test organism. But the data obtained by experiments upon a single organism can be applied only in a general way to others of the same class, for experiments which have been made show that within certain limits there are manifest differences in resisting power, and especially that there is a wide difference in this regard between organisms in active growth—micrococci, spirilla, or bacilli—and the reproductive bodies, called spores, which are developed in the interior of the bacilli at a certain period in their life history.

It will be seen from what has been said, that the germicidal power of a chemical agent can be stated in a definite manner only when reference is made to a particular germ. It is also necessary to take into account certain circumstances relating to the test organism and the medium in which it is placed, and, especially, to consider *the time* during which this has been exposed to the action of the germicide. Thus we may, by our experiments, determine how long a time will be required for the destruction of a given germ by means of a standard solution of a certain chemical agent. Or, on the other hand, we may determine the proportion in which this agent must be used in order to be effective in a given time. In Dr. Koch's elaborate experiments, published in the first volume of the "Mittheilungen aus dem Kaiserlichen Gesundheitsamte," the time is made the variable quantity. In the writer's numerous experiments a standard time was adopted—two hours in the more recent experiments—and the object in view was to determine the minimum quantity of the agent under trial which is effective in this time.

Evidently, a comparison of the results reported by different experimenters requires a consideration of this essential condition. But in addition to this we must consider the following circumstances:

(*a*) The presence or absence of spores.

(*b*) The physical condition of the test organism—whether it is dry or moist, whether suspended in fluid or embedded in masses of albuminous material, etc.

(*c*) The chemical properties and mode of action of the agent which is being tested.

(*d*) The temperature at the time the experiment is made. As a general rule the higher the temperature the more promptly the germicidal action of a chemical agent is manifested.

(*a*) As already remarked, spores are far more resistant than bacteria in active growth. Thus the spores of the anthrax bacillus require for their destruction a boiling temperature, while the bacillus itself is quickly destroyed by a temperature of 140° F. The same spores are not destroyed by being immersed for one month in a five-per-cent. solution of chloride of zinc, or for three months in absolute alcohol, or one hundred and ten days in a five-per-cent. solution of carbolic acid in oil; the last-mentioned solution, however, destroys the bacilli, in the absence of spores, in six days (Koch).

(*b*) The germicidal power of formaldehyd, sulphur dioxide, and of other gases is largely influenced by the physical condition of the test organisms—as to whether they are dry or moist, whether they are exposed in masses or in thin films, etc. And the same circumstances influence the result, to a less extent, in experiments with aqueous solutions of various agents. This is especially true as regards those agents which enter into combination with albuminous material; thus Schill and Fischer found that the tubercle bacillus was not destroyed in tuberculous sputum exposed for twenty-four hours to the action of mercuric chloride in solution in the proportion of 1 to 2,000, while dried sputum exposed to a solution of 1 to 5,000 failed to produce tuberculosis when inoculated into guinea-pigs. The difference was no doubt due to the fact that in the moist sputum the bacilli in the interior of the mass were protected from the action of the germicide agent. The result is also largely influenced in certain cases by the amount of non-living organic material associated with the germs to be destroyed. This is especially true as regards the oxidizing disinfectants. If, for example, we subject a given quantity of germs suspended in pure water to the action of potassium permanganate or of hypochlorite of lime, these agents will be effective in dilute solutions. But if the germs are suspended in a rich culture medium, or embedded in masses of organic material, this material will be quickly oxidized, and in the chemical reaction which occurs an amount of the reagent will be decomposed corresponding with the amount of organic material present in the solution; and only the excess of the oxidizing agent will be available for the destruction of such germs as may have escaped immediate destruction by reason of their resisting power, or because they were protected by being embedded in masses of material.

It will be desirable to extend the experimental researches in this direction as new pathogenic organisms are discovered, and to determine in an exact manner the value of each agent which has been shown to possess germicidal power for each organism of this class. In many of the experiments which have been made test organisms have been used which are known to be non-pathogenic, but which, belonging to the same class, give valuable data for the determination in a general way of the comparative germicidal value of various chemical agents. Thus, in many of the writer's experiments the bacteria of putrefaction, as found in "broken-down" beef-tea freely exposed to the air, have served as the test. As a variety of bacterial organisms are present in such material, including one or more species of spore-bearing bacilli, this serves as a general test, and there is reason to believe that all known pathogenic organisms would be destroyed by an agent capable of destroying all germs found in such material. These experiments, therefore, furnish reliable data upon which to base practical measures of disinfection. In practice it will be best to select such agents as stand the most rigid tests, and to use them in amounts somewhat in excess of what is shown by such tests to be necessary. (See article on *Disinfectants.*)

For convenience of reference we have arranged the following summary of the experimental data in alphabetical order:

Acetone.—Anthrax spores grow freely after two days' exposure to the action of this agent; after five days the development is feeble (Koch).

Acetic Acid.—A five-per-cent. solution did not prevent the development of anthrax spores after five days' exposure (Koch). In experiments made by Abbott, glacial acetic acid in the proportion of fifty per cent. failed to destroy anthrax spores in two hours, but twenty per cent. was effective with the spores of *B. subtilis,* and with the mixed organisms in broken-down beef-tea; and micrococci were destroyed in the same time by a one-per-cent. solution.

Alcohol.—In the writer's experiments it was found that ninety-five-per-cent. alcohol did not destroy the vitality of the organisms in broken-down beef-tea in forty-eight hours. The micrococcus of pneumonia was destroyed by two hours' exposure to a twenty-four-per-cent. solution. A micrococcus obtained from gonorrhœal pus required a forty-per-cent. solution. Koch found that absolute alcohol had no effect upon the vitality of anthrax spores which were immersed in it for one hundred and ten days. When saturated with camphor, alcohol does not destroy the virus of symptomatic anthrax (Arloing, Cornevin, and Thomas). In the proportion of 1 to 1.5 it destroys the bacteria which cause the acid fermentation of milk (Molke). Schill and Fischer found that when tuberculous sputum was mixed with an equal quantity of absolute alcohol, its infecting power was not destroyed (in twenty-four hours), but that, in the proportion of 5 parts to 1 of sputum, this agent was effective in destroying the tubercle bacillus, as proved by inoculation experiments.

Yersin reports that the tubercle bacillus in pure cultures is destroyed by absolute alcohol in five minutes. The experiments of Reinicke, Ahlfeld, Epstein, and others show that bacteria in a moist condition are quickly destroyed by a fifty-per-cent. solution of alcohol and that such a solution is more potent as a germicide than absolute alcohol, which has comparatively little germicidal power. For the disinfection of the hands a fifty-per-cent. solution is recommended by Epstein.

Solutions of mercuric chloride, carbolic acid, thymol and lysol in fifty-per-cent. alcohol were found by Epstein to be more active than aqueous solutions of the same strength. Alcoholic solutions have the advantage of dissolving oils and consequently of acting more promptly when the object in view is to disinfect the hands.

Ammonia.—The experiments of Koch show that ammonia does not destroy the spores of the anthrax bacillus; but, according to Behring, ammonia in solution in the proportion of 1 to 417 inhibits the growth of the anthrax bacillus. Gottbrecht also found that both ammonia and carbonate of ammonia have decided antiseptic properties. Rigler has proposed to use ammonia gas for the disinfection of rooms, and concluded from his experiments that it is a reliable disinfectant when used in the proportion of 1 kgm. of aqua ammonia, exposed in shallow vessels, for every one-hundred cubic feet of space. Moreno, who conducted a series of experiments in the laboratory of the University of Turin, was not able to confirm Rigler as to the value of this agent for practical use in infected apartments, and it is no doubt much inferior to formaldehyd and probably of less value than sulphur dioxid.

Ammonium Chloride.—A five-per-cent. solution failed in twenty-five days to destroy the vitality of anthrax spores (Koch).

Ammonium Sulphate.—A five-per-cent. solution was effective in five days, but failed in two days to destroy anthrax spores (Koch).

Aromatic Products of Decomposition.—Klein has tested the germicidal power of *phenyl proprionic* and of *phenyl acetic* acid. He finds that anthrax spores resist both of these acids in the proportion of 1 to 400 after two days' exposure; but anthrax bacilli, in the absence of spores, are quickly killed by a solution of this strength. Certain non-pathogenic micrococci were not killed by exposure for twenty-five minutes to a solution of 1 to 200. Exposure for ninety-six hours to these acids, in the proportion of 1 to 200, did not prevent the caseous matter of pulmonary tuberculosis from infecting guinea-pigs; 1 to 800 was effective in destroying the virulence of swine-plague virus.

Arsenious Acid.—A one-per-cent. solution destroyed the vitality of anthrax spores in ten days, but failed to do so in six days (Koch). The infective power of tuberculous sputum, as shown by inoculation into guinea-pigs, is not destroyed by twenty hours' exposure to a one-per-cent. solution.

Benzol.—Exposure for twenty days failed to destroy the vitality of anthrax spores (Koch).

Benzoic Acid.—This agent was found by De la Croix to destroy the bacteria of broken-down beef-tea in the proportion of 1 to 77, while 1 to 121 failed. A saturated aqueous solution failed to destroy anthrax spores in seventy days (Koch).

Boric Acid (boracic acid).—In the writer's experiments a saturated solution failed to destroy any of the test organisms—two species of micrococci and *B. termo.* A five-per-cent. solution failed in ten days to destroy anthrax spores (Koch). According to Arloing, Cornevin, and Thomas, the activity of the *fresh* virus of symptomatic anthrax is destroyed by 1 in 5 (twenty per cent.), the time of exposure being forty-eight hours.

The experiments of Pome and of Rideal show, also, that boric acid has no value as a germicide.

Bromine.—A two-per-cent. aqueous solution destroys the vitality of anthrax spores in twenty-four hours (Koch). Fischer and Proskauer have studied the action of bromine vapor upon various micro-organisms. They find that exposure for three hours, in a dry atmosphere, to three per cent. does not destroy the tubercle bacillus in sputum, or the spores of anthrax. But when the atmosphere is saturated with moisture 1 part in 500 is effective, and when the time of exposure is extended to twenty-four hours, 1 part in 3,500. Bromine vapor is the most active agent for the destruction of the virus of symptomatic anthrax (Arloing, Cornevin, and Thomas). It destroys the ferment of sour milk (*Bacterium lactis*) in the proportion of 1 to 348 (Molke). The bacteria of broken-down beef-tea are destroyed by 1 to 336 (De la Croix).

Butyric Acid.—Five days' immersion in this acid failed to destroy the vitality of anthrax spores (Koch).

Calcium Chloride.—A saturated solution has no destructive action on anthrax spores (Koch.)

Calcium Hydroxide.—According to Kitasato, the typhoid bacillus and the cholera spirillum, in bouillon cultures, are killed in four or five hours by the addition of 0.1 per cent. of calcium oxide. Liborius had previously reported still more favorable results, but his bouillon cultures were largely diluted with distilled water. From a practical point of view the experiments of Pfuhl are more valuable. Calcium hydrate was added to the dejections of typhoid patients. When added in the proportion of three per cent. sterilization was effected in six hours, and by six per cent. in two hours. When milk of lime containing twenty per cent. of calcium hydrate was used the results were still more favorable, the typhoid bacillus and cholera spirillum being killed in one hour by the addition of two per cent. of the disinfectant. The germicidal value of lime wash applied to walls has been determined by Jäger, silk threads soaked in cultures of various pathogenic bacteria were attached to boards and the lime wash was applied with a camel's-hair brush. Anthrax bacilli (without spores), the glanders bacillus, Staphylococcus pyogenes aureus, and several other pathogenic bacteria, were killed by a single application in twenty-four hours, but the tubercle bacillus was not killed by three successive applications. In the writer's experiments (1885) the typhoid bacillus and Staphylococcus pyogenes aureus were killed in two hours by a solution containing 1 to 40 of calcium oxide and 1 to 80 failed. Spores of the anthrax bacillus, and of several other species forming spores, were not killed by two hours' exposure to a milk of lime containing twenty per cent. of calcium oxide.

Camphor.—Alcohol saturated with camphor has no effect upon the fresh virus of symptomatic anthrax (Arloing, Cornevin, and Thomas).

Carbolic Acid.—Tested upon anthrax spores, Koch found a one-per-cent. solution to be without effect after fifteen days' exposure; a two-per-cent. solution retarded the development of spores, but did not completely destroy their vitality in seven days; a three-per-cent. solution was effective in two days. In the absence of spores, Koch found that a one-per-cent. solution quickly destroys the vitality of anthrax bacilli. The same author recommends a five-per-cent. solution for the destruction of the "comma bacillus" in the discharges of cholera patients, and a two-per-cent. solution for the disinfection of surfaces and articles soiled by such discharges. The writer has found that, in the proportion of 1 to 200 this agent destroys *B. termo* and a septic micrococcus (*M. Pasteuri*) in active growth, while 1 to 25 failed to destroy the bacteria in broken-down beef-tea. A micrococcus obtained from the pus of an acute abscess was destroyed by 0.8 per cent., while 0.5 per cent. failed. In all of these experiments the time of exposure was two hours. According to Salmon, the micrococcus of swine plague multiplies abundantly in urine containing one per cent. of carbolic acid, while the micrococcus of fowl cholera is destroyed by six hours' exposure in a solution of this strength (one-per-cent.). A two-per-cent. solution destroys the bacterium of symptomatic anthrax (dried virus) in forty-eight hours (Arloing, Cornevin, and Thomas). The bacteria in broken-down beef-tea are not destroyed by a ten-per-cent. solution (De la Croix).

Davaine showed, by inoculation experiments, that anthrax bacilli in fresh blood are destroyed by being exposed to the action of a one-per-cent. solution for one hour. Solutions in oil and in alcohol have been shown by Koch to be less effective than aqueous solutions. Thus a five-per-cent. solution in oil failed to destroy the vitality of anthrax spores in one hundred and ten days, and the same solution did not destroy the bacilli in the absence of spores in less than six days. A control experiment showed that olive oil alone was effective in the same time. A five-per-cent. solution in alcohol did not destroy anthrax spores in seventy days. Schill and Fischer found that the infecting power of tuberculous sputum, as shown by inoculation into guinea-pigs, is destroyed by twenty-four hours' exposure to a five-per-cent. solution. The same result was obtained with a three-per-cent. solution, while one and two-per-cent. solutions failed.

Behring (1890) reports that the bacillus of typhoid fever, of diphtheria, and of glanders, the spirillum of cholera and streptococci are destroyed in a few hours by a 0.5-per-cent. solution and in one minute by a 1.5-per-cent. solution. Staphylococci are more resistant and require a solution of from two to three per cent. The germicidal value of carbolic acid is increased by the addition of mineral acids to disinfecting solutions (Laplace), by sodium chloride (Scheurlen), and by heat.

Carbonic Oxide.—This gas has no effect upon bacteria, which freely develop in it (Hamlet).

Chloral Hydrate.—In the writer's experiments this agent was found to destroy micrococci in the proportion of twenty per cent., and to fail in ten-per-cent. solution, the time of exposure being two hours.

Chlorine.—Fischer and Proskauer have made an elaborate research with reference to the germicidal power of this agent, as tested by a variety of micro-organisms. In the absence of moisture these experimenters found that desiccated anthrax spores were not destroyed by exposure for an hour in an atmosphere containing 44.7 per cent. of this gas. When, however, the spores were moistened, an exposure for one hour in a *moist* atmosphere containing four per cent. of chlorine was effective, and by extending the time to three hours one per cent. sufficed to destroy the vitality of the spores. The anthrax bacillus, in the absence of spores, was killed by exposure in a moist atmosphere containing 1 part in 2,500, the time of exposure being twenty-four hours, and the same amount was effective for *Micrococcus tetragenus;* while the micrococcus of erysipelas and the micrococcus of fowl cholera were killed by 1 to 25,000 in twenty-four hours, and 1 to 2,500 in three hours. The bacillus of mouse septicæmia was destroyed in one hour by 1 to 200, and the same proportion was effective for the tubercle bacillus in sputum. In the writer's experiments, made in 1880, the bacteria present in urine which had been freely exposed to the air and had become putrid were destroyed by exposure for one hour in an atmosphere containing 1 to 400. Koch found that after immersion for twenty-four hours in chlorine water, anthrax spores do not develop in a suitable culture medium. Chlorine destroys the fresh virus of symptomatic anthrax, but is powerless against that which has been dried (Arloing, Cornevin, and Thomas). The bacteria of broken-down beef-tea are destroyed by 1 to 1,061 (De la Croix).

Chloride of Lime.—(See *Hypochlorites*).

Chloroform.—Immersion for one hundred days in chloroform does not destroy anthrax spores (Koch). This agent is without effect upon the virus of symptomatic anthrax (Arloing, Cornevin, and Thomas). One part to 1.22 failed to destroy the bacteria of broken-down beef-tea (De la Croix).

The more recent (1894) experiments of Behring show that in the absence of spores this agent quickly destroys bacilli and micrococci. He reports that in his experiments the cholera spirillum was destroyed by a one-per-cent. solution in less than a minute and the typhoid bacillus by a one-half-per-cent. solution in an hour.

Chromic Acid.—An aqueous solution of 1 to 100 does not destroy the spores of anthrax in two days (Koch).

Citric Acid.—In the writer's experiments upon micrococci from the pus of an acute abscess, twelve per cent. was effective and ten per cent. failed. Abbott reports that twenty-five per cent. failed to destroy the organisms in broken-down beef-tea, and the spores of *B. subtilis* and *B. anthracis*, but that 1.25 per cent. was active in the case of micrococci.

Creolin.—This is a mixture of the cresols emulsified with hard soap. According to Behring its germicidal value is considerably greater than that of carbolic acid, except when albumen is present in the material to be disinfected.

Creosote.—This agent was found by the writer to be fatal to micrococci in the proportion of 1 to 200. In the proportion of one per cent. it failed, after twenty hours' exposure, to destroy the tubercle bacillus in sputum (Schill and Fischer).

According to Yersin a saturated aqueous solution does not destroy the tubercle bacillus in cultures in twelve hours. Guttman in extended experiments upon various pathogenic organisms found that a solution of 1 to 300 is fatal to Bacillus pyocyaneus and to B. anthracis in one minute, and that 1 to 600 destroys the Finkler-Prior spirillum in the same time.

Cresol.—This is a coal-tar product obtained by the fractional distillation of crude carbolic acid. There are three forms, known as ortho-, meta-, and paracresol. A mixture of these is largely used for disinfecting purposes under the name of tricresol. A solution of cresol of 0.5 per cent. is said to be as efficient as a germicide as a two- or three-per-cent. solution of carbolic acid (Hammer). Neutral solutions are non-irritating. According to Gruber the germicidal value of the cresols is but little influenced by the presence of albumen. He found cresol to be three times as potent as carbolic acid for the destruction of Staphylococcus pyogenes aureus. The cresols are considerably less toxic than carbolic acid.

Cupric Sulphate.—This salt failed, in the writer's experiments, to destroy the spores of *B. anthracis* and of *B. subtilis* in two hours' time in a twenty-per-cent. solution. Arloing, Cornevin, and Thomas report that the dried virus of symptomatic anthrax is destroyed in forty-eight hours by a twenty-per-cent. solution. In Koch's experiments a five-per-cent. solution failed to destroy anthrax spores in ten days. The writer has found, however, that this salt is effective in the proportion of 1 to 200 for the destruction of micrococci, the time of exposure being two hours.

Ether.—Anthrax spores may germinate after being immersed in ether for eight days, but thirty days' exposure is effective for the destruction of these spores (Koch).

Eucalyptol.—The bacteria in broken-down beef-tea are not destroyed by 1 to 14 (De la Croix).

Ferrous Sulphate.—In the writer's experiments, reported in the *American Journal of the Medical Sciences* (April, 1883), a solution of twenty per cent. of this salt failed to destroy micrococci and the bacteria in broken-down beef-tea. In more recent experiments a ten-per-cent. solution was found to be fatal to *Micrococcus tetragenus*, but failed in the case of another micrococcus obtained from the pus of an acute abscess. Koch found that a five-per-cent. solution did not destroy anthrax spores in six days. According to Arloing, Cornevin, and Thomas, exposure to a twenty-per-cent. solution for forty-eight hours does not destroy the virus of symptomatic anthrax.

Ferri Chloridi Tinct.—In the writer's experiments a four-per-cent. solution was fatal to micrococci, and a two-per-cent. solution failed.

Ferric Chloride.—A five-per-cent. solution failed in two days to destroy anthrax spores, but was effective in six days (Koch).

Formaldehyd.—The experiments of Aronson (1892), Lehmann (1894), Philipp (1895), Rosenberg (1897), and others have demonstrated the germicidal value of formaldehyd. A forty-per-cent. solution of this gas in water is known under the name of formalin. According to Ascoli (1895) anthrax bacilli are killed in fifteen minutes by a ten-per-cent. solution of formalin and anthrax spores in five hours by the same solution. A five-per-cent. solution destroyed the diphtheria bacillus in ten minutes and Staphylococcus aureus in thirty minutes. Formaldehyd gas in the proportion of 1 to 100 in the air of a flask was found to destroy Staphylococcus aureus in forty-five minutes, and the micrococcus of pneumonia in fifteen minutes. Wilson (1897) and others have shown that the germicidal action of formaldehyd is considerably greater at a temperature of 37° C. and above than it is at a low temperature.

Formic Acid.—This acid, of the specific gravity of 1.120, failed in two days to destroy anthrax spores, but was effective in four days.

Gallic Acid.—Abbott finds this acid to be effective for the destruction of the organisms in broken-down beef-tea in the proportion of 2.375 per cent.; tested upon the spores of the anthrax bacillus and of *B. subtilis*, it failed in this proportion, the time of exposure being two hours. Micrococci were destroyed by 0.7 per cent., while 0.4 per cent. (1 to 250) failed.

Glycerin has no action upon the fresh virus of symptomatic anthrax (Arloing, Cornevin, and Thomas); and is inert as regards the spores of bacilli (Koch).

Heat.—(*a*) Dry heat. Werner, in 1879, found that putrefactive bacteria enveloped in dry cotton were destroyed by exposure for one hour to a temperature of 125° C. (257° F.). Wernich also experimented upon the bacteria of putrefaction, and found that exposure for five minutes to a temperature of 125° to 150° C. secured their destruction. The virulence of dried tuberculous sputum is not destroyed with certainty by exposure for one hour to 100° C. (Schill and Fischer).

Koch and Wolffhügel, as the result of an elaborate series of experiments, arrive at the following conclusions:

1. A temperature of 100° C. (212° F., dry heat), maintained for an hour and an half, will destroy organisms which do not contain spores.
2. Spores of mould fungi require for their destruction in hot air a temperature of from 110° to 115° C. (230° to 239° F.), maintained for an hour and a half.
3. Bacillus spores require for their destruction in hot air a temperature of 140° C. (284° F.), maintained for three hours.

(*b*) Moist heat. Davaine, in 1873, showed that the virulence of fresh anthrax blood which does not contain spores is destroyed by a temperature of 55° C. (131° F.), maintained for five minutes; or by 50° C. (122° F.) for ten minutes; or by 48° C. (118° F.) for fifteen minutes. The writer has fixed the thermal death point of several species of bacilli and micrococci at 60° C. (140° F.), the time of exposure being ten minutes. This temperature is also fatal to the micrococcus of swine plague, while the micrococcus of fowl cholera is destroyed by exposure for fifteen minutes to a temperature of 132° F. (Salmon). The destruction of spores is a very different matter, and requires a boiling temperature, maintained, in the case of some of these reproductive bodies, for several hours. But a temperature of 5° C. above the boiling point quickly destroys the most refractory spores. Thus the writer has found, as the result of repeated experiments, that this temperature—105° C. (221° F.)—maintained for ten minutes, is fatal to the spores of *B. subtilis*, and that the same temperature in two minutes' time destroyed the vitality of anthrax spores. Koch, Gaffky, and Loeffler also report that a temperature of 105° C. and upward, maintained for ten minutes, is fatal to all spores, as shown by their failure to develop in culture solutions. Where a temperature of 110° C. was reached, the experiment could be stopped, as no spores were capable of germinating after exposure to this temperature.

The tubercle bacillus is destroyed by a temperature of 70° C. maintained for ten minutes.

Hydrochloric Acid.—In experiments upon broken-down beef-tea, the writer found this acid to be effective in the proportion of fifteen per cent., and to fail at ten per cent. (two hours' exposure). One part in two hundred was found to destroy the virulence of septic blood (rabbit septicæmia), as proved by inoculation experiments. Anthrax spores are destroyed in ten days by a two-per-cent. solution, but not in five days (Koch).

In the experiments of Kitasato this acid in the proportion of 0.2 per cent. destroyed the typhoid bacillus in five hours. Boer found that the typhoid bacillus was destroyed by 1 to 300 in two hours, the diphtheria bacillus by 1 to 700, and the cholera spirillum by 1 to 1,350.

Hydrogen.—Bacteria may develop in an atmosphere of hydrogen (Hamlet).

Hydrogen Peroxide.—In the writer's experiments, a solution containing 3.98 per cent. of H_2O_2 was found to destroy the organisms in broken-down beef-tea in the proportion of thirty per cent. The same solution failed in twenty per cent. Tested upon a pure culture of *B. anthracis* containing spores, the same solution was effective at twenty per cent. (0.8 per cent. $H_2O_2=1$ to 125), and failed at ten per cent. Tested upon micrococci, ten per cent. was effective, and five per cent. failed. The solution used in these experiments contained five per cent. of sulphuric acid, and the germicidal power of this agent must be considered in estimating their value as determining the effect of H_2O_2 upon the vitality of the test organisms.

Gibier (1890) reports that solutions containing 1.5 per cent. of hydrogen peroxide destroy the anthrax bacillus, the bacillus of typhoid fever, Streptococcus pyogenes, and various other bacteria in a few minutes. Pave found that this agent in a one-per-cent. solution destroys spores in one hour and staphylococci in from ten to fifteen minutes.

Hypochlorites of Lime and of Soda.—Commercial chloride of lime contains from twenty to thirty per cent. of available chlorine, and Labarraque's solution of good quality from two to three per cent. According to Duggan, a solution containing 0.25 of one per cent. (1 to 400) of chlorine as hypochlorite is an effective germicide, even when allowed to act only one or two minutes, while 0.06 of one per cent. (6 to 10,000) will kill spores of *B. anthracis* and *B. subtilis* in two hours. These results are not in accord with those of Koch, who reports that a five-per-cent. solution of chloride of lime (value in available chlorine not given) failed in two days to destroy the vitality of anthrax spores, but was effective in five days. The development of the spores was, however, retarded by one day's exposure.

Indol.—When added to water in excess, failed in eighty days to destroy anthrax spores (Koch).

Iodine.—In the writer's experiments, iodine in aqueous solution with potassium iodide was found to be fatal to the micrococcus of rabbit septicæmia in the proportion of 1 to 1,000, and to a micrococcus obtained from the pus of an acute abscess in 1 to 500. De la Croix reports that 1 to 410 destroys the bacteria of broken-down beef-tea. Salmon found 1 to 1,000 to be fatal to the micrococcus of fowl cholera. "Iodine water" was found by Koch to destroy the vitality of anthrax spores in twenty-four hours. The same author reports that exposure for forty-eight hours to a two-per-cent. solution of iodine in alcohol failed to destroy anthrax spores, but that exposure in such a solution for five days was effective. In the experiments of Schill and Fischer, twenty hours' contact with a solution of the strength of 1 to 500 failed to destroy the virulence of tuberculous sputum, as tested by inoculation experiments.

Iodine Trichloride.—The germicidal value of this agent has been established by the experiments of Riedel (1887), of Behring (1890), and of Traugott (1893). The last-mentioned bacteriologist reports that a one-per-cent. solution will destroy in one minute the bacillus of typhoid fever and of diphtheria, the cholera spirillum, Streptococcus pyogenes and staphylococci.

Iodoform.—Dissolved in oil, in the proportion of five per cent., iodoform failed in an hour and a half to destroy tubercle bacilli in fresh sputum. A saturated solution in water also failed after twenty-four hours' contact; as did also a five-per-cent. solution in oil of turpentine (an hour and a half's exposure). No better results were obtained in an experiment in which the material was exposed for twenty hours to dry iodoform vapor, but in the presence of moisture dried sputum was disinfected in two hours. Mixing the sputum with moistened iodoform was also effective after twenty-four hours' contact (Schill and Fischer).

Iodol.—The writer has made experiments which show that bacteria are not destroyed by adding iodol in excess to culture solutions—probably because it is quite insoluble.

Labarraque's Solution.—(See *Hypochlorites.*)

Lactic Acid.—A five-per-cent. solution failed in five days to destroy anthrax spores (Koch). Abbott reports that a twenty-per-cent. solution of concentrated lactic acid (specific gravity 1.21) was effective for the destruction of the bacteria in broken-down beef-tea and the spores of *B. subtilis*, while fifteen per cent. failed. Upon anthrax spores lactic acid of the same strength failed in the proportion of fifty per cent. Micrococci were destroyed by a one-per-cent. solution, while 0.5 per cent. failed; time of exposure in these experiments, two hours. The bacillus of typhoid fever is killed in five hours by 0.4 per cent., the cholera spirillum by 0.3 per cent. (Kitasato).

Mercuric Chloride.—Koch's experiments (1881) gave the following results: A solution of 1 to 1,000 destroys anthrax spores in a few minutes, and 1 to 10,000 is effective after a more prolonged exposure. The writer (1884) obtained similar results—1 to 10,000 destroyed the spores of Bacillus anthracis and of Bacillus subtilis in two hours. More recent experiments indicate that failure to grow in culture solutions cannot be accepted as evidence of the destruction of vitality in the case of spores exposed to the action of this agent, unless due precautions are taken to exclude the restraining influence of the small amount of mercuric chloride which remains attached to the spores. Koch had ascertained that the development of spores is restrained by the presence of 1 to 300,000 in a culture medium, and Geppert has shown that even so small an amount as 1 to 2,000,000 will prevent the development of spores, the vitality of which has been reduced by the action of a strong solution (1 to 1,000). When this restraining action is entirely neutralized by washing the spores in a solution containing ammonium sulphide it requires, according to Geppert, a solution of 1 to 1,000 acting for one hour completely to destroy the vitality of anthrax spores. Fränkel found that a solution of 1 to 1,000 was effective in half an hour. The typhoid bacillus, the bacillus of mouse septicæmia, and the cholera spirillum, in bouillon cultures and in cultures in flesh-peptone-gelatin, are destroyed in two hours by 1 to 10,000; but in a bouillon culture to which ten per cent. of dried egg albumen was added a one-per-cent. solution was required to destroy the typhoid bacillus in the same time (Bolton). According to Van Ermengem, cultures of the cholera spirillum in bouillon are sterilized in half an hour by 1 to 60,000, but cultures in blood serum require 1 to 800 to 1 to 1,000. In experiments upon tuberculous sputum, Schill and Fischer found that exposure of fresh sputum to an equal amount of a 1 to 2,000 solution for twenty-four hours failed to disinfect it, as shown by inoculation experiments in guinea-pigs. The antiseptic power of mercuric chloride is given by Miquel as 1 to 14,300. In the writer's experiments 1 to 33,000 was found to prevent the development of putrefactive bacteria in bouillon, but a minute bacillus contained in broken-down beef infusion multiplied, after several days, in 1 to 20,000. The pus cocci were restrained in their development by 1 to 30,000.

In Behring's experiments the anthrax bacillus and cholera spirillum were killed in one hour by 1 to 100,000 when the temperature was 36° C., but at a temperature of 3° C. the proportion required was 1 to 25,000. The same author states that at 22° C. Staphylococcus aureus in bouillon is not always killed in twenty-five minutes by 1 to 1,000.

Abbott (1891) has shown that a 1 to 1,000 solution does not always destroy Staphylococcus pyogenes aureus in five minutes. He says: "Frequently all the organisms would be destroyed after five minutes' exposure, but almost as often a certain few would resist for that length of time, and even longer, going in some cases to ten, twenty, and even thirty minutes."

According to Yersin, a solution of 1 to 1,000 kills the tubercle bacillus in one minute.

The albuminate of mercury, as has been shown by Lister, is soluble in an excess of albumin, and, according to Behring, is just as effective as an aqueous solution containing the same amount of sublimate when dissolved in an albuminous liquid like blood serum (?).

In practice the addition of a mineral acid to sublimate solutions, or of sodium, potassium, or ammonium chloride, is to be recommended, to prevent the precipitation of the mercuric chloride by albumin in fluids containing it. Behring recommends the addition of five parts of sodium or potassium chloride to one of the sublimate. Such a solution is more stable than a simple solution of sublimate, and no precipitate is formed by the addition of alkalies or by albumin.

The same result is obtained, according to La Place, by the addition of five parts of hydrochloric or tartaric acid to one part of sublimate in aqueous solution.

Viquerat (1889) has made a comparative study of the germicidal value of mercuric chloride and mercuric iodide. The last-mentioned salt was found to be least efficient. A solution of 1 to 1,000 of bichloride killed the anthrax bacillus and the typhoid bacillus in five minutes; the same proportion of the biniodide required fifteen minutes to destroy these bacilli.

Mercuric Cyanide, $Hg(CN)_2$, and the *oxycyanide* of mercury have been tested, with the following results: Staphylococcus aureus is destroyed in five minutes by 1 to 100, in one hour by 1 to 1,000, in two hours by 1 to 1,500 (Chibret). The development of Bacillus anthracis in culture solutions is prevented by the presence of cyanide of mercury in the proportion of 1 to 25,000, and by the oxycyanide by 1 to 16,000 (Behring).

Boer obtained the following results with the oxycyanide —cultures in bouillon, twenty-four hours in incubating oven, time of exposure two hours:

	Restrained development.	Destroyed vitality.
Anthrax bacillus	1 to 80,000	1 to 40,000
Diphtheria bacillus	1 to 80,000	1 to 40,000
Glanders bacillus	1 to 60,000	1 to 30,000
Typhoid bacillus	1 to 60,000	1 to 30,000
Cholera spirillum	1 to 90,000	1 to 60,000

Nitric Acid.—This acid, in the proportion of 1 to 400, was found by the writer to neutralize the virulence of septic blood (rabbit septicæmia). In the proportion of eight per cent. it destroys the organisms in broken-down beef-tea, but failed at five per cent.

Kitasato reports that in the proportion of 0.2 per cent. the vitality of the typhoid bacillus and of the cholera spirillum is destroyed in four or five hours.

Nitrous Acid.—Exact experiments to determine the germicide value of this agent are wanting. The writer has tested it upon vaccine virus, and found that exposure for six hours, in an atmosphere containing one per cent., destroys the virulence of this material dried upon ivory points.

Oil.—Anthrax spores germinate after having been immersed for ninety days in pure olive oil (Koch).

Oil of Cinnamon.—According to Behring, oil of cinnamon is about three times as potent a germicide as carbolic acid. Omaltschenko (1891) has made extended experiments to determine the germicidal value of essential oils and places oil of cinnamon at the head of the list.

Oil of Mustard.—According to De la Croix, 1 to 40 destroys the bacteria of broken-down beef-tea. Koch found that ten days' immersion in an aqueous solution of this oil is not fatal to anthrax spores, but that in the proportion of 1 to 33,000 it restrains their development.

Oil of Peppermint.—A five-per-cent. solution in alcohol failed in twelve days to destroy anthrax spores, but the development of these spores is restrained by 1 to 33,000 (Koch).

Oil of Turpentine destroys anthrax spores in five days, but failed to do so in one day (Koch). Turpentine has no action upon the virus of symptomatic anthrax (Arloing, Cornevin, and Thomas). Koch has shown that the development of anthrax spores is retarded by 1 to 75,000.

Oleic Acid.—A solution of five per cent. in ether does not destroy anthrax spores in five days (Koch).

Osmic Acid.—A solution of one per cent. destroys anthrax spores in one day (Koch). No report with reference to weaker solutions.

Oxalic Acid.—This acid in saturated solution destroys the virulence of the fresh virus of symptomatic anthrax, but has no effect upon dried virus (Arloing, Cornevin, and Thomas). Abbott reports that this acid in five-per-cent. solution failed, in two hours, to destroy anthrax spores. But the spores of *B. subtilis* were killed by a one-per-cent. solution, and the organisms in broken-down beef-tea by 1.5 per cent. Micrococci resisted exposure for two hours to 1 to 1,000, but were destroyed by 1 to 400.

Oxygen.—The experiments of Pasteur upon the attenuation of virus show that long exposure to the oxygen of the atmosphere reduces the reproductive activity of the micrococcus of fowl cholera and of the anthrax bacillus, and that after a time the vitality of these organisms is destroyed. The spores of the anthrax bacillus are, however, unaffected by prolonged exposure. Paul Bert has shown that oxygen under pressure is fatal to bacteria.

Ozone.—The experiments of Chappius show that atmospheric organisms, collected upon a cotton filter, are destroyed by passing through this cotton filter, placed in a tube, a current of ozonized air.

Lukaschewitsch found in his experiments that 1 gm. in a cubic metre of air failed to kill anthrax spores in twenty-four hours. The cholera spirillum in a moist state was killed by this amount in twenty-four hours, but not in fifteen hours. Sonntag, in carefully conducted experiments, found that ozonized air passed over silk threads to which various pathogenic bacteria were attached failed to destroy these bacteria in twenty-four hours when the proportion of ozone was 4.1 mgm. per litre; when the amount was increased to 13.53 mgm. per litre the anthrax bacillus and Staphylococcus pyogenes albus failed to grow after twenty-four hours' exposure.

Picric Acid.—The bacteria of broken-down beef-tea are destroyed by 1 to 100 (De la Croix).

Potassium.—In the writer's experiments, caustic potash in the proportion of two per cent. was fatal to the micrococcus of rabbit septicæmia in one experiment, and failed in a second; eight per cent. failed to kill a micrococcus from pus, while ten per cent. was successful; ten per cent. failed to destroy the bacteria in broken-down beef-tea, and twenty per cent. was successful. Exposure to the action of a ten-per-cent. solution for twenty-four hours failed to destroy the tubercle bacillus in fresh sputum (Schill and Fischer).

According to Jäger 0.18 per cent. of potassium hydroxide kills the typhoid bacillus in four or five hours. The cholera spirillum is destroyed by 0.237 per cent. added to cultures (Kitasato).

Potassium Acetate.—A saturated solution of this salt failed to destroy anthrax spores in ten days (Koch).

Potassium Arsenite (Fowler's solution of).—In the writer's experiments this solution, in the proportion of forty per cent., failed to destroy micrococci from pus.

Potassium Bichromate.—A five-per-cent. solution failed in two days to destroy anthrax spores (Koch).

Potassium Bromide is without germicidal power.

Potassium Chlorate has no germicidal power. In the writer's experiments a four-per-cent. solution failed to destroy the micrococcus of rabbit septicæmia. A five-per-cent. solution failed in six days to destroy anthrax spores (Koch).

Potassium Chromate.—A five-per-cent. solution was without effect upon anthrax spores immersed in it for two days (Koch).

Potassium Iodide.—A solution of five per cent. does not destroy anthrax spores in eighty days (Koch). In the writer's experiments, exposure for two hours to the action of a saturated solution did not prevent the subsequent development of the organisms in broken-down beef-tea.

The cholera spirillum and the typhoid bacillus are destroyed by five hours' exposure in a solution containing 9.23 per cent. (Kitasato).

Potassium Nitrate.—A four-per-cent. solution was found by the writer to be without effect upon the micrococcus of rabbit septicæmia in fresh blood.

Potassium Permanganate.—The writer, in experiments with this agent, found that a two-per-cent. solution was required to destroy *M. Pasteuri* in the blood of a rabbit, but that a micrococcus from pus was killed by 1 to 833—time of exposure two hours. This difference depends upon the fact that the permanganate is quickly decomposed by the large amount of organic material in the blood used in the first experiments, and not upon a difference in resisting power in the two test organisms.

Further experiments showed that, in the absence of organic matter, micrococci are destroyed in two hours by solutions containing 1 to 1,000. Equal parts of a solution of 1 to 250 and of broken-down beef infusion, proved to be without effect. Anthrax spores were not destroyed by the same solution (1 to 250) in four hours, but in another experiment, in which the time was extended to four days, they failed to germinate. The spores of *B. subtilis*, however, were destroyed in two hours by a solution of 1 to 250. According to Arloing, Cornevin, and Thomas, a five-per-cent. solution destroys the fresh virus of symptomatic anthrax, but has no effect upon the dried virus. One per cent. was found by Koch not to destroy anthrax spores in two days, but five per cent. was effective in one day.

The glanders bacillus is destroyed in two minutes by a one-per-cent. solution (Löffler). The experiments of Jäger show that a one-per-cent. solution cannot be relied upon for the destruction of various pathogenic bacteria used as a test, but a five-per-cent. solution was effective for all except the tubercle bacillus.

Quinine.—One per cent., *dissolved with muriatic acid*, destroys the spores of anthrax in ten days' time (Koch). A ten-per-cent. solution of sulphate of quinine has no action upon the bacterium of symptomatic anthrax (Arloing, Cornevin, and Thomas). The writer has found that in the proportion of 1 to 800 to 1 to 1,000 quinine prevents the development of bacilli and micrococci, but its exact germicidal power for organisms of this kind, in the absence of spores, has not been determined.

Salicylic Acid.—In the writer's experiments this reagent was dissolved by means of sodium biborate, which by itself has no germicidal power. A two-per-cent. solution was found to destroy a micrococcus from pus and *B. termo* in active growth; four per cent. failed to destroy the bacteria in broken-down beef infusion. The virus of symptomatic anthrax is destroyed by forty-eight hours' exposure to a solution of salicylic acid of 1 to 1,000, and by a saturated solution in alcohol (Arloing, Cornevin, and Thomas). Salicylic acid dissolved in oil and in alcohol, in five-per-cent. solution, does not destroy anthrax spores (Koch); 1 to 200 destroys the bacteria of sour milk (Molke); 1 to 343 destroys the bacteria in broken-down beef infusion (De la Croix).

A solution of 2.5 per cent. kills the tubercle bacillus in six hours (Yersin). In the proportion of 1 to 300 it destroys the cholera spirillum in half an hour (Van Ermengem).

Skatol in excess in water has no germicidal action as tested upon anthrax spores (Koch).

Soda.—Caustic soda destroys the fresh virus of symptomatic anthrax in the proportion of 1 to 5, but has no effect upon dried virus (Arloing, Cornevin, and Thomas). A ten-per-cent. solution destroys the tubercle bacillus in dried sputum after twenty-four hours' contact (Schill and Fischer).

The experiments of Jäger show that sodium hydroxide has about the same germicidal value as caustic potash. Boer obtained the following results, the time of exposure being two hours: anthrax bacillus 1 to 450; diphtheria bacillus 1 to 300, glanders bacillus 1 to 150, typhoid bacillus 1 to 190, cholera spirillum 1 to 150.

Sodium Biborate.—In the writer's experiments a saturated solution was found to have no germicidal power. A twenty-per-cent. solution does not destroy the virus of symptomatic anthrax, as proved by inoculation experiments (Arloing, Cornevin, and Thomas); 1 to 12 failed to kill the bacteria in broken-down beef infusion (De la Croix). A five-per-cent. solution failed in fifteen days to destroy the vitality of anthrax spores (Koch).

Sodium Chloride.—In the writer's experiments a five-per-cent. solution failed to destroy the virulence of septicæmic blood. A saturated solution failed in forty-eight hours to destroy the virus of symptomatic anthrax (Arloing, Cornevin, and Thomas). A saturated solution failed, in forty days, to destroy the vitality of anthrax spores (Koch). A saturated solution failed, in twenty hours, to destroy the tubercle bacillus in fresh sputum (Schill and Fischer).

Sodium Hyposulphite.—The writer's experiments show this salt to be without germicidal power. In saturated solution it failed, in two hours' time, to destroy any of the test organisms. Exposure for forty-eight hours to a fifty-per-cent. solution does not destroy the virus of symptomatic anthrax (Arloing, Cornevin, and Thomas).

Sodium Sulphite.—The results obtained by the writer correspond with those reported in the case of sodium hyposulphite, being entirely negative.

Stannous Chloride.—Abbott reports that this agent is active in the proportion of one per cent. and failed in 0.8 per cent., the test being the organisms in broken-down beef infusion, and time of exposure two hours.

Sulphuric Acid.—In the writer's experiments this acid was found to be fatal to micrococci in the proportion of 1 to 200; but a four-per-cent. solution failed to destroy the bacteria in broken-down beef infusion, doubtless on account of the presence of reproductive spores. An eight-per-cent. solution was, however, found to be effective (strength of acid, 1.480 gm. H_2SO_4 in each cubic centimetre). Salmon has found that a solution of 1 to 200 is fatal to the micrococcus of fowl cholera. A solution of one per cent. failed to destroy anthrax spores in forty days (Koch).

The experiments of Boer show a considerable difference in the resisting power of various pathogenic bacteria. The time of exposure being two hours, the anthrax bacillus was destroyed by 1 to 1,300, the diphtheria bacillus 1 to 500, the glanders bacillus 1 to 200, the typhoid bacillus 1 to 500, the cholera spirillum 1 to 1,300.

Sulphur Dioxide.—Wernich, in 1877, found that the bacteria of putrefaction are not destroyed by the presence of 3.3 volumes of sulphur dioxide in one hundred of air, when exposed upon strips of cotton or woollen goods saturated with putrid liquids. But four to seven per cent. was effective in six hours' time. Schotte and Gärtner, in 1880, found that strips of thick woollen goods soaked in culture liquids containing the bacteria of putrefaction were not disinfected by exposure in a chamber in which sulphur was burned in the proportion of 92 gm. per cubic metre (about six volumes per cent. of SO_2). Koch exposed various species of bacilli containing spores in a disinfection chamber for ninety-six hours, the amount of SO_2 at the outset of the experiment being 6.13 volumes per cent., and at the end of ninety-six hours 3.3 per cent. The results were entirely negative. The writer has also made numerous experiments which show that this agent is without power for the destruction of spores. Even when liquid SO_2 is poured upon the spores of anthrax or of *B. subtilis*, they germinate freely when transferred to a suitable culture medium. But this agent, especially in the presence of moisture, destroys micrococci and bacilli which do not contain spores. Thus, Koch found that the anthrax bacillus obtained from the spleen of a mouse recently dead, and exposed, while still moist, upon a silk thread, in an atmosphere containing one volume per cent. of SO_2, was destroyed in thirty minutes. In one of Koch's experiments the amount of SO_2 in the disinfection chamber was at the outset 0.84 per cent., and at the end of twenty-four hours 0.55 per cent. An exposure of one hour, in this experiment, destroyed anthrax bacilli (still moist) upon silk thread. Four hours' exposure failed to destroy the vitality of *Micrococcus prodigiosus* growing upon potato, but twenty-four hours' exposure was successful. The same result was obtained with the bacteria of blue pus. In experiments with an aqueous solution of SO_2, Koch found that five days' immersion in a solution containing 5.718 per cent. by weight was required to destroy the vitality of anthrax spores. A solution containing 11.436 per cent. by weight failed to kill anthrax spores in twenty-four hours, but was successful in forty-eight hours. According to Arloing, Cornevin, and Thomas, sulphur dioxide does not destroy the bacteria of symptomatic anthrax which contain spores. The writer's experiments show that micrococci are destroyed, even in the absence of moisture, when they are exposed for eighteen hours in a bell jar containing twenty volumes per cent. of SO_2. When the proportion was reduced to four volumes per cent. the result was not uniform, the test organisms—micrococci—were destroyed in some cases, and in others were not. In experiments with an aqueous solution of SO_2 the following results were obtained: The presence of 1 to 2,000, by weight, destroyed a micrococcus obtained from the blood of a patient with vaccinal erysipelas, and 1 to 4,000 failed; the same result was obtained with micrococci obtained from a vaccine vesicle, and with another species obtained from the blood of a patient having puerperal septicæmia.

Thoinot (1890) as a result of numerous experiments arrives at the conclusion that the bacillus of tuberculosis, of glanders, of diphtheria, of typhoid fever, and the spirillum of cholera are all destroyed by exposure for twenty-four hours in an atmosphere containing SO_2 developed by the combustion of sixty grains of sulphur per cubic metre of air space.

Sulphureted Hydrogen.—Bacteria develop readily in the presence of sulphureted hydrogen (Hamlet).

Sulpho-carbolates. — In experiments upon anthrax spores, Koch found that a five-per-cent. solution of sulpho-carbolate of zinc was effective in five days, while sulpho-carbolate of soda failed in five-per-cent. solution to destroy these spores after ten days' contact.

Tannic Acid.—The writer found, in his experiments, that a solution of one per cent. in half an hour is fatal to *M. Pasteuri* in the blood of a rabbit. A twenty-per-cent. solution has no effect upon the virus of symptomatic anthrax (Arloing, Cornevin, and Thomas). A five-per-cent. solution failed in ten days to destroy anthrax spores (Koch). A twenty-per-cent. solution failed in two hours to destroy the spores of *B. anthracis* or of *B. subtilis*, but was effective upon the organisms in broken-down beef-tea. Micrococci are destroyed by 1 to 400, while 1 to 800 failed (Abbott).

Tartaric Acid.—A twenty-per-cent. solution was found by Abbott to be effective, in two hours, for the destruction of organisms in broken-down beef infusion, but the same proportion failed with anthrax spores and with those of *B. subtilis.* Micrococci did not multiply in culture solutions, after exposure to 0.25 per cent., but one-half this amount (1 to 800) failed.

Thymol.—An alcoholic solution of 1 to 400 was found by the writer to destroy *M. Pasteuri* in fresh blood. One part in twenty is fatal to the bacteria in broken-down beef infusion (De la Croix). A five-per-cent. solution in alcohol does not destroy anthrax spores in fifteen days, but the development of these spores is retarded by a solution of 1 to 80,000 (Koch).

The tubercle bacillus is destroyed by contact with thymol for three hours (Yersin). Thymol has about four times less germicidal power than carbolic acid (Behring).

Valerianic Acid.—A five-per-cent. a solution in ether failed in five days to destroy anthrax spores (Koch).

Zinc Chloride.—In the writer's experiments, *M. Pasteuri* failed to develop after exposure for two hours to 1 to 200, while a micrococcus obtained from gonorrhœal pus required for its destruction a solution of two per cent. The spores of *B. anthracis* are not destroyed by two hours' exposure in a ten-per-cent. solution. A five-per-cent. solution was, however, found to be effective in the same time in the case of *B. subtilis* spores, and upon the organisms in putrid beef-peptone solution. Koch's experiments are in accord with the above, in showing the superior resisting power of anthrax spores. He found that after being immersed in a five-per-cent. solution for thirty days, these spores still germinated freely. The development of *M. prodigiosus* was found by the same author to be only slightly retarded by exposure for more than sixteen hours to the action of a one-per-cent. solution.

Zinc Sulphate.—In the writer's first experiments with this agent, a solution of twenty per cent. failed in two hours to destroy micrococci obtained from the pus of an acute abscess. In later experiments a micrococcus from the same source resisted exposure for the same time to a ten-per-cent. solution, while *M. tetragenus* was destroyed by a 1 to 10 solution. Broken-down beef infusion, mixed with an equal quantity of a forty-per-cent. solution, was not sterilized after two hours' contact. In Koch's experiments anthrax spores were found to germinate after having been immersed for ten days in a five-per-cent. solution. *George M. Sternberg.*

GERM LAYERS.—It has long been known that the bodies of embryos consist of distinct layers, which in many cases are separable from one another, so as to be recognized in gross as discrete membranes. It is now known that all such layers may be reduced to three primitive ones, named the ectoderm, mesoderm, and entoderm (by certain writers, epiblast, mesoblast, and hypoblast). The ectoderm is a layer of epithelium; so also is the entoderm; the mesoderm is more complex. In the lower animals, the mesoderm is less developed than in the higher forms; in the hydroids the body is constituted mainly by the two epithelial layers, the ectoderm covering the outside of the body, and the entoderm lining the digestive cavity; there is very little space between them, the space being occupied by the slightly developed mesoderm. As we ascend the scale the mesoderm increases gradually, constantly acquiring a greater predominance, until in mammals nearly the whole bulk consists of mesoderm. But, in spite of this change, the three layers are preserved throughout, and their essential relations are not altered, so that we are able to assert the unity of organization throughout the whole series of multicellular animals, without which it would be impossible to accept the doctrine of evolution. The demonstration, therefore, of the homologies of the germ layers, is the most important morphological generalization since the establishment of the cell doctrine. As these homologies have already been discussed under *Gastrula,* and also the metamorphoses of the layers under *Fœtus,* it only remains for us to review, with precision and brevity, the rôle of the layers in the construction of the human body.

The ectoderm covers the external surface of the body, and persists in adult life as the stratified epithelium (epidermis) of the skin; it forms, of course, all the so-called epidermal structures—hairs, nails, sebaceous and sweat glands, lens, cornea, etc. It also lines part of the buccal cavity; and the buccal portion gives rise to the hypophysis cerebri, to the enamel organs of teeth, and probably to all the salivary glands. It forms a small invagination to meet the rectum, so that it also lines the anus. It gives rise to the entire nervous system by producing the medullary canal, which makes the central nervous system, and from which grow out all the nerves, and probably all the peripheral ganglia, and from which also grows out the evagination which makes the optic nerve, the retina, the choroid, and the epithelial portions of the iris. It forms the epithelium of the olfactory and nasal cavities, and the epithelium of the auditory labyrinth.

The entoderm [also spelled "endoderm"] forms the epithelium which lines the digestive tract, including the surface of the tongue; also the epithelium of the trachea and lungs, and of all the glands appended to the respiratory passages, and to the digestive tract, including the thyroid, pancreas, and liver. The liver cells, it should be remembered, constitute a true though much modified epithelium. The notochord is developed from the entoderm.

The mesoderm may be conveniently divided into three portions—the mesenchyma, the mesamœboids, and the mesothelium (*cf. Coelom*). 1. The *mesenchyma* produces all the connective tissues of the body, and includes therefore the cutis, the non-epithelial walls of the alimentary tract, etc.; tendons, cartilage, and bone, the marrow of bones, lymph glands, and spleen; it produces also the blood-vessels and blood, the entire lymphatic system proper, and the heart. Pigment cells, fat cells, and smooth muscles are derived from the mesenchyma also. 2. The *mesamœboids* include the leucocytes and wandering cells, and perhaps the embryonic red blood cells, and the marrow cells. 3. The *mesothelium* is the epithelium of the cœlom; it produces the peritoneal and pleural epithelia, the striated muscles (myotomes), except those of the heart, and all the non-mesenchymal tissues of the entire urogenital apparatus, except, of course, the external genitalia. (Spee traces the Wolffian duct to the ectoderm.)

Now, in classifying organs, it is best to rank them as belonging to that layer from which their functionally essential and characteristic part is derived. Thus, although the pancreas, ovary, and spinal cord all contain connective tissue, we do not call them mesodermal, but respectively entodermal, mesothelial, and ectodermal. The gland cells of the pancreas come from the entoderm; the ova and the Graafian follicles come from the mesothelium; the ganglion cells and nerve fibres (axis cylinders) from the ectoderm. Adopting this principle, we may classify the organs of the human body as follows:

ECTODERMAL.

- Skin (epidermis).
- Epidermal structures:
  - Hair,
  - Nails,
  - Glands:
    - Sebaceous,
    - Sudorific,
    - (Salivary ?),
    - (Thymus ?).
  - Corneal epithelium,
  - Lens of eye.
- Central nervous system:
  - Nerves,
  - Ganglia.
- Eye, optic vesicle:
  - Optic nerve,
  - Retina, etc.
- Olfactory organ.
- Auditory organ.
- Lining of mouth:
  - Teeth,
  - Hypophysis.
- Anus.
- Chorion:
  - Placenta.
- Amnion:
- (Wolffian duct ?).

MESODERMAL.

1. Mesenchyma:
   - Connective tissue:
     - Cutis, etc.,
     - Tendons,
     - Cartilage,
     - Bone,
     - Marrow.
   - Lymph glands.
   - Spleen.
   - Blood-vessels:
     - blood (in part).
   - Lymphatic system,
   - Fat cells,
   - Smooth muscle.
2. Mesamœboids:
   - Leucocytes,
   - Embryonic red blood cells,
   - (Marrow cells ?).
3. Mesothelium:
   - Peritoneum,
   - Pleuræ,
   - Urogenitals:
     - Wolffian body,
     - Kidney,
     - Testis,
     - Ovary,
     - Oviduct:
       - Uterus,
       - Vagina.
   - Striated muscles.

ENTODERMAL.

- Epithelium (of digestive tract):
  - Thyroid,
  - Trachea and lungs,
  - Œsophagus,
  - Stomach,
  - Liver,
  - Pancreas,
  - Intestine,
  - Yolk sac,
  - Cœcum,
  - Vermix,
  - Colon,
  - Rectum,
  - Allantois:
    - (Bladder).
- Notochord.

The human body may be defined as two tubes of epithelium, one inside the other; the outer tube, epidermal or ectodermal, is very irregular in its form; the inner tube, entodermal, is much smaller in diameter, but much longer than the outer, and has a number of branches (lung, pancreas, etc.), and is placed within the ectodermal tube. Between these two tubes is the very bulky mesoderm, which is divided by large cavities (abdominal and thoracic) into two main layers, one of which is closely associated with the epidermis and forms the body wall, the somatopleure of embryologists; the other joins with the entoderm to complete the walls of the splanchnic viscera, and constitute the splanchnopleure of embryologists. The mesoderm is permeated by two sets of cavities: (1) the heart and blood-vessels; (2) the lymphatic system. It is also differentiated into numerous tissues, muscle, tendon, bone, etc., and organs, urogenital system. The nervous system, although developed from the ectoderm, is found separated from its site of origin, and completely encased in mesoderm.

As we ascend the animal scale, we discover in all parts an increasing complexity; especially in the nervous system is this marked, but it is even more strikingly shown by the evolution of the mesoderm in relative size and differentiation. This important correspondence between the organization of the mesoderm and the degree of evolution of animals has not, to my knowledge, hitherto attracted express attention.

Charles Sedgwick Minot.

GESTATION.—The word is derived from the Latin verb *gestare* to carry, and therefore describes the function performed by the pregnant woman from the time of the fecundation of the ovum to that of delivery. Gestation and pregnancy are synonymous, but most authors do not apply either term to those pathologic conditions characterized by prolonged retention of a dead fœtus or secundines.

The German synonym *Schwangerschaft* expresses this same idea of carrying something; the French *grossesse* refers to the increase in the size of the abdomen during pregnancy; the Italian *gravidanza*, like the English terms *gravid* and *gravidity*, imply an increase in the weight of the uterus (*gravo*, to weigh down).

When more than one fœtus is present the gestation is designated as *multiple*, in distinction from a *single* or *simple* pregnancy. Normally the ovum should develop within the uterine cavity, and all other forms of gestation are known as *ectopic*, viz., out of place. In this article the subject of ectopic gestation will not be considered.

MODIFICATIONS CAUSED BY GESTATION.—The presence of the fecundated ovum at once stimulates the maternal organism, and a series of changes take place in order to meet the following requirements: 1. A place must be provided in which the fœtus can develop and be protected. 2. There must be a physiologic hypertrophy of all organs concerned in the processes of nutrition and excretion. 3. There must be preparations for labor and subsequent nourishment of the child. Under these heads will fall all the local and general changes induced by gestation, but as the genital system is the centre of physiologic disturbance it is there we expect to find the most striking modifications.

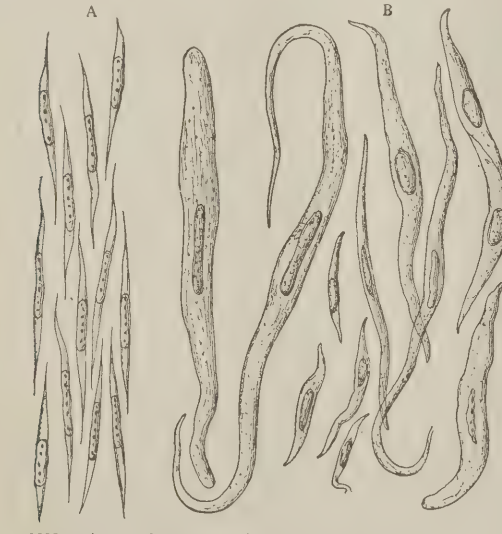

FIG. 2289.—*A*, Muscle-elements from Non-pregnant Uterus; *B*, cells from uterus shortly after delivery. (Sappey.)

Uterus—Modifications of its Body.—Increase in the size of the womb in order to keep pace with the growing demands of the fœtus constitutes one of the most prominent features of gestation. The volume of the uterus augments gradually, but not regularly, the growth during the later months being more rapid than at first. Of course the size of the uterus at term varies somewhat, depending upon the size of the fœtus, the number of children in utero, and the amount of liquor amnii; but the following figures give a general idea of the extent of uterine enlargement:

Before impregnation the uterus weighs about an ounce, its capacity is about one cubic inch, and the length of the cavity is two and one-half inches. At term the uterus weighs two pounds, has a capacity of four hundred cubic inches, and its cavity measures fifteen by ten by nine inches.

The increase in size is due chiefly to hypertrophy of all the constituents of the organ, and occurs, although in a less degree, even when the ovum develops outside of the uterine cavity. During the latter part of pregnancy distention undoubtedly plays a rôle in producing the uterine tumor.

Changes in the Form, Position, and Direction of the Uterine Body.—At first the uterus preserves its pyriform shape, but the gradual increase in its antero-posterior diameter gives it a spherical outline during the third and fourth months. From the fifth month onward the expansion of the fundus and lower uterine segment alters the sphere into an ovoid with the larger end up. Herrgott ("Essais sur les differentes variétés de forme de matrice pendant la gestation et l'accouchement," Strasbourg, 1839) found that the fundus of the uterus rarely took on a symmetrical development, but that the right half usually contained the breech and was more elevated than the left. The anterior portion of the lower segment is more developed than the posterior so that the axis of the uterine body passes in front of the cervix.

The enlargement of the uterus necessitates a change of position, especially as the organ soon becomes too large for the pelvic cavity. Many books describe a descent during the early weeks of gestation, but Tarnier and Pinard never have noted this downward movement except as a part of that pathologic condition known as prolapse. During the first months of gestation the gravid state of the uterus tends to exaggerate the normal anteflexion, and after the fourth month, when the fundus emerges from the pelvis, the degree of anteflexion is regulated by the position of the woman and the tonicity of the abdominal walls.

It usually is stated that by the fifth month the fundus has reached half-way to the umbilicus; by the sixth that it is on the level of the umbilicus, and that by the eighth, or eight and a half, the fundus lies under the ensiform cartilage. Pinard, however, says that the fundus usually is much higher than is described by most authors, and that he never found a uterus whose fundus was not above the umbilicus at the fifth month of gestation. On the other hand, Ribemont-Dessaignes mentions a case in which, at the sixth month, he found the fundus below the level of the umbilicus, the child weighing over seven pounds at birth. A possible explanation of these discrepancies may lie in the fact that the umbilicus is not a fixed point. At some time during the last two weeks of gestation the presenting part slips into the brim of the pelvis and the fundus sinks. In multiparæ this readjustment may be quite sudden and give rise to a sensation of "lightening," but it is much more gradual in primiparæ owing to greater rigidity of the abdominal walls.

The fundus of the uterus seldom lies in the median line of the abdomen. On examining 100 women at the ninth month of pregnancy P. Dubois and Pajot found a right lateral deviation in 76, a left in 4; in the remaining 20 the fundus lay in the median line. Not only does the fundus tend to fall to the right, but the body of the uterus rotates so that the left side is turned to the front. Probably both the deviation and the torsion proceed from the same cause; the distended sigmoid and rectum prevent the uterus from balancing upon the prominent vertebral column and push the organ toward the right; as the uterus rolls into the concavity at the right of the spine the right face becomes posterior. Unless this physiologic torsion of the uterus is remembered at the time of performing the operation of Cesarian section, the surgeon is in danger of making his incision into the left border of the uterus and severing some of the large vascular trunks lying in that region.

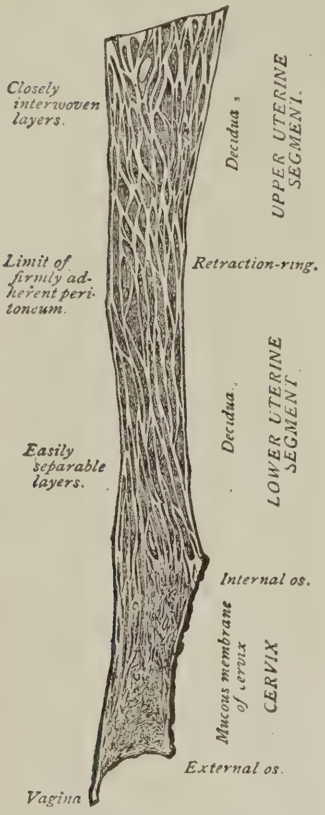

FIG. 2290.—Section of Wall of Pregnant Uterus. (Hofmeier.)

Changes in the Structure of the Uterus.—All the constituents of the uterus are involved in the process of development. There is marked hyperplasia of the serous coat, allowing the peritoneum to cover the uterus at the different stages of enlargement. The muscular fibres in the walls are greatly increased in size, but it is not proved that a true hyperplasia occurs. In the pregnant womb three layers of muscular fibres can be demonstrated. The superficial layer is made up of longitudinal and transverse fibres, which are continuous with those upon the surfaces of the tubes and round ligaments. The median layer forms the bulk of the uterine walls and contains interlacing fibres running in all directions. This layer is traversed by numerous vascular trunks around which the muscular fibres take an arciform direction. In the case of the veins, the external and middle coats of the vessels disappear so that the blood is conveyed in muscular channels lined by endothelial cells and known as sinuses. By the constricting action of these arciform fibres, which Pinard calls *ligatures vivantes*, hemorrhage is prevented after labor. The internal muscular layer is very thin and best marked by circular fibres at the orifices of the tubes, although a set of longitudinal and transverse fibres may be found just beneath the mucous membrane. In the lower uterine segment there is a predominance of longitudinal muscular fibres.

The advent of pregnancy stimulates the mucous membrane of the uterus so that it becomes congested, thickened, and thrown up into folds. The hypertrophy is the result of an increase in the interglandular tissue and a growth of the cellular layer in which may be found the large decidual cells of Friedländer. The superficial, or *compact layer*, of the decidua vera is in contact with the ovular decidua by the third month and then rapidly atrophies; it is through the deeper, or *spongy, layer* that the line of separation runs when the decidua is cast off.

All the blood-vessels of the uterus become much enlarged, and at the placental site the arteries empty directly into the lacunæ, the blood spaces penetrated by the villi. The veins form the uterine sinuses as described above and constitute an extensive plexus. The lymphatics are increased both in size and in number, communicating freely with those of the peritoneum and adnexa, an arrangement which readily explains the seriousness of puerperal infection and the ease with which it occurs. Nerve cells and trunks take part in the general hypertrophy. Keiffer (*Gaz. hebdom. de Méd. et de Chir.*, June 7th, 1900) claims that the uterus has a set of independent nerve cells which are found along the vessels and can be detected by Golgi's method of staining. These local ganglia have sensory, motor, secretory, and glandular functions, giving to the uterus an independence similar to that of the heart.

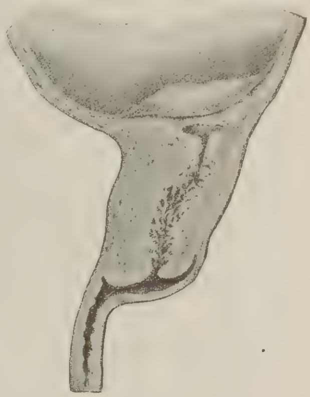

FIG. 2291.—Cervix in the Fifth Month of Pregnancy. (Leopold.)

During the first part of gestation the general hypertrophy of the tissues gives the uterine walls a thickness of five-eighths of an inch, but later distention reduces this measurement to one-quarter of an inch. Instead of being firm and unyielding, as are the walls of the virgin uterus, the tissues of the gravid womb are elastic and permit the fœtal movements, or a change in the woman's position, to alter the outline of the organ.

Modifications of the Cervix.—The hypertrophy of the cervix is much less marked than is that of the body of the uterus and is mostly completed by the fifth month of gestation. The mucous membrane of the cervix takes no part in the formation of the decidua, but the glands secrete a quantity of mucus which securely plugs the canal from the beginning of gestation. In primiparæ the form of the cervix is that of a cone with its apex down; in multiparæ the cone has its base down. In primiparæ, during the latter months of gestation when the presenting part lies low down and against the anterior wall of the

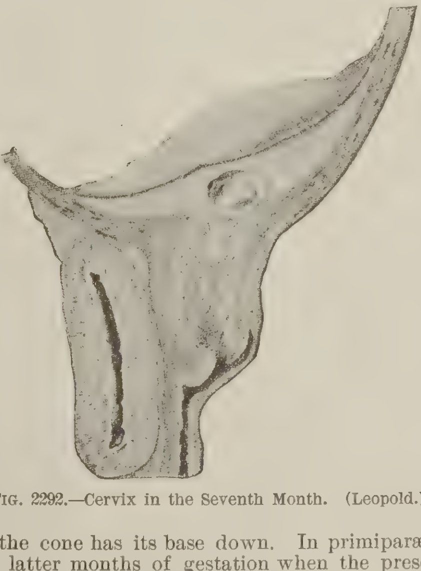

FIG. 2292.—Cervix in the Seventh Month. (Leopold.)

lower uterine segment, the external os may be carried so high into the hollow of the sacrum that students find it difficult to reach the cervical opening. The increased vascularity leads to a progressive softening of the cervix beginning at its most dependent portion; the softening is more marked and develops more rapidly in multiparæ than in primiparæ.

Physiologic Modification of the Uterus.—Associated with these anatomic changes certain physiologic properties appear. The *irritability* of the uterus increases, so that contractions are more easily evoked; this property is particularly marked at the menstrual epochs, so that at these times the danger of abortion is much increased. As the musculature of the uterus increases contractions become evident; during the latter months of gestation these contractions take place every twenty or thirty minutes; they are involuntary, slow and intermittent, differing from the contractions of labor in that they cause the woman no suffering nor have any effect upon the cervix. This systematic exercise of the uterine muscle serves to keep the organ in training for the exertions of labor. *Retractility* is a property more conspicuous during labor than during gestation; it enables the muscular fibre to hold a small portion of its contraction and remain permanently shortened. Retraction is thus dependent upon contraction and is seen at its best in the third stage of labor when the uterine sinuses are held securely closed after the contractions have ceased.

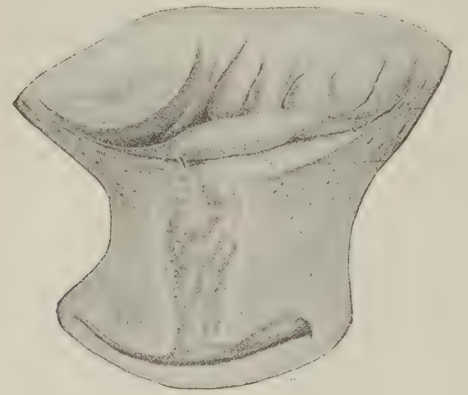

FIG. 2293.—Cervix in Ninth Month. (Leopold.)

Modifications of the Adnexa.—As the fundus rises into the abdominal cavity it necessarily elevates the uterine attachments of the round ligaments, broad ligaments, ovarian ligaments and tubes, bringing these structures into closer relation to the sides of the uterus and causing them to run in a more vertical direction. The round ligaments, tubes, and ovarian ligaments, having muscular fibres continuous with those of the uterus, take part to some extent in the general hypertrophy of the sexual organs. The folds of the broad ligaments become widely separated by the increased thickness of the uterine body.

Modifications of the Vagina and Vulva.—The congestion of the vaginal walls results in their hypertrophy and the mucous membrane becomes reduplicated and softened, favoring subsequent dilatation of this portion of the genital canal. There is often so little contrast between the feel of the softened vaginal wall and that of the cervix that the inexperienced student finds it very difficult to distinguish the one from the other. The engorgement of the vaginal vessels leads to an unusual amount of glandular secretion and produces a bluish coloration. There is relaxation and gaping of the vulva together with dilatation of the veins and increased secretion from the glands.

Modifications of the Pelvic Joints.—During pregnancy the interarticular cartilages of the pelvis become vascular and softened and allow a limited amount of motion in the joints, thus slightly facilitating the passage of the head during labor. The sacrococcygeal and symphysis pubis are the joints having the greatest degree of motility.

Modifications Produced Mechanically by the Enlarged Uterus.—The pressure of the growing uterus is apt to interfere with the functions of the bladder and rectum so that vesical irritation and constipation are often features of gestation. Owing to the diminished space within the abdomen a full bladder will cause a decided prominence of the anterior abdominal wall. Interference with venous return may produce or aggravate varicosities of the veins of the rectum, vulva, and lower extremities. When the fundus has reached the ensiform cartilage pressure upon the diaphragm interferes with respiration, particularly at times of exertion; as a compensation the thorax increases in width. The distention of the abdominal walls results in the formation of *striæ gravidarum*, which are bluish or reddish lines caused by the stretching and atrophy of some of the connective-tissue fibres in the skin. In time these striæ become pearly white in appearance so that there is a marked contrast between the scars of an earlier and those of a recent pregnancy. In severe cases of distention the recti muscles may separate and allow the fundus to fall forward and be covered only by the skin and peritoneum. By the seventh month of gestation the umbilical depression is obliterated, and during the last weeks of pregnancy there may be a protrusion of the navel. As the uterine tumor becomes large the woman can maintain her equilibrium in the upright position only by bending backward the upper portion of her trunk in order to bring the centre of gravity in a vertical line passing through the pelvis; hence her characteristic gait and posture.

Modifications of the Breasts.—The close relationship between the pelvic organs and the mammary glands explains the early and prominent changes found in the breasts: even in the second month there is an increase in size from the deposit of fat and growth of glandular tissue The enlarged lobules give a nodular feel on palpation, and when the tension of the skin is pronounced striæ form similar to those on the abdomen. The superficial veins are conspicuous and the areola, particularly in primiparæ and brunettes, becomes pigmented and shows elevations marking the sites of fifteen or eighteen sebaceous glands, known as Montgomery's follicles. By the fifth month the breast changes are at their height and a secondary areola may form having the appearance of a network of pigment containing numerous lighter spots. The nipple is hypertrophied, more sensitive and erectile; after the third month stroking the breast from the periphery inward may express a few drops of colostrum.

Modifications of the Circulatory System.—In order to carry out the new requirements laid upon the organism the quantity of blood is augmented during pregnancy and the increase is more marked in the watery constituents of the blood so that the red corpuscles are relatively diminished. The white corpuscles are said to be both relatively and actually increased in number. Many observers report an hypertrophy of the left side of the heart, accounted for by the increased labor of driving a greater amount of blood over a more extensive area, but recently this cardiac alteration has been questioned and deemed the exception rather than the rule. According to the studies of P. Longe the pulse during gestation has more tension and on the average shows a rate of 86 beats per minute.

Modifications of the Digestive System.—Nausea and vomiting are not uncommon during the first three months of gestation and the appetite may become capricious; later both the appetite and power of digestion are increased with the result that by the end of gestation the pregnant woman makes a gain equal, on the average, to one-thirteenth of her body weight. There is an increase of the amount of adipose tissue causing the figure to become fuller and rounder and serving as a reserve store of potential energy. This activity in metabolism entails greater activity in the excretory functions of the liver, lungs, skin, kidneys, and bowels.

Pigmentation of the skin is a common occurrence in pregnancy; besides the darkening of the areola there may be irregular spots upon the face and almost invariably there is a pigmented line extending from the symphysis pubis to the navel, known as the *linea nigra*.

Upon the inner surface of the skull are formed the "puerperal osteophytes," consisting of deposits of carbonate of calcium, phosphates, and organic matter.

The nervous system of the pregnant woman is extremely impressionable and often conditions of fretfulness or irritability develop. In rare instances the entire disposition changes and the patient shows unusual likes and dislikes.

MULTIPLE FŒTATION.—When the uterus contains two or more fecundated ova the pregnancy is designated as multiple or pluriparous.

Statistics as to the frequency of multiple gestation vary considerably among different writers. A fair statement would give the proportion about as follows: twins once in 120 pregnancies; triplets once in 7,900; quadruplets once in 370,000.

Among the factors predisposing to multiple pregnancy heredity and multiparity are important, but great stature, race, and the size of the ovaries also are mentioned among the causes.

Usually the fecundation of the ovules occurs as the result of a single coitus, but the instances on record in which a negress has given birth to one black and one white twin prove that the ovules discharged at the same menstrual epoch may be fecundated successively; to such cases the term superfecundation is applied. By superfœtation is meant the fecundation of ovules belonging to different periods and, theoretically, this form of superimpregnation would seem to be impossible both because ovulation is assumed to be suspended during pregnancy and because in the third month the ovular and uterine decidua come into contact, thereby preventing the access of the spermatozoon to the ovum. On the other hand, a few instances are reported in which women have given birth to apparently full-term children with a five-month interval separating the two. In the demonstrated absence of bifidity of the uterus such facts are difficult to explain on any other ground than superfœtation.

In twin conception the ova may have been discharged from different ovaries or both from the same ovary and even from the same ovisac. When twins develop from one ovum it must contain two germinating vesicles. In about sixty-six per cent. twins are of the same sex.

In all cases of multiple fœtation there is at first a separate amnion for each child, although later the partition may become absorbed or rupture, so that the children are found in the same sac at the time of labor; there are as many chorions as ova. The placentæ are originally distinct, but later the contiguous borders may fuse and an anastomosis of vessels occur; if one fœtal heart be much stronger than the other there is a disproportion in the amount of placental tissue at the disposal of the two children. The weaker fœtus may die and be so pressed upon by the survivor that it is flattened out against the walls of the uterus and forms what is known as a "fœtus papyraceous." The weight and size of twins usually are under the average and they are less likely to live than single children. Also the distention of the uterus makes premature labor more likely to occur in multiple pregnancies, and the distention is all the greater from the fact that hydramnios frequently is associated with twin pregnancy. According to Pinard's statistics out of 150 twin cases there were 108 premature deliveries.

DIAGNOSIS OF PREGNANCY.—The diagnosis of pregnancy rests upon maternal and fœtal signs; these are obtained by questioning and by inspection, palpation, and auscultation.

Subjective Signs.—Absence of menstruation usually is the first symptom noticed by the woman herself, and this sign is particularly valuable in those patients who always have been regular and in whom there is no evidence of general disease. Of course, amenorrhœa has no significance before puberty, after the menopause and during lactation. It also must be remembered that the fear of conception sometimes produces a "psychical amenorrhœa," and that in other instances the patient purposely has made false statements in the hope that an abortion will be accidentally induced. The amenorrhœa often associated with obesity has led the physician into embarrassing errors as the increase in the patient's size seems to confirm his diagnosis. Although Pinard says he never yet has observed a case of gestation in which menstruation persisted, a few instances have been reported in which a regular monthly flow occurred throughout a portion or the whole of pregnancy. Usually such periodic flowing does not have the features of normal menstruation, and is found to have its origin in cervical disease or ectopic pregnancy. It is not at all uncommon for a woman to have one period of diminished flow even after fecundation has taken place and the history of such a scanty discharge is almost as significant as amenorrhœa.

Nausea and *vomiting* on rising in the morning are mentioned as classic signs of early gestation, and certain multiparæ can make a positive diagnosis on these symptoms alone; salivation and heartburn may be associated with this gastric disturbance. Before allowing "morning sickness" to carry much weight the physician must eliminate all other reflex causes. The absence of gastric symptoms is of no value in excluding the possibility of pregnancy.

After the third month the patient notices a progressive increase in the size of her abdomen; the alleged preliminary flattening of the hypogastric region rests on no clinical basis. During the last two weeks multiparæ experience "*lightening*" or the feeling of relief produced by the marked sinking of the fundus.

Quickening is the term used to describe the sensations imparted to the mother by the fœtal movements and appears at variable times according to the experience and acuteness of feeling on the part of the patient. In some women the fœtal movements seem to be absent or unnoticed and in a few quickening occurs as early as the third month, but on the average the symptoms appear at the eighteenth or twentieth week. It is possible for even experienced matrons to be deluded and mistake muscular contractions or the passage of gas in the bowels for movements of the fœtus. A woman who once starts with the assumption of pregnancy is quite apt to experience all the confirmatory subjective signs and may succeed in leading her physician to a wrong conclusion.

Other less important signs which should not be passed over are: a sense of enlargement and tingling in the breasts, a feeling of heat in the pelvis with more or less leucorrheal discharge, irritability of the bladder, and constipation, also nervous disturbances such as neuralgia, dizziness, and change of disposition.

Objective Signs.—Pigmentation of the face, enlargement of the abdomen, and the peculiar carriage or gait may be noticed by the physician in the first few moments of the interview.

Abdominal Examination.—After having obtained the history of the case it is best to proceed next to the examination of the abdomen; by adopting this order we can make the investigation of the breasts and pelvic organs less of a shock to susceptible patients. For the abdominal examination the woman should be in the dorsal position with the knees drawn up and the surface of the body exposed from the ensiform to the symphysis: corsets and all constricting bands must be loosened and the bladder and rectum empty.

Inspection.—On inspection there should be noticed the size and shape of the abdominal tumor which usually extends more to the right than the left of the median line; during a uterine contraction the tumor becomes more prominent. If the fœtal movements are vigorous a series of irregular and temporary elevations are visible at times over the surface of the distended abdominal wall. During the latter half of gestation the umbilicus may be level with the surface or protruded. Pigmentation, in spots or along the median line, together with striæ are the other signs noted on inspection.

Palpation.—For palpation the hands should be warmed and laid flat upon the surface of the abdomen; the best results will be obtained by a series of circling motions punctuated by deeper pressure. Violent and sudden thrusts will cause a reflex contraction of the muscles and defeat the ends of the examination. The edge of the hand should be pressed down above the apparent site of the fundus and carried toward the symphysis in order to map out the upper limits of the uterus and obtain some idea of the period of gestation. The fundus is at the umbilicus at the sixth month; three fingers' breadth above at the seventh; half-way to the ensiform at the next month, and under the ensiform at the last month. If the fundus is slightly below the ensiform there may be several weeks of pregnancy remaining or "lightening" may have taken place and the labor be imminent. The peculiar doughy, semi-elastic feel of the uterus should be noted, and its increased firmness during a contraction constitutes *Braxton Hicks' sign*, which can be obtained as soon as the organ is large enough to grasp. By the sixth month the fœtal parts can be palpated and the smooth back, as well as the irregular bosses forming the shoulders, knees, or elbows, located. By pressing the fingers deep down at the sides of the superior strait the head can often be grasped between the two hands, or it may be felt as a hard, globular body lying at the fundus to the right of the median line. The breech is softer, less movable, and bears no relation to the shoulders. In thin women a hand or a foot can be grasped. During the course of palpation the physician usually feels upon the palms of his hands several distinct taps which are caused by the movements of the fœtal extremities; sometimes the entire body of the child will change its position under his hands.

External ballottement is obtained by placing a hand on either side of the abdomen and attempting to throw the fœtus, as it were, from one side to the other; or, in a breech presentation, the head will rebound from one hand to the other. If the woman be turned upon her side so that the prominent abdomen projects over the edge of the table the fœtus may be pushed up by a hand underneath and then fall again against the fingers. Ballottement depends upon the amount of fluid within the uterus and is best marked in cases of hydramnion, provided the fœtus be large enough to detect. In normal circumstances it is a sign belonging to the fifth and sixth months as previous to these times the child is too small, and in the latter months of gestation the liquor amnii, relative to the bulk of the fœtus, is not sufficient to allow of free motility.

Auscultation.—Percussion belongs under this head. Over the mass of the tumor there is dulness, while above and to the sides the coils of intestines give rise to tympanitic resonance. Usually the fœtal heart-sounds cannot be heard before the fifth month, except in favorable cases when experienced observers have detected them as early as the fourth. The rate of pulsation varies between 120 and 160, the sound being compared to that of a watch ticking under a pillow. The idea that a slow rate indicates a male and a rapid a female does not hold good in practice. In the most frequent presentations the head occupies the pelvis with occiput to the front, therefore the maximum intensity of the heart-sounds usually is found below the umbilicus and more often on the left side than the right; in posterior positions of the occiput the sounds are heard further round on the flank. When the head is at the fundus the focus of intensity is above and to one or the other side of the umbilicus.

In performing auscultation it is well to begin by applying the ear direct to the abdomen, using a thin towel for covering the skin, and examine systematically the four regions about the umbilicus. Many observers can do better by this immediate method of auscultation, besides which it is well to train the ear. The stethoscope should be used in those cases in which it is more convenient and pleasant or when the ear alone does not give satisfactory results. In order to hear distinctly the room must be very quiet, the physician's posture must be comfortable and not be such as to cause compression of the veins of his neck. A rapid maternal pulse may be misleading until its rate is compared with that of the pulsation in the radial artery; in some cases the observer will become conscious of his own heart beats, which, of course, are much slower than those of the fœtal heart.

The *uterine souffle* is heard over the left border of the uterus, which has been brought to the front by the torsion of the organ. It is a blowing sound like that of an anæmic murmur and is synchronous with the maternal pulse. The *uterine souffle* or *bruit* may be heard as early as the fourteenth week and is caused by the blood flowing through the enlarged uterine vessels; it is not peculiar to pregnancy and is often noted over large tumors.

The *funic souffle* is caused by some obstruction in the vessels of the umbilical cord, as from coiling about the neck. This sound is synchronous with the fœtal heart; it is not present in the majority of cases and appears during the latter half of gestation.

Sometimes the movements of the fœtus can be heard on auscultation as early as the fourth month of pregnancy as a succession of faint thuds or slight rubbing sounds. Gas in the bowel will closely simulate fœtal shock.

Examination of the Breasts.—The clothing already being well loosened it is easy to pass next to the search for mammary signs. On *inspection* the presence of striæ, enlarged veins, and pigmented areolæ are noted. *Palpation* detects the knotty feel, and by a little manipulation a drop or two of colostrum may be pressed from the nipple.

Examination of the External and Internal Genitals.—For the vaginal examination the patient is drawn down to the edge of the table, her clothing well pulled up and replaced by a sheet. For internal examination an empty bladder and rectum are more essential conditions than for abdominal palpation. In obscure cases and when the patient is very nervous an anæsthetic is indispensable. Disinfection of the examining hand must be a preliminary step before its introduction, and with the other hand the vulva should be held apart so that no contamination can be carried up from below.

Vaginal Touch.—As the finger passes up the vagina the velvety feel and moisture of the walls are noted. Next, the shape of the cervix and the presence or absence of softening must be determined. Goodell says that if the tip of the cervix feels like the end of one's nose the patient probably is not pregnant; if it feels as soft as one's lips there probably is a fœtus in utero. By bimanual examination the position, shape, size, and consistence of the uterus are discovered. During the fifth and sixth months *internal ballottement* can be obtained, especially in those cases in which the head presents. To develop this sign the internal finger is placed in front of the cervix and a quick push given to the fœtus; the physician will be sensible of the upward movement and subsequent return of the presenting part. By conjoined manipulation the uterine contractions may be detected as early as the third month.

Besides the softening of the cervix there are two valuable signs belonging to the first part of gestation. One is the marked angle formed by the corpus and cervix and easily noted on internal examination; the other is known as Hegar's sign and consists in the compressibility of the lower uterine segment. To obtain this sign the outside and internal fingers should compress the uterus just above the cervix. In well-marked cases there will seem to be no tissue at this point and the fundus and cervix will give an impression of being two disconnected bodies. Another way of bringing out Hegar's sign is to introduce the forefinger into the rectum and the thumb of the same hand into the vagina; while the outside hand presses down the uterus the internal thumb and finger grasp the organ just above the cervix. R. von Braun-Fernwald (*Wien. klin. Wochenschrift*, March 9th, 1899) describes a sign which he has found to be valuable in the diagnosis of early pregnancy. It consists in an asymmetry of uterine development detected by the bimanual examination. The ovum very rarely lies exactly in the centre of the uterine cavity at first and consequently the antero-posterior diameter of one horn is greater than that of the other; often a groove is perceptible between the two sides of the uterus.

Inspection.—As the finger is withdrawn from the vagina the parts are held open for a moment and the color of the vulva and lower vaginal wall is observed. A port-wine color of the mucous membrane may be noted, but is not a positive sign of pregnancy; the same color may be seen on the cervix if a speculum be introduced.

Value of the Different Signs and Symptoms of Gestation.—No one of the maternal signs or symptoms is positive, but the presence of a number of them forms a strong chain of circumstantial evidence. It is well known that all the breast signs may be present in a case of uterine disease and that uterine or abdominal enlargement may be due to the presence of a tumor. Before the sixth week a diagnosis of pregnancy is rarely positive, but strong opinion can be based upon the association of the following signs: amenorrhœa in a healthy married woman who has always been regular, an enlarged pyriform uterus of doughy consistency with a marked angle between corpus and cervix, softening of the cervix with compressibility of the lower segment. The pathognomonic signs of pregnancy come from the fœtus and are fœtal heart-sounds, ballottement, and fœtal movements; provided fallacies be excluded any one of these signs establishes the diagnosis. The Röntgen rays are of no use for early diagnosis, although late in gestation they have given information concerning the presentation and the condition of the mother's pelvis.

DIFFERENTIAL DIAGNOSIS.—Early gestation must be differentiated from those conditions which cause uterine enlargement; advanced pregnancy from those producing abdominal distention. *Fibroid enlargement* usually fails to give the uterus the shape and consistency belonging to pregnancy; the rate of increase in size does not correspond with that shown by the gravid uterus; there is menorrhagia rather than amenorrhœa. *Chronic metritis* presents many of the same differential points. *Hæmatometra* is a rare condition caused by the retention of menstrual blood within the uterus. Symptoms denoting pain and disturbance appear at puberty and are repeated each month but are unattended by flowing; an examination often discloses an obstructed vagina. The abdominal enlargements with which pregnancy has been confounded are those produced by *fat, tympanites, ascites, ovarian* and *fibroid* tumors.

Fat.—The amenorrhœa of obesity must be remembered. The thickness of the abdominal wall may be estimated by lifting a fold of tissue and also by observing the general fat-deposit of the patient. There are no uterine signs of pregnancy. As an adipose condition greatly interferes with bimanual examination it may be necessary to administer an anæsthetic in order to detect intra-abdominal conditions.

Tympanites.—Thorough cleansing of the bowels will diminish the size of the tumor which is resonant instead of dull.

Ascites.—When the patient lies in the dorsal position the tumor has a characteristic shape, namely, flattened on top and bulging at the sides. Fluctuation is marked and the change of position on the part of the patient changes the physical relations of flatness and resonance.

Ovarian Cyst.—An ovarian tumor may cause symmetrical enlargement of the abdomen but usually is unaccompanied by amenorrhœa; Braxton Hicks' sign is absent and fluctuation may be obtained. Of course no fœtal signs are present and the uterus usually is found to be displaced and not enlarged.

Fibroid Tumor of the Uterus.—A large fibroid usually is very irregular in outline and has a history of longer duration than that of pregnancy; menorrhagia usually is a prominent symptom.

It is important to remember that although various pathologic conditions may be present pregnancy is not necessarily excluded. There are many instances in which an operator has found gravidity associated with a fibroid or ovarian tumor.

Pseudocyesis.—Spurious pregnancy, or phantom tumor, is a condition met with in some women who are very desirous of having children as well as in those who dread maternity. There are instances in which women after the menopause have deluded themselves with the idea of pregnancy and made all the preparations for confinement. In these cases the physician can obtain an almost complete subjective history in which he may place undue reliance if the patient already has had experience in bearing children. Abdominal distention usually is present but due to the accumulation of gas or fat. It is said that often under an anæsthetic the tumor of pseudocyesis will disappear and the test should be made in doubtful cases. Under no circumstances should a physician make a diagnosis of pregnancy on the statements of the patient, nor must he allow them to give his mind a bias; in fact he should never give a positive opinion until signs from the fœtus are clearly manifest, although, before this time, he may feel justified in advancing a probable diagnosis.

DIAGNOSIS OF MULTIPLE PREGNANCY.—Having established the existence of pregnancy the presence of more than one fœtus in utero is indicated by the following signs: the uterus is larger than it should be for the estimated period of gestation; it is broader in proportion to its length than is the case in a single pregnancy; a multiplicity of fœtal parts is present; two hearts are heard, having different rates of pulsation and foci of intensity.

DIAGNOSIS OF DEATH OF THE FŒTUS.—When the death of the fœtus occurs in utero usually the contractions of the organ expel its contents, but there are cases in which the dead products of conception are retained and undergo saponification, mummification, putrefaction, or even become totally absorbed. The diagnosis of fœtal death may be very difficult and the signs vary according to the period of gestation at which it occurs. Lactation may be present for a few days and the subjective symptoms of gestation usually disappear. Except when there are profound disturbances following putrefaction there are no general symptoms distinctive of fœtal death and the diagnosis rests upon the results of physical examination. During the first half of gestation palpation, performed at intervals, reveals no increase in the size of the uterus and often a diminution; the softening of the cervix disappears. While comparisons are valuable, if the case is not seen until some time after the death of the fœtus, there may be great difficulty in making a diagnosis of pregnancy. During the second half of gestation the absence of certain fœtal signs, especially if they have been present, is most valuable. The patient no longer feels the movements of the child, nor can the physician detect the fœtal heart-sound; the absorption of the liquor amnii leads to diminution in the size of the uterus. If the head of the fœtus can be palpated, either in the lower uterine segment or at the fundus, crepitus may be obtained owing to the motility of the loosened bones of the skull. It is claimed that in all cases the urine of the woman contains acetone.

Care must be taken not to make an error in concluding that the fœtus is dead, for the fœtal movements may be absent because the intra-uterine space has become so limited and the heart-sounds may appear to be wanting merely because the physician is unable to find them. Usually considerable study of the case is required before any positive opinion can be formed. In a case of multiple pregnancy the diagnosis of the death of one child alone usually is impossible.

Duration of Gestation.—Even when the date of the fruitful coitus is known the duration of the pregnancy is found to vary from two hundred and sixty to two hundred and ninety-four days; in the majority of cases, however, confinement takes place at the end of two hundred and seventy-one days. For practical purposes it is found convenient to estimate the duration of pregnancy as two hundred and eighty days and count from the beginning of the last menstrual flow. This method is fairly reliable except when the conception occurred just previous to the first missed menstrual period. Labor is apt to take place on or near the tenth menstrual epoch, and to estimate this date we count back three months from the date of the first day of the last period and add seven days. Every visiting list generally contains a table which enables the physician to make his prediction in a given case. If the date of the last menstrual period is not available other data are the time of quickening and mensuration of the uterus. The period of quickening is not at all a fixed one but an approximate estimate of the day of confinement can be made by adding twenty-two weeks to the date of quickening. Mensuration of the uterus is very uncertain, as the size and number of the fœtuses vary and the amount of liquor amnii is not always the same. The position of the fundus at the different months has been stated.

Hygiene and Management.—Gestation being a physiologic condition a pregnant woman needs to do little more than observe the rules for normal living, but as derangements readily occur she should be under the supervision of her physician from the beginning to the end of gestation.

Diet.—No rules can be given for diet during pregnancy as, in normal cases, the patient may be allowed to follow her inclinations, provided she takes a sufficient quantity of nutritious food and avoids what is indigestible. During the early months when nausea and vomiting are present the diet should be simpler than usual. Breakfasting in bed and the use of some alkaline gastric sedative are sufficient for the ordinary case of stomach disturbance.

Clothing.—In order to avoid all pressure upon the growing uterus the clothing should be quite loose and the corset omitted; garters constricting the veins of the legs are objectionable. If the abdominal walls are relaxed so that the uterus drops too far forward a light well-fitting supporter should be worn.

Exercise.—Walking in the fresh air is the best form of exercise; horseback riding or any form of activity which entails straining or jolting should be forbidden. Long journeys in the cars are liable to induce abortion, especially if taken at the menstrual epochs. Those women who are accustomed to work hard for a living seem less easily disturbed and pass through the period of gestation without making any change in their daily life until the abdominal tumor acts as a mechanical hindrance. The pregnant woman requires a large supply of oxygen, so she should remain in the open air as much as possible and avoid all crowded or ill-ventilated rooms.

Rest.—An abundance of sleep is essential for the welfare of the gravid woman, and during the last part of gestation she should take a large amount of rest. Pinard's observations show that those patients who work close up to the time of their confinement bring forth children of less weight and vigor than do those woman who enter the hospital a month or six weeks previous to labor.

Bathing.—The gravid state does not prevent the woman from taking her daily bath, but on the contrary is an additional reason why she should keep the function of the skin as active as possible. Care, however, must be taken not to have the water at so low a temperature as to produce shock.

Hygiene of the Pelvic Organs.—On account of the increased secretion frequent bathing of the external genitals is required. If there be any affection of the vagina or cervix, so that leucorrhœa is troublesome, warm vaginal irrigations are indicated, care being taken not to inject the water with too much force. Gonorrhœal inflammation calls for active treatment on account of the danger to the child's eyes during delivery and the risk to the mother should the infection ascend. Sexual intercourse during pregnancy is an abnormality and by producing congestion may lead to an abortion.

Care of the Breast and Nipples.—During the last three months of gestation the nipples should be gently scrubbed daily with a soft nail-brush, water, and castile soap, after which a little albolene or cocoa butter should be applied. This course of treatment will toughen the nipples and at the same time keep them pliable. Exposure to the air, as by leaving the nightdress open, also is supposed to render the nipples less sensitive. If they are flattened or retracted they should be drawn out daily by means of the thumb and finger or by applying a breast-pump. Careful preparations for the function of lactation do much to add to the comfort of the woman after confinement.

Attention has been called to the fact that the nervous system of the pregnant woman is in a most susceptible state. Without entering into the much debated subject of the influence of maternal emotions upon the fœtus, it is quite certain that some nervous impressions of the mother have an unfavorable effect upon the child as well as upon her own well-being. Therefore it is wise to make every effort to surround the patient with a pleasing environment and to remove, as far as possible, all sources of irritation.

Urinary Examinations.—From the beginning of pregnancy it is the duty of the physician to keep himself informed as to the state of the woman's urine. At first the examination should be made every fortnight, but during the last two months of pregnancy every week; any abnormality will call for more frequent attention. The examination should be based on the twenty-four-hour sample, and the estimation of the urea and total solids is of the utmost importance. A great many pregnant women are troubled with leucorrhœa sufficient to contaminate the urine and give the test for albumin; therefore it is well to direct the patient to take a vaginal douche and introduce a tampon of absorbent cotton just before urinating; a string tied to the tampon makes removal easy.

Obstetric Examination.—As soon as the fœtus is viable, the physician should make an examination of the uterus and pelvis; the diameters of the superior and inferior straits should be measured; the size of the fœtus estimated and note taken whether the uterine enlargement corresponds to the supposed period of gestation. Some time during the last month of gestation a second examination should be carried out in order that the physician may be thoroughly informed as to the presentation and condition of the birth canal at the time of labor.

Pathology of Gestation.—Under this head will be considered the important pathologic conditions brought about by the gravid state itself and not the effect of gestation upon disease already existing.

Toxœmia of Pregnancy.—Gestation is a time of increased metabolism, for the woman must build up the uterine structures as well as nourish the fœtus, hence the greater the amount of waste-products to be eliminated. During pregnancy the excretory organs of the patient, particularly the bowels, liver, and kidney, undergo a physiologic hypertrophy and the poisonous substances of retrograde metamorphosis are removed before a dangerous degree of accumulation takes place. What is known as the toxæmia of pregnancy is an auto-intoxication due to deficient elimination and may arise in several ways.

The pressure of the enlarging uterus may hinder the proper performance of the functions of the eliminating organs, the waste-products being prepared for excretion and yet remaining locked up within the body. In other cases the intoxication occurs through the fault of the transforming organs, particularly the liver, which fail to reduce the waste matter to a chemical structure appropriate to the cellular activities of the eliminating tissues. Pinard looks upon the auto-intoxication of pregnancy as hepato-toxæmia, and Bouffe de Sainte Blaise (*Med. Rev. of Rev.*, June, 1899) mentions the following as diagnostic features of deficient hepatic action: progressive decrease in the quantity of urea with increase in the proportion of uric acid and such intermediate substances as leucin and tyrosin; alimentary glycosuria, *i.e.*, if the woman ingests a fixed amount of glucose a portion will appear in the urine owing to the impairment of the glycogenic function; there is urobilinuria and the toxicity of the blood serum is increased. The chemistry of auto-intoxication is not yet elucidated, but it is apparent that, whatever the source of the toxins, their presence irritates the tissues and establishes a circulus vitiosus.

Predisposing Causes.—Women who suffer from insufficiency of elimination while in the non-pregnant state may not be able to meet the added demands of gestation.

Such conditions as hydramnion, multiple pregnancy, and primiparity are attended with the greatest amount of intra-abdominal pressure and thus interfere to the greatest degree with the action of the liver, intestines, or kidneys; multiple pregnancy at the same time adds a large amount of waste material. It is during the latter months of gestation that the intra-abdominal pressure is most marked and the amount of waste matter coming from the fœtus at its maximum.

Symptoms and Diagnosis.—The circulation of an increased amount of toxins affects particularly the nerve centres and gives rise to such symptoms as headache, dizziness, irritability, and disturbances of vision; vomiting and diarrhœa are not uncommon and represent efforts at elimination. Auto-intoxication constitutes the prodromal state of eclampsia and the majority of the so-called disorders of pregnancy belong to its symptomatology.

The modifications of the urine in toxæmia are extremely important. The total amount passed in the twenty-four hours usually is much diminished and the elimination of urea lessened. Although urea probably is not the most important poison concerned in the production of the toxic condition, the amount present in the urine affords us a valuable index of elimination. In a normal quantity of urine the urea, according to Davis, should be from 1.4 to 2 per cent.; below one per cent. lies the danger zone. Jewett has pointed out the fact that eclampsia very rarely develops when the daily amount of urine is over three pints and that a large amount of urine, say seventy ounces in the twenty-four hours, will eliminate the poisons even when the tests show a diminished quantity of urea. These facts confirm the importance of making quantitative estimations of the urine in all cases of gestation. In normal pregnancy the toxicity of the urine in relation to that of the blood serum is much increased, but when symptoms of toxæmia appear the toxicity of the blood serum is heightened while that of the urine is diminished.

Albuminuria.—This is a common symptom of toxæmia, but it must also be remembered that albumin is present in five per cent. of all cases of pregnancy, as a rule not appearing until the latter months of gestation. Allbutt does not believe that pressure is an important cause of albuminuria, as the renal veins are not easily pressed upon and albumin often is absent when the pressure is greatest; he thinks that the poisons absorbed from the intestinal canal are responsible for the kidney disturbance. Under all circumstances albuminuria calls for treatment, as there has been established a definite relation between this condition and a lessened development of the fœtus; albuminuria frequently has been found associated with hemorrhages into the placenta. Vallois (*L'Obstétrique*, No. 6, November 15th, 1899) reports two cases of albuminuria during pregnancy which were not severe nor permanent and were treated by a milk diet, yet were followed by fœtal death and expulsion. In both these cases the placentæ were found to be the seats of numerous hemorrhages. According to Jewett albuminuria is present in from eighty to ninety per cent. of eclamptic patients previous to the first convulsion.

Treatment of Toxœmia.—The plain indications are to diminish the amount of waste and stimulate elimination. The diet should be simplified: in mild cases it is sufficient to cut off all meat and heavy articles of food. In the severe cases and whenever there is marked albuminuria, the patient must confine herself to an exclusive milk diet. It is very uncommon for women to become eclamptic who have been upon a milk diet for two or three weeks. The milk may be taken hot or cold, and the addition of a little salt, a few drops of coffee, or some effervescing mineral water will suit some tastes.

All the emunctories should be called into play to increase elimination, and one of the advantages of the milk diet is its diuretic action. Water should be given freely either by mouth or per rectum; irrigations of the bowel with saline solution have a valuable effect upon the kidney and at the same time cleanse the intestinal canal. The use of salines each morning, with occasional doses of calomel at night, will stimulate the action of the bowels, and the skin should be made active by the use of hot-air baths, massage, and the adoption of flannel underclothes. The energy of the treatment must be proportionate to the severity of the symptoms. Abundance of fresh air is a necessary part of the treatment and the inhalations of oxygen seem to do good in many cases.

If, in spite of the preventive treatment, the symptoms continue and the condition of the urine does not improve the artificial induction of abortion or premature labor is indicated.

Vomiting.—A certain amount of gastric disturbance during the first months of pregnancy is so common that "morning sickness" has become one of the presumptive signs of the gravid state. What is designated as *simple vomiting* appears very early in gestation, perhaps during the first week or two, and ceases about the end of the third month. The patient may become nauseated and vomit on first arising in the morning or the stomach may remain quiescent until food is taken; in a few cases the vomiting takes place only at night; in others the attacks of emesis are scattered irregularly throughout the day, the vomited matter consisting of mucus, bile, and ingested food. The distinctive feature of simple vomiting is that the patient's general nutrition suffers little or not at all and the affection ceases spontaneously, having had no influence upon the course of the pregnancy.

Pernicious or Uncontrollable Vomiting—Hyperemesis.—Whenever the gastric disturbance becomes so severe that the health of mother and child is threatened it may be classed as *pernicious*. Simple vomiting may merge into the uncontrollable form by the symptoms becoming more and more intense. The patient rejects the simplest form of food or drink and in consequence makes fewer and fewer attempts at ingesting food. In the classic description of the disease by Dubois three stages are described, but it is very rare that the divisions are as distinct as he would make us suppose.

First Stage: The vomiting immediately follows the swallowing of food and there are attacks even when the stomach is empty, the ejected mucus and bile often being streaked with blood. There are epigastric pain and tenderness on pressure over the region of the stomach. Emaciation soon becomes evident, associated with increasing weakness; ptyalism and diarrhœa may appear as complications.

Second Stage: In this stage there may be an elevation of temperature caused by auto-intoxication, but more serious is the rapid and weak pulse ranging from 120 to 140. The general condition of the patient is very bad: the skin is dry, the face is emaciated, and the eyes are sunken; sordes appear on the teeth and the breath has an offensive odor; the mouth and throat are dry. The urine is scanty in amount and of high specific gravity and fœtid odor; it may contain albumin and casts. The increasing weakness of the patient is apparent in the attacks of syncope, so that she is obliged to remain in bed.

Third Stage: In this stage the vomiting ceases and there is the advent of nervous symptoms such as disturbances of vision, delirium, and hallucination; coma usually precedes death.

Pinard has pointed out that in cases of pernicious vomiting the nervous symptoms may be detected in the early stage, and that Dubois drew his conclusions regarding the febrile stage from the pulse and not from the thermometer, as that instrument was not used in medicine at the time he wrote. All of the cases do not end fatally, but the physician must not be deceived by the sudden remissions which occur even in the most serious cases and which do not indicate any permanent improvement.

The pathologic lesions are variable and more often indicate that pregnancy has supervened upon some diseased condition than that gestation is a direct cause; frequently there is no demonstrable lesion at all. Such conditions as disease of the decidua and cervix, tumors of the uterus and ovaries are looked upon by Pinard as accidental accompaniments in those cases in which such lesions are present.

Causation.—The two important elements in the vomiting of pregnancy are the condition of the nervous system and reflex stimulation. The impressionable state of the nerve centres which is a feature of beginning gestation, may permit the growing uterus to have a more profound effect during early pregnancy than later when nervous equilibrium is attained; or, the reflex from the pelvis may be heightened by the existence of some abnormality, such as a displacement, laceration, inflammation of the cervix, or new growth. Such conditions as these may account for the *simple vomiting* of pregnancy, but for the explanation of hyperemesis they are not fully satisfactory. Pinard considers that hyperemesis is a part of the symptomatology of auto-intoxication and it seems reasonable to suppose that toxins circulating in the blood may be the sole causes except in such cases in which their action is reinforced by some abnormal stimulus coming from the pelvis. It is a striking fact that even the simple form of vomiting is absent or slightly marked in those women whose excretions are naturally sufficient, or have been made so by appropriate treatment.

Prognosis.—The disease is serious in the first stage, more so in the second, and almost always fatal in the third. Death of the fœtus, or abortion improves the outlook for the patient. Gueniot found that in 118 patients recovery took place in 72 and 46 died; of the 72 who recovered, 42 either spontaneously aborted or else abortion or premature labor was induced. Of the 46 who died, 28 did not abort, and 18 had abortion or premature labor induced, or miscarriage was spontaneous.

Diagnosis.—In a case of severe vomiting the question of pregnancy must first be established and then it must be decided whether or not the gastric disturbance is due to some intercurrent or pre-existing affection. If the case undoubtedly is hyperemesis of gestation the stage of the disease must be determined.

Treatment.—Every case of simple vomiting calls for investigation, as the physician cannot know whether or not it is the beginning of serious disturbance. The adoption of Pinard's theory of hepato-toxæmia entails the examination of the urinary excretion and those medicinal, dietetic, and hygienic measures described under the heading of toxæmia. Large doses of chloral and sodium bromide per rectum may diminish the reflex action of the centres after the toxæmia has been overcome; in this same connection may be mentioned such measures as spinal douches and blisters or stimulating liniments applied over the region of the fourth and fifth dorsal vertebræ.

The local treatment consists in the correction of any abnormality discovered in the pelvis. Dilatation of the cervical canal, by means of the steel branching dilators, has been performed with the idea that some cicatricial contraction of the cervix might originate the reflex irritation. Moreau and Grailly Hewitt consider uterine displacements to be the most frequent causes of irritation; of course if any malposition of the uterus be discovered it should be corrected. Inflammation of the vagina or cervix should receive appropriate local treatment, but no local applications nor manipulation must pass the internal os and strict asepsis must be observed.

In those cases in which vomiting has continued for some time the stomach becomes so irritable that complete rest must be given it, therefore rectal feeding may be employed to advantage. The long list of drugs which are advised as gastric sedatives is an evidence of the unsatisfactory results obtained before the mechanism of the disorder was understood; the list comprises all those drugs mentioned in the text-books on general medicine for treatment of stomach diseases.

If, in spite of treatment addressed to local and general conditions, the hyperemesis continues, artificial abortion is the last resort and it is wise to adopt this measure before the patient has advanced so far in the second stage of the disease that the shock of the operation uses up her remaining strength.

Ptyalism.—When this affection develops it usually begins early in gestation and lasts until the fourth or fifth month. The discharge of saliva may be so profuse that the patient is obliged to wear a napkin or use a cup for the reception of the secretion which may amount to as much as three quarts in the twenty-four hours.

The cause of the disease is not clear; in some cases it seems to be merely sympathetic; in others there is auto-intoxication, the poison acting upon and being eliminated through the salivary glands.

The treatment of ptyalism is unsatisfactory, except when it is relieved by overcoming the toxæmia. Benefit is sometimes derived from the use of astringent mouth-washes, by the administration of tincture of belladonna or pilocarpine, and by the application of a weak galvanic current to the glands.

Dental Caries.—There is a popular saying that each pregnancy costs the woman a tooth, and it certainly is a fact that gravid women are apt to suffer from dental caries, due either to alteration in the buccal secretions or to the demand on the part of the fœtus for lime salts. At the beginning of gestation the woman should have her teeth put in order, but all extensive or painful operating should be postponed until after delivery on account of the nervous irritation. Temporary fillings, the use of dental floss and antiseptic mouth washes after meals, and the administration of syrup of lactophosphate of lime will do much to preserve the teeth during the term of gestation.

Gingivitis.—During gestation the gums may become red, swollen, and bleed easily. The disturbance comes on about the fourth month and may not disappear for one or two months after confinement. The treatment consists in keeping the mouth clean and disinfected by the use of a solution of chlorate of potassium and applying tincture of iodine to the gums.

Constipation and Diarrhœa.—On account of the pressure of the growing uterus the majority of pregnant women suffer from constipation which is a potent element in the production of toxæmia. Furthermore the loaded rectum tends to promote pelvic congestion and develop hemorrhoids. There is nothing peculiar about the treatment of constipation during pregnancy, except to utter a warning against the use of irritant cathartics which sometimes will produce uterine contractions. In a limited number of cases the patient suffers from diarrhœa instead of from constipation and under such circumstances the physician should investigate the case with the view of discovering a possible toxæmia of which the diarrhœa is but a symptom.

Disorders of the Circulatory System.—Attacks of palpitation and syncope are not uncommon during gestation and are apt to occur in nervous, anæmic women from a number of reflex causes. In the last few months of pregnancy, especially when there is overdistention of the uterus, the pressure of the fundus against the diaphragm may be the cause of the disturbance. The treatment is the same as in the non-pregnant.

Hemorrhoids and Varices.—Hemorrhoids may become very troublesome during the latter half of pregnancy, and varices of the legs or vulva, accompanied by more or less œdema, may be present. As the cause is the pressure of the gravid uterus interfering with the return flow through the veins, treatment should be palliative. Constipation should be prevented, elastic bandages applied to the lower extremities, and the patient kept in the recumbent position as much as is feasible. There is some danger of rupture of enlarged veins in the leg or vulva, so the patient should be taught how to apply a pad in order to control the hemorrhage pending the arrival of the physician.

Anæmia.—Unless the blood hypertrophies to meet the demands of the pregnant state the woman will suffer from anæmia. Many women are temporarily anæmic during the early months until the richness of the blood is established. If the blood remains impoverished, or becomes so, the usual symptoms of anæmia appear and there are a few cases on record in which the disease took the pernicious form. The routine treatment by diet, oxygen, iron, and arsenic is indicated, and in grave cases it may be necessary to bring the pregnancy to an end.

Disorders of Respiration.—Cough and dyspnœa sometimes are troublesome to the pregnant woman and the cause may be reflex or mechanical. For those cases of sympathetic origin valerian and bromides are useful, but the mechanical element cannot be removed until the end of pregnancy, although the patient may get some relief by avoiding exertion and wearing extremely loose clothing.

Disorders of the Nervous System.—Neuralgia.—The pregnant woman often suffers from attacks of neuralgia in various parts of the body. The growing uterus may press upon the pelvic nerves, especially if there be inflamatory deposits around the uterus. In other cases the pain is due to constipation which permits hardened fæces to act as irritants or produces toxæmia. In primiparæ, during the latter months, the distention of the abdominal tissues may cause suffering. The face and breasts are regions often affected.

The treatment consists in removal of the cause whenever possible: irrigations of the bowels will remove the hardened fæces and elevation of the fundus will relieve the pressure upon the pelvic nerves. In facial neuralgia the teeth should be examined for caries. The general treatment lies in overcoming toxæmia, in administering iron and arsenic as well as employing the usual hygienic means for the cure of anæmia. For the relief of pain the coal-tar products should be preferred to opium or morphine.

Herpes.—This is one of the most unpleasant nervous disorders to which the pregnant woman is liable, but fortunately it is not very common. The disease usually has appeared between the third and fifth months and in certain patients has recurred in successive pregnancies. The disorder presents no peculiarities during gestation nor does it seem to affect its course. Herpes is included among the various manifestations of toxæmia.

The treatment consists in attention to general hygienic conditions together with the administration of hypophosphates, arsenic, and iron. As local applications carbolized vaseline, dusting powders, and soothing lotions are recommended.

The Mental Disturbances of Gestation.—It is stated that eight per cent. of the cases of insanity among women originate during pregnancy, labor, or the lying-in-period, and we can understand how such may be the case when we recall the frequent alterations in the mental characteristics of gravid patients. Mental disorder is less apt to develop during pregnancy than during or subsequent to labor, but the peculiar irritability or depression present during gestation may be but the prodromal symptoms of marked melancholia with suicidal tendencies. In some cases there is merely mental confusion or stupor, and mania is much less common than melancholia. Occasionally, instead of depression, there is mental exaltation and the patient becomes very talkative, showing great activity both of body and mind.

Heredity is an important predisposing factor in the insanity of pregnancy and renders the patient extremely susceptible to such influences as toxæmia, fear of the approaching confinement, or remorse for an illegitimate conception.

The prognosis is not so bad as among the non-pregnant. In 19 cases collected by Marcé the results were as follows:

Cured after delivery	7
Worse after delivery	1
Cured during pregnancy	2
Became chronic	9

The insanity is said to have no effect upon the course of the pregnancy, although in five cases out of eleven Marcé reports the children as born dead or dying shortly after delivery.

The prophylactic treatment is very important; the physician should recognize the signs of irritability and depression and see that, as far as possible, all disturbing influences are eliminated. At the same time he should impress upon the family the necessity for constant watchfulness and anticipate any attempt at suicide. The insanity itself is managed by maintaining the patient in peaceful surroundings, by attention to the nourishment and excretions, by the use of sedatives and those drugs employed for the relief of anæmic conditions.

Œdema during Gestation.—In the last two or three months it is not uncommon for the pregnant woman to suffer from œdema of the lower extremities and vulva, associated with albuminuria, increased intra-abdominal pressure, and varicosities. Pinard has called attention to a more or less generalized form of œdema which he considers to be due to toxæmia and in which such causes as pressure, varices, and renal disturbance are absent. Stolz designated this œdema as *serous cachexia;* the infiltration of the tissues may be quite as well marked in the abdominal wall above the symphysis as in the lower extremities; in rare instances there is effusion into the serous cavities of the body.

The treatment consists in regulating the elimination, rest in bed, and a milk diet, together with the administration of iron and arsenic. In severe rebellious cases puncture of the labia may be necessary, but it is to be remembered that there is some danger of stimulating uterine contractions and that the low vitality of the tissues predisposes to gangrene and infection. The use of the trocar may be required to evacuate fluid from the chest or abdomen.

Disorders of the Genital Apparatus.—Pruritus Vulvæ.—Some gravid women suffer from an intolerable itching of the vulva and the constant scratching soon produces local lesions which intensify the irritation. The causes of the pruritus are either the local action of vaginal discharges or an irritable condition of the nerves or both combined. In bad cases the woman is prevented from sleeping and the constant torture brings about deterioration of the general health. Treatment lies in the use of warm vaginal irrigations, together with hot sitz-baths and the application of soothing lotions. A tampon of absorbent cotton introduced within the vagina and frequently changed will prevent the discharge from reaching the external parts. When the nervous element is prominent, tonic and general hygienic measures are indicated in combination with the local applications.

Vegetations upon the Vulva.—The increased vascularity of pregnancy stimulates the growth of warty masses upon and around the vulva. These growths may become as large as the fœtal head; they are of a rosy or livid color and, except upon the surface, are moist and exude a foul discharge. These so-called *venereal warts* or *condylomata acuminata* are often associated with a gonorrhœal inflammation, but there are cases in which no venereal element seems to be present, the cause being dependent upon pregnancy alone. Sometimes the tumors are sources of obstruction to the delivery of the fœtal head.

Treatment.—The extreme vascularity of the parts makes the removal of the masses during pregnancy rather a dangerous operation and also exposes the patient to the risks of abortion. When possible the treatment during gestation should be palliative by the application of antiseptic washes or astringent dusting powders. Successive portions of the growths may be touched with a glass rod dipped in nitric or pure carbolic acid. After the confinement the warts may spontaneously disappear or their vascularity be so lessened that surgical treatment is a simple matter.

Displacements of the Pregnant Uterus.—The gravid uterus may be found displaced forward, backward, sideways, or downward. The most frequent uterine displacement complicating pregnancy is retroversion.

Retroversion.—In 24,000 cases of pregnancy Martin found retroversion or retroflexion 121 times. The cause of the displacement usually antedates the pregnancy, except in those cases of acute dislocation of the organ from a fall or blow, and from the muscular exertions of lifting, vomiting, or defecating. When pregnancy develops in a retroverted uterus the organ usually becomes elevated as the increase in size takes place and, by the fifth month, is too large to occupy a posterior position. Certain conditions, however, may hinder the elevation of the fundus: the uterus may be adherent and unable to break away; an over-prominent sacral promontory may not give sufficient space for the fundus to swing upward; a tumor in the posterior uterine wall, or one superimposed, may imprison the organ. No doubt retention of urine, with the consequent distention of the bladder, is a mechanical hindrance at times. If the uterus is unable to rise above the pelvic brim either abortion takes place or the symptoms of *incarceration* show themselves. There are two varieties of incarceration, *complete* and *partial:* in the complete form the entire organ is held beneath the pelvic brim; in the partial the uterus becomes sacculated, a portion, made up of the posterior wall, remains in the pelvis, while the fœtus develops in the anterior free portion.

Symptoms.—Symptoms rarely appear before the third nor after the fifth month; after the latter date the uterus is too large to become retroverted and before the third it is too small to give rise to signs of compression. At first, owing to the increased weight of the gravid womb, the symptoms are merely an intensification of the common signs of backward displacement. There are backache, dragging sensations, feeling of weight in the pelvis, irritation of the bladder and rectum, and, at the same time, there may be considerable difficulty in emptying those reservoirs. When the displacement occurs suddenly there are no prodromal symptoms; the patient experiences a sudden pain in the lower abdomen followed by signs of pressure. After the incarceration has developed the prominent symptoms come from the urinary organs. The cervix presses upon the urethra and a cystitis results which may pass into a gangrenous form, the urine becoming foul and containing pus, blood, and broken-down tissue. The patient may have chills and fever, and the infection ascend to the kidney, causing death by uræmia. In some cases the bladder cannot empty itself and rupture occurs. If the incarceration continues the pelvic pain becomes very intense and the uterine wall may become gangrenous, leading to a termination of the case through septic peritonitis. In rare cases the fundus has been expelled through a ruptured vaginal wall and perineum.

Prognosis.—In retroversion of the pregnant uterus the prognosis is very serious unless the condition relieves itself or is promptly treated. Unless abortion occurs incarceration is always fatal if left to itself. Gottschalk's statistics, based upon 67 fatal cases of backward displacement, give the causes of death as follows: uræmia and collapse, 16; septicæmia from the bladder, 4; gangrene of the bladder, 3; rupture of the bladder, 11; peritonitis from injury of the bladder, 17. The other causes of death were peritonitis, pyæmia, and gangrene of the intestine. These figures illustrate the frequency with which the urinary organs are involved.

Diagnosis.—In addition to the presence of pressure symptoms there are certain important physical signs. On digital examination the finger detects an elastic rounded body lying in Douglas' pouch and filling more or less of the pelvic cavity; the cervix may be hard to reach or found directly behind the symphysis, the external os looking upward in cases of retroversion or more or less downward in flexion. On feeling above the pubes the fundus of the uterus is missing from its normal position and its place may be occupied by a cystic tumor formed by the distended bladder unless catheterization has been performed in advance. Per rectum more of the tumor is accessible to the finger. A retroversion must be differentiated from all those tumors which may lie in Douglas' pouch, such as an ovarian cyst, ectopic gestation, or a fibroid; a combination of tumor and normal pregnancy is particularly difficult to diagnosticate unless an anæsthetic be administered.

Treatment.—As soon as retroversion of the gravid uterus is discovered efforts at reposition must be made. The woman should be placed in the knee-chest position, a Sims speculum introduced, and the fundus pushed upward while the cervix is drawn down by means of a tenaculum; sometimes the upward pressure can be made to better advantage through the rectum. In difficult cases an anæsthetic should be administered, the patient put in the lithotomy position, and, by means of bimanual manipulation, the fundus swung *around* the promontory to the front. As soon as the uterus is in proper position tampons or a pessary must be employed until its growth has rendered it too large to enter the pelvis again. When adhesions exist three courses of treatment are at the disposal of the physician: 1. Repeated tamponade of the vagina with cotton or wool soaked in boroglyceride and ichthyol with the hope of causing gradual absorption of the restraining bands and elevation of the fundus. This method of treatment can be carried out only in those cases in which there are as yet no urgent symptoms. 2. Posterior vaginal section followed by manual separation of the adhesions and replacement of the uterus. 3. Abdominal section and manual replacement.

The choice of methods will depend upon the urgency of the case. When incarceration has developed attention must first be paid to the bladder, and if careful attempts at catheterization fail the urine must be evacuated through a suprapubic puncture. If manipulations through the vagina fail the abdomen should be opened and the fundus lifted into position. Abdominal section for the relief of incarceration has been performed twice by M. D. Mann, twice by Mouchet, and eleven times by Jacops; all the cases were successful except one of Jacops' which aborted. Artificial abortion needs to be performed but very seldom and the difficulties and dangers of emptying and draining the incarcerated uterus are much greater than those connected with the intra-abdominal method of treatment if the case is in skilled hands. Vaginal hysterectomy would be proper for those cases in which the uterine walls have become inflamed and damaged by the compression.

Anterior Displacements of the Pregnant Uterus.—These may occur in the first or last part of pregnancy. When the ovum develops in an anteflexed uterus usually the fundus elevates itself without trouble unless the uterus is bound down by inflammatory deposits, pressure from above, or the operation of ventral fixation has been performed. If the organ does not right itself there are more or less pain and disturbance of the bladder followed by abortion.

The diagnosis is made by bimanual examination, and treatment consists in elevating the fundus by the use of tampons and massage. If the uterus is fixed on account of adhesions or previous operation abdominal section would be justifiable. In the latter months of gestation an anteversion may take place from weakness of the abdominal muscles and especially from a separation of the recti. Multiparity, contracted pelvis, lumbar lordosis, and excessive distention of the uterus are all predisposing causes.

The symptoms are marked when the patient is upon her feet; she experiences discomfort and difficulty in locomotion. When the patient is standing or sitting the uterine tumor is very prominent, the fundus may incline directly forward and the external os look backward; in exaggerated cases the uterus is inverted so that its anterior surface rests against the thighs. On external palpation the fœtal parts may be easily felt, as the uterus is covered only by a layer of skin and peritoneum. The cervix may be inaccessible unless the entire hand be introduced within the vagina. In the dorsal position both the signs and symptoms disappear.

The treatment is to keep the patient upon her back as much as possible and order her to wear a well-fitting abdominal supporter. During the last weeks of gestation it is important to keep the uterus in the correct axis of the superior strait so as to insure proper engagement of the presenting part.

Prolapse of the Pregnant Uterus.—This displacement is an uncommon complication of pregnancy. The increase in weight is likely to produce a recurrence in those patients who already have suffered from this form of uterine dislocation; in rare instances blows, falls, or strains have produced a sudden descent of a uterus which heretofore occupied its normal position. As pregnancy advances usually the prolapsed organ becomes spontaneously replaced, but if such be not the case either abortion takes place or the symptoms of incarceration appear. A few authors claim that it is possible for gestation to go to term in a uterus prolapsed between the thighs of the patient.

The treatment consists in replacing and retaining the organ until danger of repetition of the displacement is prevented by the size of the uterus. If replacement is impossible and there are signs of incarceration abortion should be induced; removal of the uterus is justifiable in septic cases.

Lateral Displacement of the Pregnant Uterus.—Pathologic lateral deviations of the uterus are rare during gestation, the inclination of the fundus to the right being regarded as physiologic. Excessive lateral flexion will produce symptoms of pressure, such as œdema and pain in the leg corresponding to the side toward which the axis inclines. The chief importance of lateral deviations is their influence in producing faulty presentations or positions at the time of labor.

Relaxation of the Pelvic Joints.—In certain cases the physiologic softening of the interarticular cartilages is carried to excess and an abnormal amount of movement in the joints is permitted. The symptoms come on during the last two months of gestation and consist of pain in the region of the symphysis, groin, and lumbar region; walking becomes difficult or impossible both on account of the pain and from the effort required to maintain the proper balance of the body. Pressure over the symphysis is painful. The patient should be examined in the standing posture by introducing a finger into the vagina and pressing against the inner surface of the symphysis while the patient supports her weight first upon one leg and then upon the other; in this way the movement in the joint will be appreciable to the examining finger. The same result will be attained when the woman is lying down, by directing her to flex the thighs alternately.

Treatment.—During pregnancy a snug bandage about the pelvis will give some relief, except in bad cases when the patient must remain in bed. General tonics are sometimes beneficial. The condition usually cures itself in a month or two after labor, and during the interval a harness to immobilize the pelvis should be worn.

Traumatism and Surgical Operations during Gestation.—There are instances in which a gravid woman has suffered from severe injuries without interruption of the pregnancy and yet sometimes trifling accidents will cause abortion. The irritability of the uterus, the seat of the injury, and the amount of blood lost are important factors in affecting the result. According to Cohnstein penetrating wounds of the abdomen, without injury to the uterus, are apt to arrest gestation; but Harris has reported a case in which the abdomen of the woman, six months pregnant, was lacerated by the horn of a bull so that the omentum and intestines protruded, yet the pregnancy went to term. The existence of pregnancy seems to have no influence upon the healing of wounds, although there is evidence that the gravid state may cause retardation in the union of fractures.

Major surgical operations, such as amputation at the hip-joint, the removal of ovarian tumors and even fibroids from the uterus, do not necessarily interrupt the pregnancy. Sir James Paget summed the matter up by saying that it would be mere recklessness to operate upon a pregnant woman without good cause; yet, if good cause exists, she may be treated very successfully. Operations upon the rectum seem to be particularly dangerous as regards the risk of inducing abortion and, to a less extent, do those upon the vulva. Pregnancy is not a contraindication to removal of the breast for cancer. When fixing the date of an operation upon a gravid woman the time of the menstrual epoch should be avoided, and in all cases particular care should be taken to diminish shock and hemorrhage.

Hernia of the Pregnant Uterus.—The gravid uterus is very rarely found occupying the inguinal canal, and when such is the case the ovum usually is in one horn of a uterus bicornis. In the *Arch. f. klin. Chir.*, xlix., 4, W. Rosanoff has reported a case of inguinal hernia of the gravid uterus in which the tumor reached almost to the knee; its largest circumference measured 80 cm. After delivery he reduced the uterus into the abdominal cavity, the left ovary and a part of the left tube remaining in the canal until an operation for radical cure was performed. Rosanoff considered that in the beginning the canal was occupied by the ovary, left tube, and coils of intestine, the uterus gradually following.

Montgomery A. Crockett.

GETTYSBURG SPRINGS.—Adams County, Pennsylvania.

Post-Office.—Gettysburg. Hotels. Gettysburg is reached by the Philadelphia and Reading and by the Western Maryland Railroads (separate depots). The springs are easily accessible by street car or omnibus. Two prominent springs, known as the Gettysburg "Katalysine" and the Gettysburg "Lithia" Springs, are reported by the Government Geological Survey. The following remarks refer to the former, as we have not been able to gain any recent information concerning the Lithia springs. The Katalysine Springs are located in a picturesque valley a short distance west of the town. It is said that the great battle of Gettysburg began in the immediate vicinity (Walton). The following analysis of the Katalysine water was made by Professor Genth, of Philadelphia:

One United States Gallon Contains:

Solids.	Grains.
Sodium carbonate	0.22
Magnesium carbonate	.33
Iron carbonate	.02
Manganese carbonate	Trace.
Calcium carbonate	5.02
Sodium chloride	.66
Lithium chloride	Trace.
Potassium sulphate	.21
Sodium sulphate	.25
Magnesium sulphate	6.78
Calcium sulphate	.83
Calcium phosphate	Trace.
Calcium fluoride	Trace.
Magnesium borate	.03
Silicic acid	.20
Organic matter, with trace of nitric acid, etc	.70
Impurities suspended in water, like clay, etc	1.10
Total	16.35

In addition, traces of carbonate of copper, sulphate of strontium, alumina, carbonate of nickel, carbonate of cobalt, and sulphate of baryta have been found. This water is said to be efficient in gout and rheumatism, and has proved of value in gravel, catarrh of the stomach, and dyspepsia. The combination of an alkali with the salts of lime, as observed in this spring, is a very valuable one. The water is used commercially.

GEUDA SPRINGS.—Cowley County, Kansas.

Post-Office.—Geuda Springs. Hotel and boarding-houses.

The Geuda Mineral Springs are located on the St. Louis and San Francisco Railroad, one mile distant from the Arkansas River and eight miles north of Indian Territory. The town of Geuda Springs, which has about 800 inhabitants and is rapidly growing, is pleasantly situated at the edge of a beautiful and undulating plateau, which is everywhere dotted with fine farms and neat farm-houses. The elevation above the sea is about 1,400 feet, and the atmosphere is pure and wholesome. The winters are short and open, making constant outdoor exercise possible. There are very few hot days in the summer, the thermometer rarely extending above 100° F., but, as a rule, the days are balmy and the nights cool and refreshing. The springs are seven in number, and bubble up in a space less than twenty feet square. Near the springs is a beautiful lake of salt water, with an area extending to the westward nearly two miles, and another to the southward nearly half that distance. The evaporation of the water causes the beach to be covered with pure, crystallizable salt. This picturesque body of salt water, constantly fed by salt springs, furnishes fine advantages for bathing. The lake bottom is hard and sandy, and bathers can secure any depth of water desired. A commodious bath-house in connection with the springs affords opportunities for any variety of bath which may be desired. Following is a detailed analysis of the seven springs by Professor Bailey, of the Kansas State University:

These waters may be classed as belonging to the muriated and sulphated-saline variety (carbonated). They have found their most suitable application in liver, kidney, and stomach disorders, general debility, anæmia, and rheumatism. Some of the springs have gained considerable celebrity in the local treatment of conjunctivitis, indolent ulcers, leucorrhœa, etc.

GEUM. See *Avens.*

GIANT CELLS.—These are very large cells of mesenchymal origin, often many times as large as other cells with which they are associated. They frequently have many nuclei—sometimes as many as two hundred,—or a single nucleus which may be deeply lobulated or "beaded," that is, broken up into a number of portions connected by threads of nuclear material. But the giant cell is sometimes distinctly mononuclear and on the other hand there are in the body many polynuclear cells, such as the ordinary polymorphonuclear leucocytes and the striated muscle fibres, which cannot be classed as giant cells. Therefore the important point in the definition is the size rather than the number of nuclei.

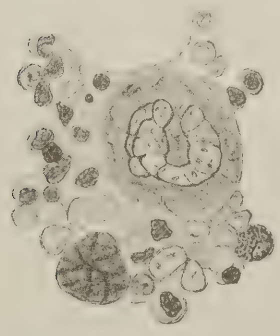

FIG. 2294.—Bone Marrow, Showing Giant Cells. × 830.

As to their origin, it is not probable, as has been believed, that they ever arise by the fusion of small mononuclear cells. Occasionally, under artificial conditions, cells without cell walls may fuse, but the formation of a true syncytium is rare and the appearance is generally due to faulty technique (Henneguy). It is more probable that each giant cell begins as a single mesenchymal cell in which growth continues while the process of division fails or is not completed. Nuclear division, when it occurs, usually follows the direct or amitotic method, though the indirect or karyokinetic may be seen. Nedjelsky, who studied chiefly cell division in malignant growths, describes different varieties of amitosis in which the separation, partial or complete, usually began in the nucleolus, and later often failed to involve the rest of the nucleus or the protoplasm. A multinuclear giant cell may subsequently divide into a number of small mononuclear cells.

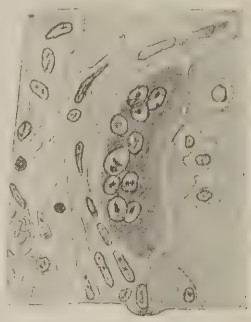

FIG. 2295.—From Section of Snout of Embryo Pig, Showing Osteoclast. × 410.

Without attempting to ascribe a common function to all giant cells we may safely assert that there is often evidence of phagocytosis. Thus in tuberculosis the giant cells often contain bacilli; in tumors degenerating elastic fibres may be seen in them; and in the case of the osteoclasts they undoubtedly play an important part in the removal of lime salts in developing and growing bone. Phagocytosis is even more clearly seen in the giant cells which are found in the neighborhood of foreign bodies.

Giant cells occur most commonly in connection with reticular and related tissues and in the blood-forming organs. Normally they are perhaps most familiar in marrow. Here, away from the bone, are large giant cells with partially divided and irregularly lobulated nuclei, and also large masses of nuclear matter having an obscurely reticulated structure and not appearing to be surrounded by protoplasmic bodies. Close to the bone are osteoclasts, large cells with few or many nuclei, apparently completely divided. They lie in shallow excavations in the bone, Howship's lacunæ. Their action leads to the destruction or dissolution of the adjacent calcareous matrix.

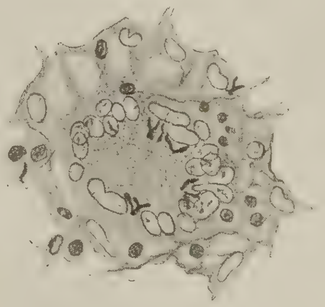

FIG. 2296.—Portion of a Tubercle, Showing a Giant Cell Containing Bacilli. × 410.

In the spleen we can recognize large mononuclear cells, in which the presence of red corpuscles suggests phagocytosis. These cannot properly be called giant cells; but in the young of many animals and in the embryo the spleen contains larger cells with lobulated nuclei (megacaryocytes)—not as a rule to be found in the adult. Giant cells are also described as occurring in hæmolymph glands and in the embryonic liver.

Pathologically, giant cells are more widely distributed. They arise from fixed tissue cells of the diseased part, connective-tissue cells, or endothelial cells of blood and lymph capillaries—not, as some have believed, from leucocytes. Multinucleated forms are seen in hyperplastic and regenerative growth of connective tissue. They occur in tumors, especially in sarcomata originating in the marrow or periosteum. Large polynuclear forms may also be seen in the vicinity of foreign bodies, which they enclose in their protoplasm if small, and whose dissolution they otherwise tend to bring about.

Perhaps their most familiar occurrence is in tuberculosis. Here, though not always present, they are often large and prominent and are important landmarks in the identification of the disease. They occupy the centres of miliary tubercles. Their nuclei are very numerous, completely divided and commonly arranged about the border of the cell or gathered into unequal or irregular groups at the poles. They often have protoplasmic processes, whose relation to the reticulum is not at present clear. They may have necrotic centres and contain tubercle bacilli. *Ralph C. Larrabee.*

GILROY HOT SPRINGS.—Santa Clara County, California.

Post-Office.—Gilroy Springs. Hotel. These springs are located on the Coyote River, nine miles northeast of the town of Gilroy, in the Santa Clara Mountains. They are reached by the Southern Pacific Railroad to Gilroy, and from thence by stage over a picturesque mountain road. The springs lie nestled in among the mountains, surrounded by fragrant forests of spruce and pine. The atmosphere is rich in ozone, and the climate very genial. There is one main spring, which flows in great abundance. The temperature of the water varies from 108° to 115° F. Anderson's analysis:

One United States Gallon Contains:

Solids.	Grains.
Sodium chloride	31.75
Sodium carbonate	1.42
Sodium sulphate	.75
Potassium iodide	Trace.
Potassium sulphate	2.16
Magnesium carbonate	2.45
Magnesium sulphate	9.04
Calcium chloride	8.50
Calcium sulphate	2.70
Ferrous carbonate	.26
Ferrous oxide	Trace.
Arsenic	Trace.
Silica	3.31
Organic matter	.52
Total solids	62.86
Gases.	**Cubic Inches.**
Free carbonic acid gas	12.17
Free sulphureted hydrogen	9.25

The analysis shows a light alkaline-sulphureted water. It is used with considerable benefit in syphilis, rheumatism, and tuberculosis, in glandular swellings, in chronic skin eruptions, etc. The water is also used for bathing, for which excellent facilities have been constructed. *James K. Crook.*

GINGER.—Zingiber. The rhizome of *Zingiber Zingiber* (L.) Rusby (*Z. officinale* Roscoe, U. S. P.) (fam. *Zingiberaceæ*). This plant belongs to a remarkable order of tropical perennial herbs with horizontal, fleshy, often lobed and branched rhizomes, more or less developed upright stems, with two-ranked, alternate, parallel-nerved, sheathing leaves, and, theoretically, trimerous, irregular flowers in various clusters.

The flowers vary greatly in color, from nearly white to a purplish-blue. The richer the soil, the better the ginger, and the product of newly cleared land holds a special place in commerce. It is probably a native of Southern Asia, but is not known wild, having been cultivated for many hundred years. It has also been transplanted to tropical Africa and the West Indies, besides many other places, where it is extensively cultivated.

It has been used as a spice, even in Europe, almost since the beginning of this era, having been imported from the East by way of the Red Sea. The plant was carried to the West Indies soon after the discovery of the New World, and a few years later ginger was exported from St. Domingo back to Europe.

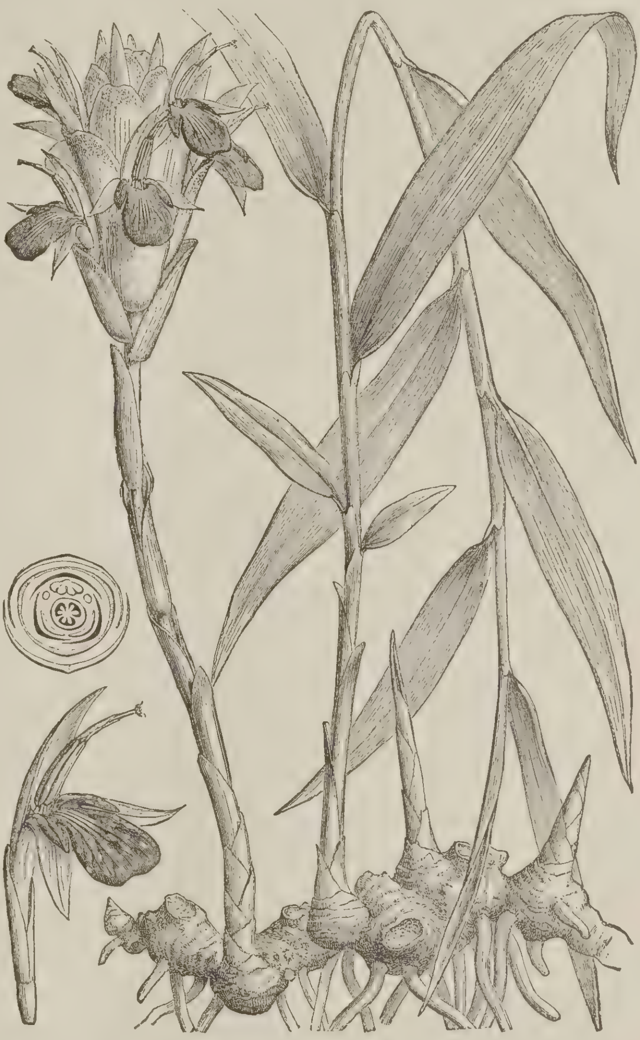

Fig. 2297.—Ginger Plant about One-third Natural Size. (Baillon.)

Description.—Ginger is either coated, that is, simply washed and dried without removing the cuticle, or else scraped, when the outer surface is peeled or scraped away. When the bark is stripped from the two flat sides, it is known as "half-coated." It is in pieces technically called "hands," "about three-fifths of an inch broad, flattish on one side, lobed or clavately branched; deprived of the corky layer (peeled ginger), pale buff-colored, striate, breaking with a mealy, rather fibrous fracture, showing numerous small, scattered resin cells and fibrovascular bundles, the latter enclosed by a nucleus sheath; agreeably aromatic, and of a pungent, warm taste." When ginger is not peeled it has a grayish or brownish wrinkled surface. Inferior and dark-colored grades are sometimes bleached with sulphur, chlorinated lime, etc., or are even "whitewashed" with chalk and water, or some such mixture, to give them a whiter and more salable appearance. This treatment also protects them against the attacks of insects. The relative commercial and medicinal values of ginger do not agree. For medicinal purposes it is better with the very active rind left upon it, but its commercial value depends more upon its ability to yield a clear, light-colored preparation, which is true of the peeled articles. The principal varieties in the order of their estimation are Jamaica, Cochin, and African. The last, though the cheapest, contains the largest amount of active constituents, and is to be preferred for medicinal use.

Composition.—Ginger contains a pale yellow *volatile oil* to the extent of about one or two per cent., having its odor and taste without its pungency. The remaining constituents are a composite *resin*, besides the real source of its pungency, *gingerol*, which, however, is not volatile or aromatic. Twenty per cent. of starch, fat, gum, and various amorphous and uninteresting substances make up the rest. The oil and resins are contained in cells resembling those of the parenchyma, and irregularly scattered among them. The ethereal extract (*Oleoresina Zingiberis*, U. S. P.) is composed of these resins in combination with the essential oil, fat, etc., and is yielded by different varieties to the extent of five to ten per cent.

Action and Use.—Ginger is a spice more aromatic and less pungent than pepper, and, like others of its class, in suitable dose is gently stimulating to the stomach and intestines, and in its way a carminative tonic. In large doses it is irritating; locally applied to the skin it is rubefacient to a less degree than mustard, and useful where a mild counter-irritation is desired. It is used in colics, atonic dyspepsia, flatulence, etc., and is a favorite flavor for cakes, drinks, and preserves.

Administration.—In powder the dose may be taken as from 0.5 gm. to 1 gm., usually mixed with other aromatics. An infusion, under the name of "ginger tea," is a favorite preparation in the country. A fluid extract is official (*Extractum Zingiberis Fluidum*, U. S. P.), but not much used. The tincture (*Tinctura Zingiberis*, U. S. P.) is in universal employment; its strength in this country is twenty per cent. The *oleoresin* or ethereal *extract* (*Oleoresina Zingiberis*, U. S. P.) is a very concentrated form suitable to add to pills and boluses. Dose, a decigram or so. The official syrup contains three per cent. of the fluid extract, and the troches each about three minims of the tincture, with a little of the syrup. Ginger also enters into the compound rhubarb powder and the aromatic powder, both official.

A little of the preserved ginger of the shops makes a delicious and wholesome addition to the meal.

The alcoholic preparation popularly sold under the name of "Jamaica Ginger" is used to some extent, especially in mining communities, as an intoxicant. The cerebral effects have not been suitably studied, but are markedly distinct from those of ordinary alcoholism, there being narcotic effects apparently due to the ginger itself. A number of cases of blindness may be due to the employment of methyl alcohol. *Henry H. Rusby.*

GINGER, OIL OF.—This is an article of commerce, possessing the odor and flavor, but not the pungency nor full physiological effects, of ginger. It is pale yellow, with a specific gravity of 0.880 to 0.885, and contains camphene as one of its active parts.

Henry H. Rusby.

GINSENG.—A name applied to the roots of several species of *Panax* L. highly prized in superstitious Chinese medicine, and chiefly so used, though they have some mild aromatic properties (see *Araliaceæ*). The original Ginseng ("Schin-Seng") is *P. Ginseng* C. A. Meyer, of China, never seen in commerce here. The American variety, from *P. quinquefolium* L. (*Aralia q.* Decne), is chiefly exported to China and is bought eagerly, at high prices, by Chinese merchants for that purpose. It used to be very abundant in rich forest lands of the Eastern United States, but has been largely exterminated, except in remote sections. It is of very slow growth and, when well developed, presents two principal branches, and occasionally a small intermediate one. From this peculiar form, it is regarded as effective in determining the sex of the unborn child, whence its high repute in China. It contains considerable gum and starch and a little volatile oil and resin and the peculiar, but apparently inert, sweetish substance *Panaquilon*, soluble in alcohol and water. Obviously, there is no dose for so inactive a drug. *Henry H. Rusby.*

GLANDERS.—An infectious disease caused by the Bacillus mallei and characterized by foci of inflammation, often assuming nodular form, in the skin, subcutaneous tissue, muscles, and lungs. The disease is most commonly found in the horse; the cases in man arise by infection from the horse or some member of the Equidæ. According to Hecker,[1] the disease was first described under the name malleus in the fourth century. The first reliable observation of the disease in man was made by Schilling in 1821, and this was followed in 1837 by a monograph by Rayer[2] on the human form of the disease. The idea that the disease was contagious was held by all the early writers, and it was not until 1749 that Lafosse[3] affirmed it to be a spontaneous disease not transmitted by contagion. In 1840 the contagiousness of the disease was definitely established by animal inoculation.

The Bacillus mallei was discovered by Löffler and Schütz[4] in 1882. They isolated the bacillus in pure cultures, and by animal inoculations proved that it was the cause of the disease. The bacillus is slightly curved, not quite so long as the Bacillus tuberculosis, but somewhat thicker than this. The ends are rounded. It is non-motile in fluid cultures. It is a facultative anaërobe. In old cultures various involution forms are seen. The bacilli may grow out to long rods with irregular swellings along them, or they may form chains of small granules resembling cocci. In cover-glass preparations made from the lesions the bacilli usually appear somewhat longer and thicker than the tubercle bacilli, and show numerous sharply defined, clear, or faintly stained areas in their protoplasm. According to Csoker,[5] there are five pale and five dark points in each bacillus. They grow readily on most of the culture media, and have a characteristic growth on potato. On potato, after thirty-six hours in the incubator, a rather thick, colorless viscid growth appears which soon assumes a brownish tint and resembles honey in appearance. Later, the brown color changes to a dark reddish-brown, and the growth becomes thicker and more opaque, while the potato takes on a dark gray color. No other organism produces on potato exactly the same growth. The bacillus of glanders is one of the most easily destroyed of all the micro-organisms, and to this is probably due the relative infrequency of the disease. In pure cultures the bacilli die usually at the end of a few weeks, and they lose their virulence by the eighth day. Being vegetative forms only, heating to 55° or 60° C. for a few minutes destroys them. They are destroyed in the pus in forty-eight hours, when this is dried in a thin layer, and under the best conditions they will not stand drying more than three weeks. They are also very susceptible to the action of germicides. The bacilli are decolorized by the Gram stain. They easily stain in the basic aniline colors, but are easily decolorized. In sections they may be stained by Löffler's solution, but are less intensely stained than the nuclei of the cells. From the impossibility of staining them intensely it is often difficult to demonstrate them in tissues even when they may be present in considerable numbers.

A substance to which the name mallein is given is obtained from cultures of the bacilli. When this is injected into an animal affected with glanders in any form a characteristic reaction is produced which is diagnostic. This substance was prepared in 1888 by Helmen, a Russian veterinarian. Its diagnostic value was first demonstrated in 1891 by Kalming, of Dorpat, who became infected with the bacilli in the course of his laboratory experiments, and died of glanders.[5] Since this time its use as a diagnostic agent has become general. The mallein is obtained by the sterilization and filtration of a virulent culture of the bacilli in glycerin bouillon. The culture should be one month old. The filtrate is then evaporated to one-tenth of the weight of its volume, which gives a brownish syrupy fluid, and this is diluted ten times with one-half-per-cent. solution of carbolic acid. The dose is 0.5 cm. of the undiluted, or 5 cm. of the diluted solution. When this dose is injected subcutaneously into a healthy horse no reaction is produced. In a horse with glanders the injection is followed by extensive œdema of the subcutaneous tissue around the point of injection, chills, and an elevation of temperature which begins some hours after inoculation, reaches 3-4° C. above normal in twenty-four hours, and persists for several days. The method is especially important in making possible the diagnosis of latent glanders in which no lesions are evident. It is absolutely sure as a means of diagnosis when certain precautions which have been formulated by Nocard[7] are observed. The reaction can be considered typical only (1) when there is fever of from 1 to 5 degrees Centigrade; (2) when there is a large, hot, sensitive œdematous swelling around the point of injection; (3) when there is a general affection shown by weakness, loss of appetite, and muscular trembling. If there is no reaction, it is proof that the animal is not affected. It is necessary to see that the animal has no fever at the time and that afterward it is not exposed to weather conditions which may affect the temperature. In some of the animals which show the reaction there may be very insignificant lesions consisting only of a few small nodules in the lungs.

McFadyean[8] considers the local reaction of the most importance and sufficient alone for the diagnosis. In healthy horses there may be a slight local reaction, but the swelling is rarely more than three inches across and reaches its acme in from fourteen to sixteen hours. In infected horses the swelling is rarely under five inches across, often twice this, and continues to increase for twenty-four hours.

The ass is the most susceptible to natural infection, and the disease assumes a more acute form in this animal than in the horse. The mule is also more susceptible than the horse. Field mice are very susceptible, while white mice and rats are immune. Cats, guinea-pigs, squirrels, and rabbits are all susceptible in the order named; sheep and goats are less susceptible; dogs, birds, with the exception of the dove, beef cattle, and hogs are immune. Natural infection is very rare except in the Equidæ and in man. Lions and other carnivorous animals in menageries have been infected by feeding on the flesh of glandered horses.

In the horse various forms of the disease may be recognized, dependent upon its situation and acuteness of course. In the acute form the period of incubation is short. The disease begins with intense fever preceding all local manifestations. The prostration is extreme, the animal is insensible to excitation, locomotion is painful, the hair is rough, and there are muscular twitchings of the shoulders and chest. Appetite disappears completely, cold water is drunk greedily, and emaciation is rapid and extreme. According to Nocard,[9] the loss in weight may be more than 20 kgm. in twenty-four hours. These primary symptoms give place in from one to three days to the specific local symptoms. The lesions are in the mucous membranes and skin. The mucous membrane of the nose is intensely reddened or often of a violet tinge, and small ecchymoses may be seen. An abundant secretion flows from the nostrils; at first it is thin and watery, but later it becomes muco-purulent and often contains streaks of blood. In the swollen mucous membrane small pustules appear which open and give rise to small shallow ulcers, with raised edges and a bright red base. These ulcers rapidly enlarge, they become confluent and give rise to large irregular ulcerated surfaces covered with muco-pus. The ulcers are sometimes formed by the rupture of œdematous areas beneath the surface. In these areas extensive destruction of tissue seems to take place without any reaction, the softening finally extending to the surface. When the ulceration is advanced the nasal discharge is very abundant and contains fibrinous coagula and portions of necrotic tissue. While these lesions are taking place in the mucous membranes, hot painful tumors appear in various places, especially on the extremities, the flanks, and the shoulders. The œdema about them disappears, leaving hard, solid nodules which ulcerate rapidly. The ulcers become confluent, forming large irregular surfaces which produce an abundant, thin, odorless, often bloody pus. A similar infiltration extends along the course of the neighboring lymphatics, leaving hard cord-like swellings which ulcerate at various points and form thinner chains of ulcers uniting the larger. The lymph nodules belonging to the affected regions become swollen and indurated, finally breaking down into abscesses. The disease owes its name to the frequency with which the affection involves the lymph nodes (lymph glands). During this period the temperature continues high, often reaching 42° C. The loss of appetite and emaciation continue, there appear evidences of occlusion of the nasal respiratory passages, and at the last either general œdema of the lungs makes its appearance or foci of pneumonia develop. The acute form of glanders is always fatal, the disease lasting from eight to thirty days.

The chronic variety of the disease does not take the definite course of the acute, and may assume a number of forms which differ so much the one from the other that they have been regarded as different diseases. Thus the skin lesions have been considered a separate disease under the name of farcy. In the two classic types of the chronic form the predominant lesions are found in the one in the skin, and in the other in the mucous membranes and parenchymatous organs. The chronic lesions are of the same general type as the acute, their evolution is much slower, and their special characteristics are better marked. The first lesions to appear in the skin are the hard nodules (farcy buttons) followed by ulceration. Hot, painful, œdematous tumors appear in various places in the subcutaneous tissue, especially where the skin is thin and the subcutaneous tissue abundant. These tumors may be the size of a nut or of an egg. Gradually they become smaller in size by the absorption of fluid, and the central mass becomes hard and definitely circumscribed. The hair falls out, the skin becomes thinned, and finally an abscess is formed which contains a viscid yellowish liquid streaked with blood. The opening does not close, and the abscess gives rise to an ulcer. The edges of this are elevated and covered with thick granulations. The ulcer may extend laterally or in depth, both by continuous extension and by the formation of neighboring nodules which follow the same course and finally unite with the main ulcer. The skin in the vicinity is hard and indurated. The ulcers may finally cicatrize. The same swelling which preceded the formation of the nodules and ulcers extends along the subcutaneous lymphatics. The acute swelling subsides, leaving a hard cord (farcy pipe). A number of lymphatics may be affected, giving rise to a network of cords. These may persist for a long time without change, or in some cases nodular swellings appear along them at intervals, and these nodules may soften and ulcerate in the same way as the nodules first described. The ulceration may extend between adjoining foci along the course of the vessel and in this way large irregular ulcerated tracts may result. The lymph nodes are swollen and become finally converted into hard, indurated, adherent masses. They rarely soften and give rise to abscesses as in the acute cases.

The specific affections of the nose are very similar to those in the skin, with differences due to the different character of the tissue. They consist in the formation of nodules and in ulceration which may terminate in extensive cicatrization. The nodule is preceded by a diffuse swelling of the tissue. The nodules are round, hard, and much smaller than those of the skin. The centre softens and is discharged, leaving a shallow irregular ulcer with elevated edges. Large irregular ulcers are formed by the union of adjoining ulcers. The edges are hard and indurated, and cicatrization is often found in one part while the ulcer is extending in another. Dense white radiating cicatrices are found, and these are the most characteristic lesions of the disease (Fig. 2298). The ulcers may extend in depth, both cartilage and bone may be destroyed, and perforation of the septum may be produced. The nasal discharge varies in character and amount, depending on the character of the lesions. It is more abundant while the animal is at work. In the beginning of the process it is thin and watery, but later it becomes muco-purulent. In some cases a lymphatic fluid is discharged which coagulates on exposure. When the ulceration is marked it may contain necrotic tissue, and when large vessels are opened by the extension of the ulcers there may be epistaxis. The lesions in the lungs which may be very extensive, do not give rise to any characteristic symptoms. There may be cough and evidence of respiratory trouble, and when the pleura is involved in the process there may be the physical signs denoting this.

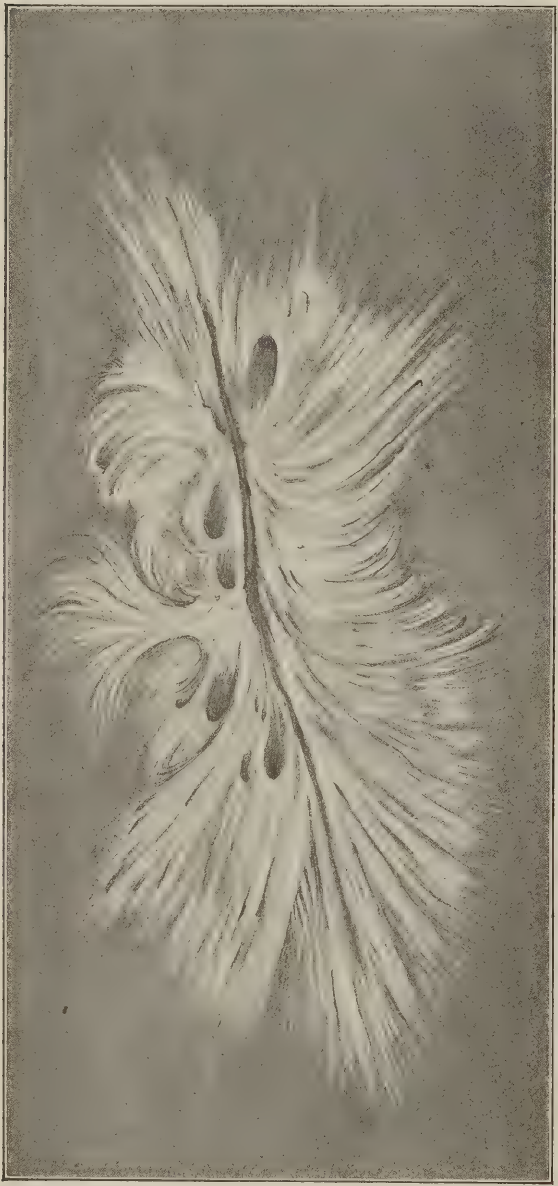

FIG. 2298.—Stellate Cicatrix from Nasal Septum. From a case of chronic glanders. (Kitt.)

In addition to these more common conditions of chronic glanders there are others which are only occasionally met with. A diffuse swelling of the subcutaneous tissue, at first hot and painful, later indurated and contracted, much resembling the nodule in its general features, may take place. The induration becomes brawny and may ulcerate at several points. In stallions swelling of the testicle is often seen and may form the first symptom of the disease. The gland is at first greatly enlarged, hot, and painful. The acute swelling and œdema subside after some days, and then the gland is felt to be indurated and the cord thickened. Affections of the joints varying in degree are not uncommon. The disease may last for an indefinite time. Often all the symptoms disappear for a long time and then again break out. A considerable proportion of the cases end in recovery. Semmer[10] has described a rather benign form of glanders which he thinks is more common in South Russia than elsewhere. The animals react to mallein in the same way as in the malignant disease, but very slight lesions are found at the autopsy.

When the disease is produced experimentally in the horse or ass by introducing the bacilli into scarified surfaces or by injecting them subcutaneously, the acute form is produced. Strauss[11] in 1886 showed that the intraperitoneal injection of the bacilli in the male guinea-pig was followed by characteristic lesions, and this method is one of the best and surest for confirming the diagnosis of the disease. Inoculation into the peritoneal cavity is followed, on the second or third day, by a recognizable degree of swelling of the testicles. The swollen testicles are painful, and the skin of the scrotum is red or violet and adherent to the underlying glands. The lesions reach the greatest intensity by the sixth or eighth day, and the animal dies in twelve or fifteen days. The method is not absolutely sure as a diagnostic test, and for several reasons. Nocard[12] has shown that an affection of horses, characterized by swelling and ulceration of the extremities, is due to a bacillus which will produce lesions in the testicle similar to those observed in glanders. In other cases the guinea-pig may die of septicæmia due to entry of the bacilli into the blood before the characteristic lesions of the testicle have had time to develop. For this reason some prefer to inoculate subcutaneously.[6] The inoculation had better be made with a pure culture than with the products of disease containing the bacilli, for the glanders lesions may be masked by an infection with pus organisms. In an early stage the lesions of the testicle consist in small, yellowish foci in the tunica vaginalis, or the two surfaces may be united by a thick purulent exudation containing numbers of bacilli.

In man the disease appears in both the acute and the chronic form. Taken in its entirety the clinical history of the disease, both in the acute and in the chronic form, is almost characteristic, but at a given period, and indeed for a long time, it may be impossible to make the diagnosis. This is particularly true of the chronic form. In general, the disease in man presents many points of similarity to the equine disease, but there are notable differences. The skin lesions which are so prominent in the horse appear in man only in the later stages of the disease, and abscesses in the muscles (which are very rare in the horse) are common in man and often constitute the first evidence of the disease. The disease is comparatively rare in man despite his evident susceptibility to the action of the organism and his frequent opportunities for infection. In the last ten years in Boston I have seen but two cases of infection in man despite the fact that the disease is not rare in horses. The fact that the disease is not an extremely common one in both animals and man must be attributed solely to the slight viability of the organism and to the fact that it cannot lead a saprophytic existence.

The acute disease begins in man with chills and high fever, which sometimes takes a typhoid form. There is often intense pain in the joints and muscles, with general weakness and malaise. This condition is followed by the development, in the muscles or subcutaneous tissue, of hard swellings which rupture and discharge a thick mucoid pus mixed with streaks of blood. Even at an early period of the disease the skin over almost the entire body may be covered with pustules. In some cases there is a diffuse erysipelatous inflammation of the skin preceding the formation of pustules, or large ulcers may be formed by necrosis of the skin. The ulcers show no tendency to heal and become covered with thick, pale granulations. The nasal discharge is not so marked as in the horse, but an examination of the mucous membrane will rarely fail to show nodules, ulcers, and diffuse swelling. In two of Küttner's[13] cases the frontal and sphenoidal sinuses were affected, the most evident lesion being the great swelling of the mucous membrane. The muscle abscesses are usually present. Although all the muscles may be affected, the lesions are most common in the biceps, the flexors of the forearm, the rectus, and the pectoral muscles. The pustules of the skin are most common toward the termination of the disease and often appear only just before death. The pustules may be seated immediately beneath the epidermis in the corium or in the subcutaneous tissue. They may somewhat resemble smallpox pustules, but they vary greatly in size and are not umbilicated. Tedeschi[14] has reported a case in which there was a terminal acute meningitis. In some cases it is possible to find the atrium of infection. The disease may begin by abscess and ulceration at this point and the generalization take place by an acute lymphangitis. In many cases, and those the most severe ones, it is not possible to determine how the infection took place. This acute form of the disease is almost invariably fatal, death taking place usually between the sixth and the thirtieth day of the disease.

The chronic form may have a duration of several years. Hallipeau[15] has reported a case of six years' duration. The well-known case of Aufrecht, reported by Kernig,[16] lasted for one year and a half. In these cases there is usually an infection from a local lesion of the extremities followed by a lymphangitis extending to the lymph nodes. The local lesion may take the form of an ulcer; and abscesses may develop, followed by ulceration, the infection extending along the lymphatics. The hard cord-like affection of the lymphatics which is seen in the horse, does not take place in man. Later, abscesses appear in the subcutaneous tissue or in the muscles in various places. In some cases these muscular abscesses form the only evidence of the disease. In the case reported by Hallipeau there were numerous abscesses at intervals during the first three years of the disease, but they did not exert much influence on the general condition. These healed spontaneously in some cases, and in others after cauterization. There was then a period of latency for three years, followed by an acute attack and death. In the case reported (Kernig) the first anatomical evidence of the disease was a hard nodular swelling in the calf of the leg. This was followed after a long interval by an infiltration of the abdominal wall resulting in suppuration. Sommerbrodt[17] gives a case in which the symptoms were chills with fever and intense pain in the extremities. Two weeks after entry into hospital death took place from acute glanders. In the case reported by Neisser[18] the disease began as a small ulcer at the internal angle of the eye, and this was followed in two months by the development of an abscess in the left cheek; then later a purulent discharge from the ear and nose set in, abscesses developed in different parts of the body, and ulcers formed on the hard palate, in the nasal cavity, and in the larynx. In nearly all of the chronic cases reported the disease passes into an acute form a short time before death. The most common lesion in fatal cases of both the acute and the chronic form, consists of pustules of the skin, particularly on the face. Chronic glanders has a very much smaller mortality than the acute, Sims Woodhead[19] placing it at forty per cent.

The characters of the lesions are similar in both animals and man. The glanders bacillus seems to exert about the same influence on all tissues, and the lesions vary only in the intensity of the action set up and in the different degree of reaction of the surrounding tissues. There has been a general misconception among German authors as to the character of the lesions. Virchow, who studied the macroscopic character of the lesions more than the histological details, lays particular stress upon the nodular character of the lesions, and places the disease among the granulation tumors. Baumgarten compares the nodule with the tubercle, and says that it differs from this, as regards its histogenesis, chiefly in the participation of the polynuclear leucocyte in its formation. In the glanders nodule the polynuclear leucocytes play the part that the lymphoid cells do in the tubercle, the main mass of the nodule in both being formed of epithelioid cells derived from the fixed cells of the tissue. The anatomical descriptions of the lesions given by French authors are more correct. An excellent account of the histology and the histogenesis of the lesions in man and in the guinea-pig is given by Wright.[20] I have been able to study the lesions in the horse by aid of a number of specimens furnished by Dr. Frothingham and by the examination of preparations secured by Drs. Wright and Magrath from human cases autopsied by them.

The most characteristic lesions in the lungs are the nodules or tubercles. These are found more frequently, and their characteristics are better marked, in the horse than in man. They may be found in any part of the lung, but are more numerous beneath the pleura than elsewhere. In their most characteristic form they vary in size from a pin's head to a pea, and are hard and circumscribed. On section they show a dry, opaque, central mass, which can often be pressed out, surrounded by a pale transparent zone (Fig. 2299). On microscopic examination the centre is found to be composed of granular *débris* in which no tissue can be recognized. On the outside of this is a zone composed of epithelioid and giant cells with considerable lymphoid infiltration and firm

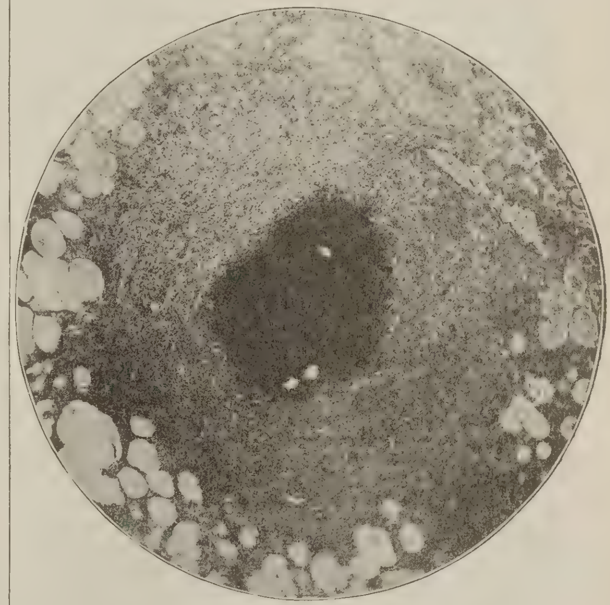

FIG. 2299.—Section of Chronic Glanders Nodule in the Lung of Horse. The dark central mass is composed of cell and nuclear débris in which no lung structure can be recognized.

intercellular connective tissue. Immediately around the central mass of *débris* is often a mass of large phagocytic cells similar to the cells in the corpus luteum. On the outside the connective tissue extends into the surrounding lung structure as a thickening of the alveolar walls. In some of these nodules the central necrotic mass may be extremely small or it may be absorbed completely by the surrounding granulation tissue, the entire nodule being transformed into a small mass of connective tissue. Lime salts may also be deposited in the necrotic centre. The histogenesis of this more fully developed nodule, which very much resembles a tubercle, can be studied in those less advanced. Such a nodule is seen in Fig. 2300. In this the structure of the lung is preserved in the centre, and around this is a definite zone of connective tissue. In the dark central area the tissue is entirely necrotic, and the cells both in the exudation and in the walls are broken down and represented by nuclear detritus. In the tissue around this the necrosis is not so complete, and there is some thickening of the alveolar walls due to the formation of connective tissue. This passes in turn into the surrounding connective-tissue capsule. A more diffuse and earlier nodule is shown in Fig. 2301. In this there is a centre which is situated in close proximity to an interalveolar septum in the lung, and which is composed of a dense cellular exudation in the alveoli. All the cells in the exudation are broken down, the dark color of the centre here as in the other figures being due to the immense amount of nuclear detritus. In the surrounding alveoli there is an exudation composed of fibrin, of fragmented leucocytes, of coagulated serum, and of effused blood. In all of the younger nodules hemorrhages play an important part, and we may find areas represented by hemorrhages alone. Fig. 2302 shows a much larger area in which there are several centres filled with the closely packed nuclear detritus and around these there is an exudation similar to that in Fig. 2301. Nocard lays great stress on the presence, in the early cases, of small, rather transparent nodules in the lung close beneath the pleura. They may appear as early as on the third day after infection. They are formed by a small area of exudation surrounded by intense hyperæmia and hemorrhage. One thing is striking in the examination of all these nodules: they are not in relation to the bronchi. In all of the figures bronchi but little altered can be seen in the vicinity of the nodules. In the material at my disposal it has not been possible to trace the formation of these masses by serial sections, but they do not appear to be due to a bronchiogenic infection of the lung by the bacilli. They occur in the lung with too great regularity and at too early a stage to suppose them due to an infection coming from the air passages higher up. In addition to such nodules it is not uncommon to find areas of diffuse pneumonia. In the horse these are often definitely lobular. In man they resemble more closely the areas of embolic pneumonia. They may be composed of cellular and hemorrhagic exudation in which there are large areas filled with nuclear detritus. The bronchi in these foci are filled with the same exudation as that in the alveoli. In some cases the surrounding interlobular tissue is greatly thickened from an infiltration with masses of lymphoid cells, and the adjoining lung tissue is involved to a greater or less extent. Such an area is represented in Fig. 2304, which shows a longitudinal section of a large bronchus filled with exudation. In the horse foci the size of an apple and manifesting evidences of purulent exudation may be found, and these may break down so as to form abscess cavities. In man the lung lesions are rarely absent, but at the same time they rarely take the distinctly nodular form which is so often seen in the horse. In the chronic cases fibrous nodules have been described, but no detailed description of their tissue has been furnished. In the acute cases the lesions, always present, take the form of larger and smaller foci of pneumonia and abscess-formation. Hyperæmia and evidences of hemorrhage are always found in the vicinity, and there are occasionally large areas of effused blood similar to infarctions. The pneumonia areas may resemble the nodules in having a centre totally necrotic and filled with nuclear *débris* and around this a less intense fibrinous, cellular, and hemorrhagic exudation. The liquefaction of the exudation gives rise to abscesses. In man also

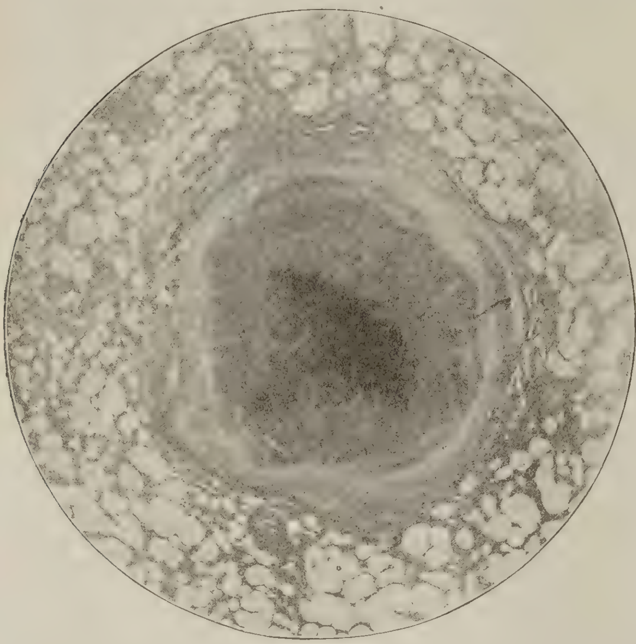

FIG. 2300.—Section of Chronic Glanders Nodule in the Lung of Horse, less advanced in its formation than Fig. 2299. In the centre of the nodule the lung structure is still visible.

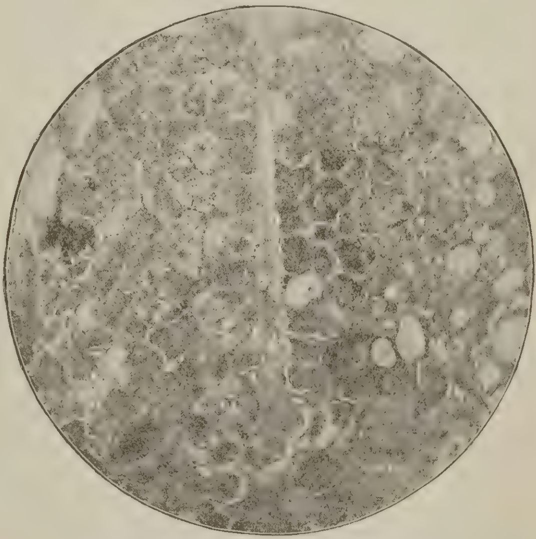

FIG. 2301.—Section of Beginning Nodule in Horse's Lung Adjoining an Interlobular Septum. The darker central portion is composed of cellular and nuclear detritus. The walls of the alveoli are necrotic.

the foci are more frequently found beneath the pleura. There is no reaction in these acute cases on the part of the lung. It is not an uncommon thing to find abscesses without any walls, representing cavities in the tissue surrounded by hemorrhagic and partly necrotic lung tissue.

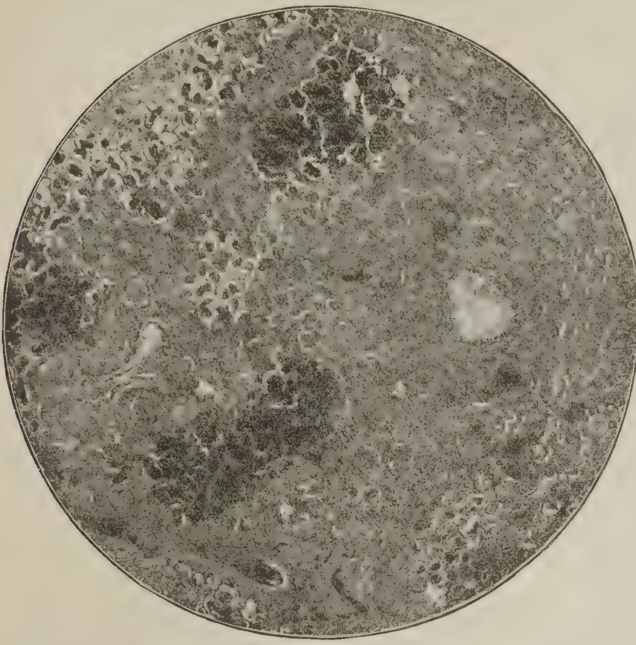

FIG. 2302.—Section of More Diffuse Acute Nodule in Lung of Horse Showing Several Centres.

There is rarely opportunity to examine the more chronic abscesses in the muscle. In those of an acute character the contents are composed of cell and nuclear detritus with scarcely a single cell showing well-preserved nucleus and protoplasm. In a small abscess in the pectoral muscle, in one of our cases, the abscess cavity contained on the edge a small amount of detritus, and all around there were degenerated and hyaline muscular fibres. There was no reaction on the part of the tissue and little or no surrounding cellular exudation. The muscular fibres seemed literally to melt away in the process.

The skin nodules (farcy buttons) in the horse are formed by an intense leucocytic infiltration of the skin and subcutaneous tissue with numerous foci of hemorrhage. In the beginning intense congestion and œdema of the surrounding tissue are present. There is also a proliferation of the fixed cells with formation of epithelioid and giant cells. The epidermis over the nodule may be infiltrated with cells and penetrated by the exudation. The hairs become loosened and drop out. The central area where the exudation is most intense becomes necrotic, the epidermis over it shares in the necrosis, and an abscess forms. The latter is likely in time to become converted into an ulcer. In other cases the necrotic mass may remain in the tissue and be gradually absorbed by a surrounding mass of granulation tissue. The formation of the skin nodule is very similar to the formation of the lung tubercle. The affection of the lymphatics giving rise to the so-called glanders cords (farcy pipes) pursues the same course as that in the nodules. There is an exudation in and around the lymphatics in the subcutaneous tissue or in the cutis. This is accompanied by intense congestion and œdema of the surrounding tissue. The whole central mass undergoes necrosis and may remain for a long time as a hard cord gradually undergoing absorption, or it may soften from place to place, or along its course, and give rise to ulcers. In some cases the necrotic tissue is discharged as a single mass. In man the skin lesions are somewhat similar to those produced by the streptococcus. In some places there seems to be very little reaction on the part of the surrounding tissues, and abscesses similar to those in the muscles are produced. Such abscesses are in the subcutaneous tissues. Sections made from the large areas of infiltration show lesions affecting both the skin and the subcutaneous tissue, but they are more marked in the skin. This shows an intense general infiltration with leucocytes and foci composed of these. The glands of the skin and hair follicles are often embedded in this and show but little change. Most of the exudation cells are broken down, and in places there is nothing but a mass of nuclear detritus. The epidermis over the area shows various changes, some of them almost peculiar to the disease. In some places the entire epidermis is cleanly separated from the tissue beneath by an exudation. In other cases and over small areas only the horny layer of epidermis remains, elevated, and covering a mass of cellular and nuclear detritus formed by leucocytes and the fragments of epithelial cells and nuclei (Fig. 2305). In still other cases there is a peculiar condition caused by a fluid exudation which has extended into the epidermis and has separated the cells. In the epidermis there may be found foci which are composed of masses of epithelial cells each separated from its connections. In the loose subcutaneous tissue there may be a considerable amount of fibrin in the exudation. The cellular infiltration may extend down deeply into the muscle, the fibres of which undergo necrosis. There are but few lymphoid cells and epithelioid cells in the surrounding tissue. In places the connective-tissue nuclei and the endothelial cells of blood-vessels and lymphatics have large vesicular nuclei with but little chromatin. The nuclei become increased in number, and no nu-

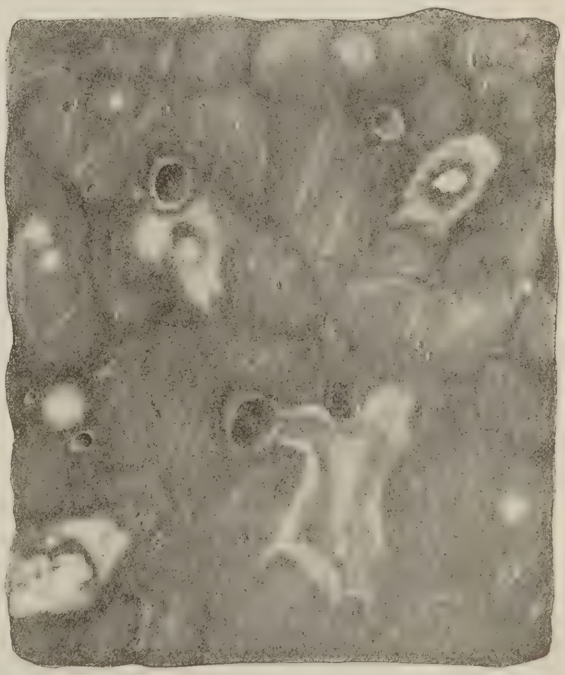

FIG. 2303.—Section of Lung of Horse (Natural Size), Showing Nodules and Cicatrices. The lobules are more prominent than is natural. (Kitt.)

clear figures are found, but occasionally there are biscuit-shaped nuclei. The process is one of degenerative direct nuclear division, and not a true proliferation of cells. The smaller vesicles and pustules show the same condition, but in these the process is confined to the dermis. The blood-vessels in the lesions and in their vicinity are often found thrombosed. The thrombi may be composed of cells, the nuclei of which show the fragmentation which is so common a feature. Nothing can be seen of the lymphatics where the process is most intense, but a study of the surrounding œdematous tissue shows that the same condition can be found here which is so common in the horse. Both the smaller and the larger lymphatics lying in a tissue which shows no lesion beyond a slight cellular exudation and the separation of the fibres due to the œdema, may be filled with masses of cells and nuclear detritus (Fig. 2307). In some cases the process extends through the wall, and a small abscess may be formed of which the lymphatic is the centre. Fig. 2306 shows such an area. The space in the centre represents the vessel from which the exudation has fallen in the preparation of the specimen.

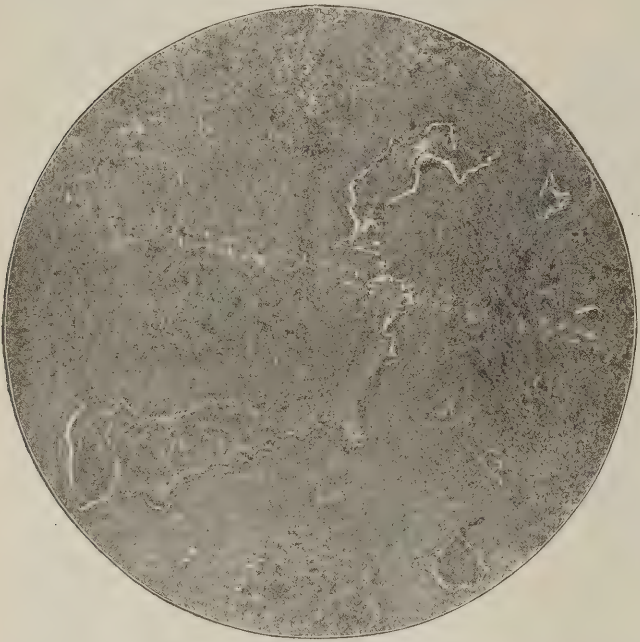

FIG. 2304.—Section of Chronic Lobular Glanders Pneumonia from Lung of Horse Showing a Large Bronchus in the Centre Filled with Exudation. In addition to exudation and hemorrhage in the alveoli there is marked connective-tissue formation.

The lesions in the mucous membranes are similar to those in the skin, with the exception that there is a great deal more extensive proliferation of the fixed cells. I have not had an opportunity to examine any of the distinct nodules formed in the mucous membrane, nor have I examined any of the chronic lesions. In the acute cases, in which swelling of the mucous membrane is the most marked characteristic, there is a dense accumulation of lymphoid and epithelioid cells in this membrane. Polynuclear leucocytes are numerous, both diffusely scattered among the other cells and in small masses chiefly on the surface. However, the individual accumulations of these leucocytes are never so large here as they are in the other tissues. Many of them, especially those scattered diffusely, have normal nuclei, but in most of them the nuclei are fragmented. The epithelium is for the most part destroyed, only fragments of it remaining. The participation of the connective-tissue cells in the process is shown in the horse by the enormous radiating cicatrices formed in the healing (Fig. 2298). It is difficult to explain these differences in the character of the process in the mucous membrane except by the assumption that in the mucous membrane there is a comparatively free opportunity for the escape of the exudation, carrying with it both the bacilli and the toxic products.

The lesions in the testicles consist in the presence of small foci of suppuration in the tunica, rarely in the testicle itself. In the other viscera the lesions are unimportant. One case of death from acute meningitis in man is reported by Tedeschi, the infection of the meninges having taken place, most probably, by way of the blood. Abscesses have been described in the liver in several cases in man, but they are more common in animals, particularly in the guinea-pig. Several cases also of abscesses of the bone marrow have been reported, and in the Tedeschi case of meningitis there was osteomyelitis of the tibia following an abscess. I have not found any descriptions of cases of acute nephritis, and in the kidneys of the human cases examined by me the degenerative lesions were slight. Nor are there any of the focal necroses in the liver which are so frequently found in other infections. There is some swelling of the spleen in the acute cases, but the lesions are confined to hyperæmia. In the lymph nodes there may be abscesses and foci of leucocytic infiltration.

The relation of the bacilli to the lesions is obvious. The bacilli are always present, but in variable numbers. In some cases they may be numerous, and in others they are found only after long search. They are difficult to find in sections, for there is no distinctive stain for them, and they are colored less deeply than the fragments of nuclei. They are found in the exudation and not in the surrounding tissue. They are always associated with the products of the disease, and the free discharge of these products from the affected mucous surfaces gives every possibility of the extension of the infection. When the bacilli enter the tissues they may or may not produce a lesion at the point of entrance. In Wright's case there was an intense inflammation of the thumb where the infec-

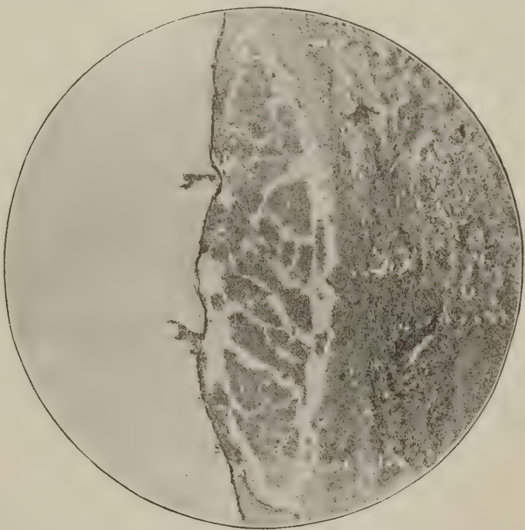

FIG. 2305.—Section of an Unruptured Pustule in the Skin of Face from an Acute Case of Glanders in Man. The horny layer is still intact. The other cells of the epidermis are necrotic and their fragments are mingled with the exudation.

tion took place, and this was followed by gangrene. In one of Küttner's cases in which the infection took place in the foot, there was a large ulcer on the heel. In other cases there has been no local lesion at the probable point of infection, or else it was of an insignificant character. The bacilli rapidly enter into the lymphatic circulation and into the blood. From the blood they may be deposited in various tissues, and in many cases they remain in the blood or are again introduced into it, and so give rise to septicæmia. They have repeatedly been found in the blood in acute cases in both animals and man. They may be found in cultures, on microscopic examination, and by inoculating other animals with the blood. The situation of the lesions points to blood infection, but the bacilli, probably generally distributed, find in but few tissues suitable conditions for growth. There are great differences in this respect in different animals. Thus the testicles which are constantly affected in the guinea-pig are rarely affected in the horse, and still more rarely in man. Abscesses in the muscles, frequent in man, do not occur in the horse. There seems to be an equal tendency in all animals to affections of the lungs, skin, and mucous membranes of the nose. There is little probability that the lesions in the nose come from surface infection. They are almost constantly present even in cases in which the infection surely was from other surfaces. Wherever the lesions are produced by the bacilli they tend to extend further by means of the lymphatics. This is seen particularly in the skin and also in the diffuse lesions in the lungs. The general character of the lesions is the same in all animals. The bacilli produce a rapid and abundant exudation of polynuclear leucocytes. These form the central focus. Around these foci there will be found evidences of intense congestion, of hemorrhage, and of fibrinous and serous exudation. These changes will be found to be less marked in the mucous membrane. The bacilli are found in greatest numbers or exclusively in the central mass of leucocytes. Destruction of the leucocytes and of the tissue containing them rapidly follows. The cells are fragmented and the nuclei converted into masses of nuclear detritus. The broken-up chromatin has a peculiar way of flowing together and forms large irregular clumps. In some cases a single well-preserved leucocyte is found in the central exudation. Lymphoid cells may be found in the surrounding tissue, but none in the centre. There is no other infectious process which produces such complete destruction and disintegration of the exudation cells. In certain cases in which the bacilli are less virulent or the tissues more resistant or in which unknown favoring conditions are present, there is a marked reaction of the surrounding tissues leading to the formation of an encircling band of granulation tissue and afterward of connective tissue. In the mucous membranes the tissue reaction is more marked than in either the lungs or the skin.

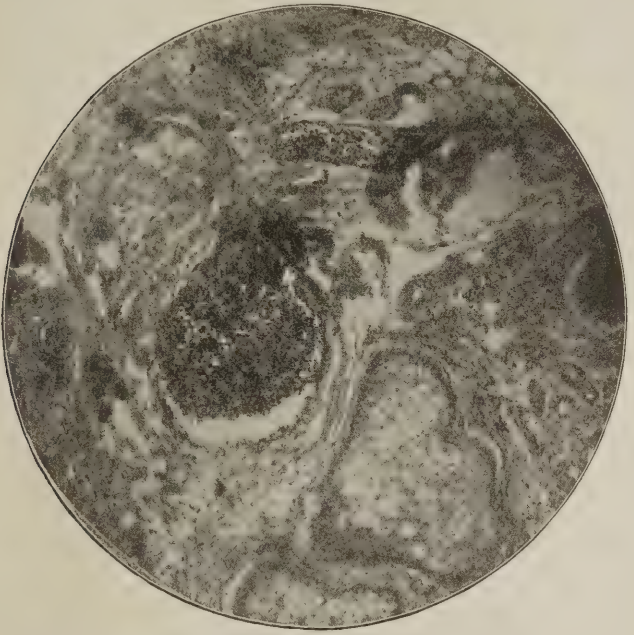

FIG. 2306.—Section of the Human Skin in the Vicinity of an Area of Infiltration and Pustule Formation Showing a Lymphatic Filled with Cellular and Nuclear Detritus. Slight cellular infiltration in the surrounding tissue.

Mixed infections occur, but they are not the rule. Streptococci have been most frequently found as the accompanying organism.

The way in which the bacteria infect the surroundings is apparent from the situation of the lesions. Everything that the horse touches, everything in his vicinity may become contaminated and a conveyer of the organism. The abundant discharge from the nose, which by the snorting of the animal may be thrown a considerable distance, contains the bacilli in large numbers. The abundant discharge from the skin ulcers contains them. They are contained in the urine even when there is no lesion in the kidney, and they pass through the vessels of the placenta. The skin becomes contaminated either from the ulcers or from the nasal discharge. The harness, especially the bridle or halter, the stall, the litter, the food, the drinking-vessels all become infected. There is little doubt that many cases of infection in horses take place from the public drinking fountain. The water becomes infected from a horse with

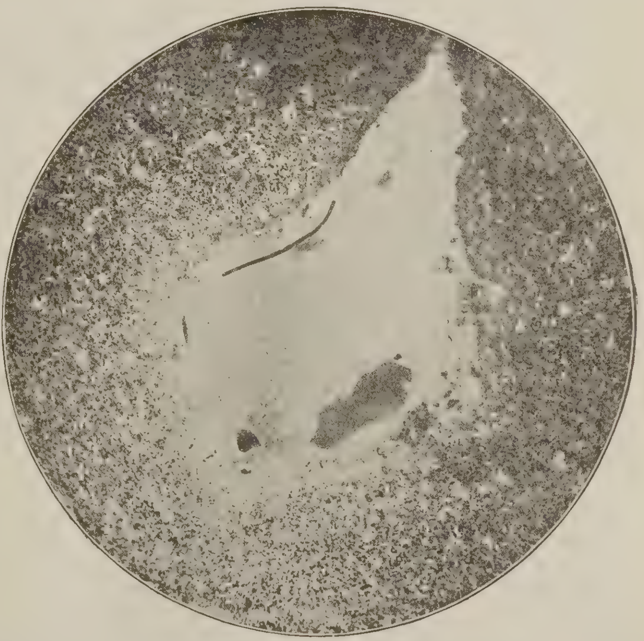

FIG. 2307.—Section through a Small Abscess in the Dermis which has Formed Around a Lymphatic. The space in the centre represents the lymphatic from which the contents have been lost.

nasal discharge, and a horse drinking shortly afterward from the same fountain will almost surely be infected. Close contact of the horses favors infection. Thus horses in a pasture where they are mouthing each other and where the food is infected are more apt to acquire the disease from one another than are horses in a well-managed stable. Not only the acute but the chronic cases are a source of infection. Chronic cases which show no evidence of the disease and which have only a few nodules in the lung are often the sources for infection. Nocard relates cases in which the disease persisted in stables, and the source was discovered only by the use of mallein. Infection in the horse takes place most usually from the intestinal canal. It may be conveyed either in the food or in the drink. Nocard gave twenty horses water to drink in which he had mixed a pure culture of the bacilli. All acquired the disease, reacted to mallein, and at autopsy showed in the lungs the small acute lesions on which he lays so much stress. Infection generally takes place from small lesions in the mouth, which are very generally present and which are due to the coarse fodder. It may also take place from lower down in the intestinal canal. Infection by the respiratory tract is rare. Babes caused guinea-pigs to breathe dust mixed with a dried culture, and succeeded in producing infection in two out of four cases. Nocard found that when virulent cultures were mixed with dust, dried, and injected into the peritoneal cavity of the guinea-pig there was no result. Cadeac injected a pure culture directly into the trachea of an ass without producing infection. Infection through the uninjured skin probably does not take place in natural conditions. Both Babes and Nocard succeeded in infecting guinea-pigs by rubbing the skin with pure cultures mixed with vaseline, but Nocard was not able to infect the ass in this way.

The disease in man is almost confined to those concerned in the care of horses, as coachmen, stablemen, etc. It is curious that more cases are not found in women, in view of the way in which they sometimes lavish caresses on a favorite horse. I have found but two cases in which infection has taken place from man to man: one the well-known case of Aufrecht (infection from autopsy), and a case reported by Zowadski[21] in which a physician infected himself in opening a supposed pyæmic abscess of the leg. Both physician and patient died of glanders. The mode of infection seems in a number of cases to be from small wounds of the skin which become contaminated with the virus. There have been several cases in which the infection took place from the conjunctiva which had become contaminated by the snorting of a glandered horse. In many cases the mode of infection is unknown, and even in a number of cases in which, from the situation of the first lesions noticed, the infection seems to have taken place from the skin, it is not certain that the skin lesions were not secondary.

Diagnosis.—A careful study of the phenomena of a case of acute glanders in man, from the beginning to the terminal pustular eruption of the skin, will generally enable us to make a diagnosis with some certainty. The diagnosis should always be made and can be made with certainty by the examination of the products of the disease. The microscopic examination of the pus from an abscess in the muscles of an extremity, showing the complete destruction of cells and nuclei, together with the presence of bacilli resembling glanders bacilli morphologically, is almost sufficient to make the diagnosis. Certainty can be reached by culture of the suspected material and by inoculation of a guinea-pig. In one of the acute cases seen here in Boston, the diagnosis was made from the microscopical and bacteriological examination of the sputum. Early in the disease when the symptoms may simulate typhoid fever, acute articular rheumatism, or some other acute infection, the diagnosis cannot be made. The disease so rarely appears except in those concerned with the care of horses that the occupation should be carefully considered. When the lesions are established and when it is possible to examine their products,—whether they are abscess contents, lung expectoration, or nasal discharge,—the diagnosis can and should be made by bacteriological examination and animal inoculation. In those cases in which there is an abundant pustular eruption the disease may present some similarity to variola. It can be distinguished from this by the character of the pustules (the almost universal absence of the umbilication; the varying size; the accompanying bullæ with frequently hemorrhagic contents; the subcutaneous abscesses, the loss of epidermis without actual suppuration; and the grouping of the pustules, in glanders). Very little is known of the use of mallein in man. Bonome[22] reports a chronic case (in a man and of three years' duration) in which mallein was given as a therapeutic agent and in which recovery took place. It produced a violent reaction. It has not been used sufficiently to determine its value as a diagnostic agent in the case of human beings.

In horses there is little difficulty in making the diagnosis when the disease is established, and in cases of doubt the careful administration of mallein will settle the diagnosis.

Treatment.—The treatment of glanders in man should be directed to the relief of the conditions. Abscesses and ulcers should be treated surgically. There is no reason to believe that the course of the disease can be influenced by the internal administration of drugs. Mercurial preparations have been used and they are recommended by Koranyi. All medication has been used with the greatest effect in chronic cases, and in estimating the results of treatment it must be remembered that a large percentage of these cases recover independently of treatment. There should be no attempt at treatment of animals, but they should be killed when the diagnosis is made, or, in case the necessary knowledge for making this is not available, when the disease is suspected.

With our present knowledge of the bacteriology and pathology of the disease, the sources and modes of infection, there should be no excuse for the existence of the disease. No disease could be more easily stamped out. The Equidæ are the sole source of infection. The disease is easily recognized by the mallein test, which should be made in all suspected cases. If there is a suspicious case in a stable, and this case gives a positive reaction, all the animals in the stable should be tested. It may happen that a chronic case with slight lesions located in the lungs, and giving rise to no suspicious symptoms, can be a constant source for spreading infection. Public drinking-fountains undoubtedly assist in the extension of the disease.

GLAUCOMA.—The name of this affection of the eye has been bestowed upon it on account of a greenish appearance (γλαῦκος) of the pupil, which, although present only in rare cases, may be observed as one of its symptoms. This name is a misnomer. It is, however, generally adhered to. More recent names, which were adapted to special theories regarding the character of the affection—as, for instance, ophthalmia arthritica, choroiditis serosa, etc.—have never been universally adopted.

PATHOLOGY.—The chief characteristics of glaucoma are a slowly or rapidly progressing diminution of the acuity of vision, combined with an occasional or continued increase of the intra-ocular pressure, and an excavation of the optic-nerve papilla. Around these chief symptoms and conditions we find grouped a number of other symptoms which characterize the different varieties of the disease. These varieties are known as *glaucoma simplex acutum*, *glaucoma simplex chronicum*, *glaucoma inflammatorium acutum*, *glaucoma inflammatorium chronicum*. When any one of these forms of glaucoma occurs in an eye which has not previously been affected in a manner such as to cause the development of glaucoma, we speak of the glaucoma as being *primary;* when, on the other hand, a previously diseased eye is, in consequence of this former disease, attacked by glaucoma, we call it a *secondary* glaucoma. We can furthermore, as a rule, recognize three stages in the development of all forms of glaucoma, the first of which is called the *prodromal* stage, the second that of *glaucoma evolutum*, and the last that of *glaucoma absolutum*.

What are usually described as the *prodromes* of glaucoma are observed in a large majority of the cases, and are in reality a series of slight attacks of acute glaucoma. This prodromal stage may last for many months, or even for years, until the attacks and their consequences become more serious. The prodromal attacks are not equal either in duration or in degree; yet they are not serious enough, as a rule, to cause cupping of the optic disc, nor to reduce the visual acuity lastingly. On the other hand, their early recognition is of grave importance to the patient, as the disease in these early stages is more tractable than later on. The symptoms which characterize this prodromal stage are the following: There is an appearance of a mist before the eye or eyes, and this mistiness may change in density. Rainbow colors are seen, especially in the shape of a ring around a candle flame. These rainbow-color rings do not touch the flame, but are separated from it by a dark space. The range of accommodation is reduced, and the eye appears prematurely presbyopic. This symptom is probably due to the hyperæmia of the ciliary body. In some cases the eye becomes myopic, which fact can be explained only by the assumption that the crystalline lens *in toto* is pressed forward toward the cornea, and that, in spite of the fact that in this manner the zonule of Zinn is stretched, and that an applanation of the lens is taking place. There is pain, which may be slight or even excruciating, and which is located in and around the eye, and in the forehead, the eyebrows, the cheek bones, the nose, and the temple. There is an increase of the intra-ocular pressure, which will manifest itself by an increase in the degree of tension of the eyeball; this increased tension varying from a barely perceptible to a stony hardness. The intra-ocular pressure is tested by directing the patient to look downward, then gently laying the tips of the forefingers upon the upper lid, and alternately pressing them upon the eyeball, as we do when we are searching for fluctuation elsewhere. By comparing the amount of impression we are able to make on a diseased eyeball with that which we can produce on its healthy fellow, or on the healthy eye of a third person, we can form an estimate of the increase of intra-ocular tension in the given case. According to the degree of hardness, we speak of it as $+$ T. (tension) $+ T_1$, $+ T_2$, and $+ T_3$. Several instruments (tonometers) have been invented to give an exact measurement, but they do not seem to be altogether reliable.

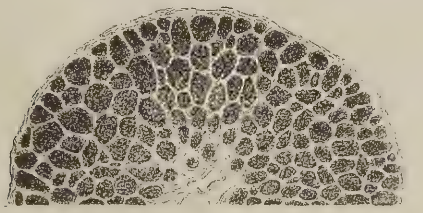

FIG. 2308.

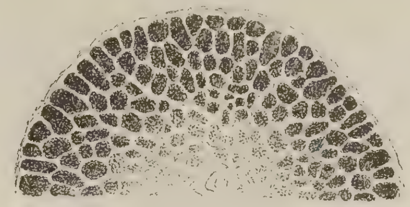

FIG. 2309.

The prodromal stage passes over into that of the *glaucoma evolutum* as soon as the visual acuity is lastingly reduced.

The *Glaucoma simplex acutum* is, if ever, very rarely observed. It would seem to have existed in a few cases in which sight was lost within a few hours without any inflammatory symptoms, and with barely increased pressure.

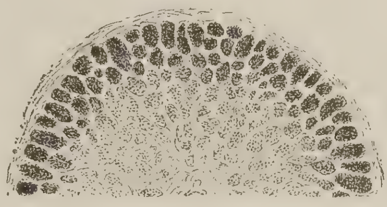

FIG. 2310.

Glaucoma simplex chronicum is characterized by the fact that externally the eye shows no marked signs of disease. The cornea, anterior chamber, iris, and pupil appear normal. The main symptoms are: the loss of vision, the excavation of the optic papilla, and the increase of the intra-ocular pressure. The latter symptom may, however, be imperceptible, or it may be present only at times.

An increase of the intra-ocular pressure is generally accepted to be the cause of the glaucomatous excavation of the optic papilla. The normal optic papilla has a central depression (physiological excavation) which may, in rare cases, reach so far toward the periphery of the optic papilla that at first sight it will strike the observer as a glaucomatous excavation. I have seen several cases in which the absence of all other symptoms alone convinced me of the fact that I was not dealing with a chronic glaucoma. Such a physiological excavation may have a sloping or a sharp edge, and may appear quite deep, yet it can never reach farther back than the anterior surface of the normal lamina cribrosa. In our judgment of the width as well as of the depth of such a physiological excavation we must take into consideration the fact that the optic nerve fibres, after they have passed through the lamina cribrosa, lose their marrow, become non-medullated, and are then diaphanous. Thus, a physiological excavation of the optic papilla is likely to appear much larger than it actually is. The illustrations, Figs. 2308, 2309, 2310, and 2311, will give a more palpable illustration of this fact. They are taken from specimens of a very short (hypermetropic) eye. Fig. 2308 is a transverse section taken from the optic nerve just behind the lamina cribrosa. Fig. 2309 is taken from near the anterior surface of the lamina cribrosa, and Fig. 2310 just from the anterior aspect of the lamina cribrosa. Fig. 2311 is a longitudinal section of the optic nerve entrance of the same eye.

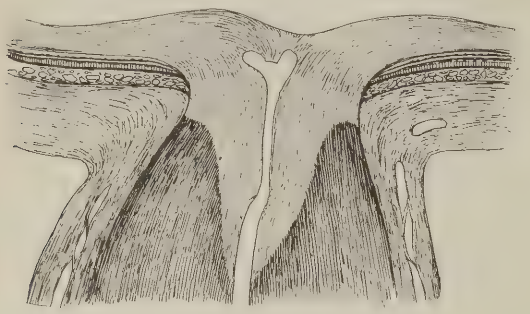

FIG. 2311.

The eye from which these specimens were taken probably showed during life an apparently very large physiological excavation, while the central (actual) excavation, caused by the manner in which the nerve fibres pass over into the retina, is only very slight. The condition illustrated by these drawings is chiefly found in hypermetropic eyes, while in myopic eyes the double-contoured nerve fibres reach farther forward and end in a straight, or even slightly convex, line.

If we now compare with this physiological excavation the typical glaucomatous excavation (see Fig. 2312), we find that here we have to deal with an actual and deep hollowing out of the optic papilla.

We furthermore see, in this figure, that the actual excavation has for its floor a thin layer of atrophic nerve fibres and the compressed lamina cribrosa. The nerve-fibre layer and the lamina cribrosa are together pressed out of the sclerotic, and behind it into the trunk of the optic nerve. The walls of the excavation are also lined with a very thin layer of atrophic nerve fibres. These fibres follow very closely in their course the indentations and projections of the surrounding scleral tissue, and finally pass over into the atrophied nerve-fibre layer of the retina.

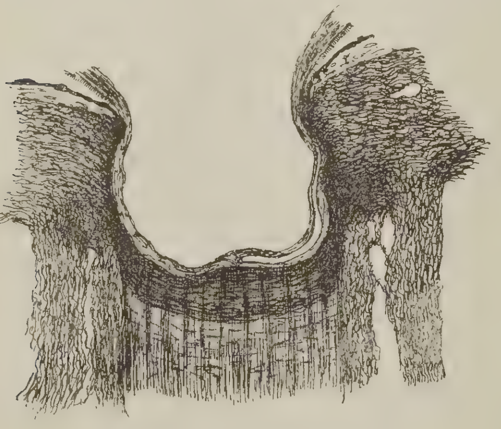

FIG. 2312.—Glaucomatous Excavation.

From the foregoing we understand that the physiological excavation in the normal eye may appear as having a sharp edge, but usually it has none, and cannot, for obvious reasons, reach to the periphery of the optic papilla; that the typical glaucomatous excavation, however, has always a sharp edge, and can reach to the very periphery of the optic papilla (when all nerve fibres are destroyed), and always comes very close to it. Moreover, in the typical glaucomatous excavation the lamina cribrosa is pressed backward and out of its normal position. It can, therefore, not well be confounded with a simple atrophic excavation, since this is always very shallow, and the lamina cribrosa is found in its normal position and of normal appearance.

By the aid of these anatomical facts we shall now easily understand the ophthalmoscopic picture of a glaucomatous excavation (see Fig. 2313).

The most striking phenomena of a glaucomatous excavation pertain to the retinal blood-vessels. Just before reaching the optic-nerve papilla these blood-vessels are seen to pass over a yellowish ring, which corresponds neither to the normal scleral nor to the normal connective-tissue ring as seen around the normal optic papilla. On the inner margin of this yellow ring the blood-vessels are seen to bend inward, then they disappear partially or altogether, and reappear dimly in the depth of the excavation, but in a parallactic displacement. If the excavation is very deep, it may be impossible to see those vessels which are located in the floor, while those which occupy the retinal portion are distinct, and *vice versa.* The depth of the excavation may thus be approximately measured by means of the glasses necessary to see the two portions distinctly.

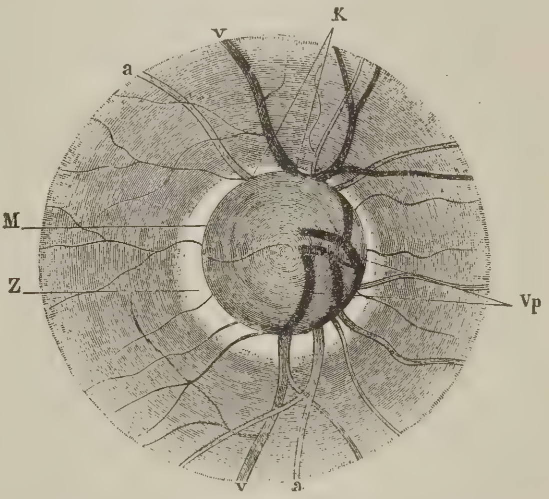

FIG. 2313.—Glaucomatous Excavation as Seen with the Ophthalmoscope. (From Edward von Jaeger.) *a, a,* Arteries; *v, v,* veins; *K,* points, on the border of the papilla, where the vessels make a sharp bend; *Vp,* portions of blood-vessels lying in the excavation; *M,* border of the excavation; *Z,* surrounding yellow zone.

The optic nerve forming the bottom of the excavation appears punctated. It has usually a white appearance in the centre, where it is directly illuminated, while the parts which are only indirectly illuminated appear bluish or greenish. By moving the mirror slightly the view may be changed in such a manner as to make a formerly greenish part appear whiter. The punctation is probably produced by the fact that the meshes of the anterior surface of the lamina cribrosa are visible on account of the atrophy of the nerve fibres.

The yellowish ring around the optic papilla, or at least what is left of it, is caused by an atrophic condition of the choroid, which is undoubtedly due to the stretching of this membrane during the development of the excavation, and is not due, as some authors maintain, to a chronic choroiditis.

A further vascular symptom is the spontaneous pulsation of the retinal arteries. This is but rarely seen in recent cases. It can frequently be produced by pressure on the eyeballs.

The gradual loss of sight (central visual acuity and visual field) is in a general way in proportion to the size and extent of the excavation of the optic papilla and the consequent atrophy of the optic nerve fibres. Nevertheless, a number of cases have been observed and reported in which an apparently large and deep excavation had not yet become associated with a great loss of vision. In some cases the central or paracentral vision will be destroyed before the periphery seems to be materially altered, and in other cases the loss of vision at first affects the peripheral vision alone. The contraction of the visual field begins frequently on the nasal side, and gradually extends upward and downward, so that in some cases at a certain stage a perfect hemianopia has been observed. Gradually the visual field grows smaller and smaller. It often has the shape of an ellipse with the point of fixation lying in the nasal focal point. This form of contraction of the visual field is pre-eminently found in glaucoma, while an actually concentrical limitation of the visual field is usually due to diseases of the optic nerve alone, or to retinitis pigmentosa with subsequent atrophy of the optic nerve.

All these symptoms are accompanied by a gradual diminution of the light sense. The color sense is usually well preserved, even when the visual field is reduced to almost nothing.

The loss of vision and the reduction of the light sense are the symptoms of glaucoma simplex which usually bring the patient to seek relief. Generally one eye is then already found to be badly affected, while the trouble is beginning in the second eye.

Glaucoma Inflammatorium Acutum.—The attack of acute inflammatory glaucoma comes on suddenly, and probably more frequently during the night than in the daytime. The pain, which is the most prominent symptom of this form of glaucoma, is often fairly excruciating. It is seated in the eyeball, the eyebrow, the forehead, and temple, and it may extend even to the occipital region. It may be combined, furthermore, with nausea and vomiting. There is usually a considerable secretion of tears and of watery fluid from the nose, and photophobia is likely to be present. These symptoms are, moreover, accompanied by some œdema of the eyelids, and especially of the upper one. Ayres has seen a case which was ushered in by intense chemosis. When the lids are separated the conjuntival blood-vessels are found to be considerably injected, and the bulbar conjunctiva to be slightly chemotic. The episcleral vessels around the cornea, too, are hyperæmic, and form a reddish-blue ring around the corneo-scleral margin. The anterior ciliary veins are distended and tortuous.

The cornea has a dead appearance, like glass which has been breathed upon. Under oblique illumination its surface appears irregular, as if pricked with a needle, and there may be slight deposits of fibrin on Descemet's membrane. If the cornea is touched with the end of a probe, a feather, or a thin roll of tissue paper, it is found to be almost anæsthetic, and the reflex contraction of the orbicularis muscle of the eyelids follows the insult long after it does so in a healthy eye. This anæsthesia may be noticeable over the whole area of the cornea or only in portions of it. By palpation the eye is found to be hard. This sudden increase of the intra-ocular pressure is the cause of the dimness as well as of the anæsthesia of the cornea.

The anterior chamber is shallow, the iris and crystalline lens being pressed forward toward the cornea. The pupil is wide, and reacts but very slightly under the stimulus of light. There may be some posterior synechiæ.

When the attempt is made to get an ophthalmoscopic view of the interior of the eyeball, it is often barely possible to see a reddish reflex, but no details of the fundus. This is due as well to the dimness of the cornea as to a diffuse opacity of the vitreous body.

Sight is considerably reduced, and it may be diminished to the bare perception of light. This symptom is most probably due to the pressure exerted upon the optic nerve fibres, the retina, and the retinal blood-vessels, and to the resulting paralysis of the nervous elements and ischæmia of the retina. That this is the correct explanation of the symptoms seems to be proven by the pulsation of the retinal arteries, the systole of the heart alone being able to overcome the intra-ocular pressure to some extent, and by the fact that a release of the pressure by operation will restore sight. The dimness of the cornea and the vitreous body, moreover, help to reduce the vision.

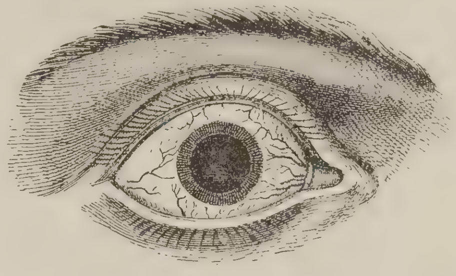

FIG. 2314.—Chronic Inflammatory Glaucoma. (After Schmidt.)

The attack of acute inflammatory glaucoma may last from a few hours to several weeks, and sight may again considerably improve as the attack passes over. Nevertheless, the eye, although it may look so, is no longer in the same condition as before the attack, and every new attack will leave it in a worse state. Repetitions of the attack are the rule. In the intervals between the attacks the anterior chamber remains usually shallow, the movements of the iris are restricted, and the tension remains somewhat increased. In other cases the acute stage passes directly over into the chronic one. When all these symptoms are less marked, the affection is called *glaucoma subacutum.*

There is, furthermore, a limited number of cases of acute glaucoma on record in which sight was absolutely destroyed during the first attack, and in the course of a few hours. These cases have been given the name of *glaucoma fulminans* (von Graefe).

Glaucoma Inflammatorium Chronicum.—In the chronic inflammatory form, which may follow an acute attack or begin with a chronic character, all of the glaucomatous symptoms are slowly developed, and the external inflammatory signs are less marked than in the acute form. The injection of the conjunctiva is there, but there is no œdema of this membrane, nor of the eyelids. The episcleral blood-vessels, and especially the anterior ciliary veins, are plainly visible and tortuous (see Fig. 2314). There is a marked injection of the deeper-seated blood-vessels around the corneo-scleral margin, and in the later stages the sclerotic tissue has a peculiar leaden appearance. The cornea may be perfectly clear, or it is slightly hazy, and it often shows minute superficial or even deeper points of ulceration. The anterior chamber is shallow and becomes more and more so as the disease advances; and the pupil, which is at first of medium size and acting sluggishly, soon undergoes an increasing degree of dilatation and becomes immovable. The iris tissue, at first swollen and discolored, will be found, at a later date, attenuated, and undergoes a slow process of atrophy. The intra-ocular pressure is increased above the normal, and there is a gradually increasing excavation of the optic papilla with a consequent atrophy of the optic nerve fibres.

The patients suffer at times from considerable pain and neuralgia, especially at night. The visual acuity, the visual field, and the light sense are gradually more and more reduced. This is the more noticeable after each exacerbation of the process.

The chronic inflammatory glaucoma seems to be the most frequent form in which this disease is observed. We must state here that the acute inflammatory, as well as the chronic inflammatory, variety may be preceded by a simple chronic glaucoma.

When the sight, through the effects produced by the glaucoma in one of its different forms, has been perfectly abolished, or at least to such a degree that merely the perception of light is retained, we speak of the condition as *glaucoma absolutum.* The progress of the disease, however, does not end here, and a further glaucomatous degeneration of the eyeball takes place. In some cases the eye is only at times painful and shows but slight external alterations, and the media remain for a long period in such a condition that an ophthalmoscopic examination can easily be made. In most cases, however, the increasing malnutrition leads to the formation of glaucomatous cataract. The anterior chamber becomes so shallow that the anterior lens capsule almost touches the posterior surface of the cornea, or actually does so. The eye remains painful, and the pain is at times very considerably exaggerated. Gradually ulceration of the cornea and the formation of scleral or corneal staphylomata may take place. The ulceration may lead to perforation and subsequent shrinking of the eyeball. All these symptoms may be accompanied by very annoying photopsiæ.

In the foregoing we have considered what is designated as primary glaucoma. We come now to the forms of secondary glaucoma.

Secondary glaucoma may appear in the shape of a simple or inflammatory glaucoma. It has been observed to follow various diseases of the eyeball. It may follow a diffuse or sclerosing keratitis, vesicular (bullous) keratitis, or that form which is known as ribbon-shaped keratitis; yet it is more frequently observed in cases of anterior synechia, with or without leucoma of the cornea.

Serous iritis and irido-choroiditis are apt to cause glaucomatous symptoms. Glaucoma may furthermore follow a plastic iritis when it has led to the formation of posterior synechiæ, and especially when a total circular synechia has been formed, whether this has led to the seclusion of the pupil alone, or to seclusion combined with occlusion of the pupil. But an occlusion of the pupil alone (which can, for instance, follow an operation for cataract extraction) may also be sufficient cause for the production of glaucoma.

Dislocation of the crystalline lens, or a too rapid swelling of the lens substance after the operation of discission or after an injury to the lens capsule, may lead to glaucoma. This is one of the bad results which often followed the old method of couching cataractous lenses.

Serous choroiditis, although leading more frequently to detachment of the retina, may give rise to glaucoma.

The most important one among the diseases of the retina which may be followed by glaucoma is the hemorrhagic retinitis (*glaucoma hæmorrhagicum*). In fact, hemorrhages into the retina from any cause may lead to hemorrhagic glaucoma. The pathological substrata are some form of disease of the blood-vessel walls, an inability of the filtration channels to carry off the corpuscular elements of the blood, and a consequent blocking up of these channels. Glaucoma has been furthermore observed in cases of pigmentary retinitis and of atrophy of the optic nerve. In these cases the occurrence of glaucoma was, however, probably a coincidence only, and it would seem to have been a primary glaucoma, not a secondary one.

Collins, Keyser, Buller, Knapp, and the writer have had occasion to see glaucoma follow cataract extractions and needle operations. In these cases the lens capsule or the vitreous body, with or without some part of the iris, was found to have blocked the filtration angle.

Secondary glaucoma is apt, furthermore, to occur in eyes suffering from staphyloma, and the increase of pressure then helps to the further increase of the staphyloma.

All intra-ocular tumors are likely to cause a glaucomatous condition of the eye during their growth.

Hydrophthalmus congenitus (cornea globosa; buphthalmus; keratoglobus) must probably be regarded as intra-uterine glaucoma.

Ayres saw a case of glaucoma caused by a very large nasal polypus. A cure was effected by the removal of this tumor.

The instillation of any and all mydriatics, even of one as weak as euphthalmin, may, under favorable circumstances, bring about an attack of acute glaucoma.

Diagnosis.—The differential diagnosis between glaucoma simplex chronicum and amblyopia caused by a simple atrophy of the optic nerve may be sometimes rather difficult, especially since there are cases of simple glaucoma in which there is no *appreciable* increase of the intra-ocular tension, and they may come under observation when as yet there is only a partial excavation of the optic papilla. This difficulty is to be met only by repeated careful examinations, until one of the necessary symptoms is marked enough to make the diagnosis secure. In this connection I may mention that the yellowish halo around the optic papilla which is characteristic of glaucoma, though little marked, seems to be but seldom wanting, and may therefore help in making the diagnosis. Furthermore, a simple atrophy of the optic nerve may at a comparatively early stage lead to diminution of the color sense, while glaucoma does not seem to interfere often with the color perception.

The diagnosis of an acute primary inflammatory glaucoma may appear plain from the condition of the eye when it comes under observation; yet the same general condition might also be a secondary one and due to an intra-ocular tumor. Here the position of the defect in the visual field, the usual absence of the perception of rainbow rings, and the gradual and continuous loss of vision which is likely to have preceded the glaucomatous condition under consideration, may help to the diagnosis of an intra-ocular tumor, even if it cannot be otherwise demonstrated. To distinguish between a hemorrhagic and a primary acute glaucoma will hardly be possible, except in cases in which the retinal hemorrhages had obscured vision very materially, or in which the observer has had occasion to see the occurrence of such hemorrhages previous to the glaucomatous attack. The acute glaucoma might, furthermore, be confounded with serous iritis. Yet, the deposits on Descemet's membrane which are so marked in this affection, the depth of the anterior chamber, and the low degree of injection of the visible external blood-vessels (there may be none at all) will usually make it possible to exclude a primary glaucoma in such cases.

Glaucomatous, as well as any other complicated, cataract may, of course, by a careless observer, be taken for an uncomplicated cataract.

The primary chronic inflammatory glaucoma cannot well be confounded with any other eye affection.

Glaucoma is observed in about one per cent. of all eye patients. It seems to be a little more prevalent among females than among males. It has been seen to occur in children as well as in old age. Yet the majority of the cases are observed after the fiftieth year of life has been reached, and it is very seldom seen before the twentieth. Although glaucoma may at first attack only one eye, it is the rule that it will sooner or later attack the fellow-eye. In this connection we may state that the attack in the second eye seems to be apt to make its appearance soon after the first one is operated upon.

In the relative frequency of their occurrence the chronic inflammatory glaucoma takes the first, the chronic simple glaucoma the second, the acute inflammatory glaucoma the third, and the (doubtful) acute simple glaucoma the last place. The disease is almost confined to eyes afflicted with hyperopia or hypermetropic astigmatism, although it is found also occasionally to appear in myopic eyes. Some authors maintain that there is an inherited tendency to glaucoma in some families.

Where there is a tendency to glaucoma, an attack may be brought on by an extraordinary straining of the eyes, by mental disturbances, by excesses of various kinds, by various diseases, by the stopping of habitual secretions, especially of the menstrual flow in the climacteric period in females, and, as stated, by the instillation of a mydriatic into the conjunctival sac.

Before considering the nature of this disease we will next see what data the anatomical examination of eyes afflicted with glaucoma gives us to build our theories upon.

PATHOLOGICAL ANATOMY.—The most interesting part of a glaucomatous eye has been for a long time the optic-nerve papilla, with its excavation. In a case which is not very far advanced, we find a comparatively shallow excavation, which is deepest usually in the centre, sometimes at one side (especially the temporal one). The bottom of this excavation lies behind the level of the choroid, and consists of a thin layer of nerve fibres. Nerve fibres are, furthermore, seen to line the walls of the excavation, and to join the retina at a more or less acute angle. The retinal blood-vessels lie within this nerve-fibre layer, and come, according to the stage of the disease, more or less close to the edge of the excavation. The fibres of the lamina cribrosa appear pressed closely together, so as to render this membrane thinner than in the normal eye, and the whole lamina is bulged outward. Its choroidal portion is no longer in distinct connection with the choroid. The small blood-vessels found in the normal eye in this region are reduced in numbers or wanting altogether, and the nerve fibres are atrophied. The retinal veins are usually hyperæmic. All these conditions are considerably exaggerated in an advanced case like the one from which Fig. 2312 was taken, yet I have never seen a glaucomatous excavation which had not, though ever so thin, a lining layer of nerve fibres.

The portions of the choroid and the retina which surround the excavation are drawn to some extent down into it and toward its axis, and the choroid is, even in the more recent cases, very thin and atrophic. It lacks blood-vessels, especially capillaries, its pigment cells have, in a certain measure, or altogether, disappeared, and the pigment molecules are found lying in the adjoining tissue of the sclerotic. This condition is undoubtedly the anatomical explanation of the glaucomatous halo. In some cases small foci of infiltration are found in this portion of the choroid.

The choroid in general shows an anæmic condition of the capillary layer; while the venæ vorticosæ are usually choked with blood. Atrophic patches are sometimes found in its periphery.

The retinal nerve-fibre layer in very advanced cases is atrophied, and the blood-vessels of this membrane are partially or altogether obliterated.

In more recent time (Knies) the interest of the examination has been centred especially on the condition of the iris angle. We find here, although not at all invariably, an adhesion between the periphery of the iris and the posterior surface of the cornea. Thus the spaces which in the normal human eye lie between the fibres of the ligamentum pectinatum, and correspond with the canal of Fontana, are partially or totally obliterated. In recent cases the tissue surrounding Leber's venous plexus (corneo-scleral tissue) is infiltrated with round cells, and the periphery of the iris, being pressed forward, comes in contact with Descemet's membrane, the endothelial coat of which begins to proliferate. In this way a small amount of new connective tissue is formed between Descemet's membrane and the periphery of the iris, and this glues the two together, thus causing the obliteration of the spaces of Fontana (see Fig. 2315).

It is doubtful whether this agglutination of the iris to Descemet's membrane is due alone to the increased intraocular pressure, or to the direct pressure (Weber, Brailey) of the swollen and hyperæmic ciliary bodies. According to Brailey, the blood-vessels of the ciliary region are found to be considerably dilated, and their walls are reduced in thickness. Later on, the ciliary bodies and muscles are found to be thin and atrophic, and the smaller blood-vessels are obliterated. Leber's plexus is found patent or closed. In other cases the iris angle is found to be quite large and not blocked by iris tissue. In such cases the filtration channels are filled with cell detritus and fibrin, and thus a stoppage results.

Cusco stated that the sclerotic coat is always thicker in glaucomatous eyes, and especially near the entrance of the optic nerve. Weichselbaum and others found the episcleral veins filled with blood, and dilated and surrounded by foci of round cells. In some cases a proliferation of the endothelial coat of the venæ verticosæ has been observed.

Ulrich examined pieces of the iris which he had excised from glaucomatous eyes when making an iridectomy. He found the tissue of the iris atrophied and thin, and lacking cellular elements. The blood-vessels were partially dilated, and the thickness of their walls was considerably reduced—a part of them (especially of the smaller ones) were totally obliterated.

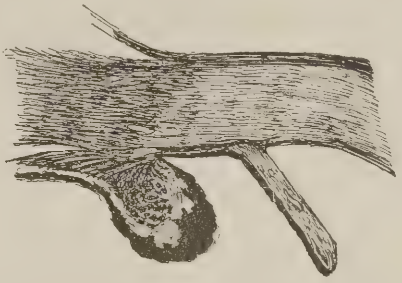

FIG. 2315.—Adhesion of Periphery of the Iris to Descemet's Membrane, causing Dilatation and Immobility of the Pupil, and Obliteration of the Iris Angle.

In some cases the vitreous body has been found detached. The cornea is usually œdematous.

It will be seen from the foregoing remarks that our knowledge of the pathological anatomy of glaucoma is as yet very meagre. This is the more astonishing, as a great many able workers have devoted considerable study to this interesting, and as yet mysterious, disease. Glaucoma, or at least a similar condition, has been experimentally produced in animals by ligating the venæ vorticosæ, by burning the corneo-scleral margin (Schoeler), and by injecting oil into the anterior chamber (Weber).

It is therefore evident that even to this day it has been impossible to find a common cause for all the different forms of affections which produce the increase of intraocular pressure, as well as the gradual destruction of vision, combined with an excavation of the optic nerve, —in brief, for the disease which we call glaucoma. Consequently, it is not to be wondered at that the number of theories constructed for the explanation of the nature and seat of glaucoma is legion. These theories may be classed under three heads: those which make the increase of the intra-ocular pressure the main feature; the theories which deal with the disease as originally due to a strange affection of the optic nerve; and, finally, those which seek the cause in an inflammation of the choroid.

THEORIES PUT FORWARD IN EXPLANATION OF THE DISEASE.—The theories making the increased intra-ocular pressure the main feature attribute it to a hypersecretion into the vitreous body, consequent upon an active but somewhat atypical inflammatory process in the choroid; or they consider it due to an irritation of the secretory nerves; or the increase in pressure is thought to be the result of reduced facilities of excretion from the eyeball, or of stasis of the venous blood (passive hypersecretion, Mauthner).

Von Graefe thought that glaucoma was a choroiditis or an irido-choroiditis, with diffuse imbibition of the vitreous body—processes which would lead to an increase in volume of the vitreous body, and consequently to increased intra-ocular pressure. Later on, he thought this choroiditis to be due to an irritation of the secretory nerves. Arlt and Sattler adhere to the former theory. The latter found inflammatory changes in the choroid, but his description of these changes is such that it seems hardly possible to attribute a disease of the character of glaucoma to so slight a cause. If this explanation were correct, why, it may be asked, is not a glaucoma produced in every case, or at least in the majority of cases, by an exudative choroiditis?

The neurotic theory has been put forth by Donders. He says that in glaucoma chronicum simplex we have no signs of an inflammatory character, and, furthermore, the increase of pressure has always preceded the inflammatory symptoms where they exist. The cause of the increased pressure must, therefore, lie in the irritation of secretory nerves. Von Graefe, as stated before, partially adopted this theory; but he characterized even the glaucoma chronicum simplex as an inflammatory condition. Schnabel, who also supports the neurotic theory, refuses to acknowledge the inflammatory character of any form of glaucoma. He claims that the glaucomatous ophthalmia is simply a neuralgia of the sensory nerves, while the increased pressure is due to a neuralgia of the secretory nerves of the eye. Glaucomatous ophthalmia, then, and anomaly of pressure, spring from the same root.

The cause of the secretory neurosis is found in the atrophy of the ciliary processes and the consequent enlargement of the diameter of the circle formed by these processes, which enlargement causes an increased tension of the suspensory ligament of the crystalline lens.

The intra-ocular irritation of the secretory nerves lies, therefore, in the anterior part of the eyeball, the iris, and the ciliary body (Donders, Schnabel, Roeder), and is a reflex neurosis.

It might, however, with the same right be claimed that it is an extra-ocular affection which brings about such a reflex neurosis, and thus Hutchinson and Schmidt-Rimpler have considered a neuralgia of the trigeminus nerve as the cause of glaucoma. Mooren finds the cause in affections of the brain or spinal medulla.

Weill has formulated and elaborated a theory in which he tries to prove that all the symptoms of glaucoma are due to irritation of the sympathetic nerve.

The most plausible theories yet advanced are those which refer the cause of glaucoma to mechanical obstructions to the drainage of the fluids from the eyeball, either by obliteration of the lymphatic channels in the iris angle and, perhaps, in the optic nerve, or by obstruction of the reflux of the venous blood from the eyeball. Such obstructions must undoubtedly cause an increase of intra-ocular pressure, if at the same time the afflux remains the same.

The present status of our knowledge of the course of the nutritive fluids of the eyeball is chiefly due to the labors of Knies. He found that the fluids are secreted by the choroid, ciliary body, and iris. The fluids coming from the chorio-capillary layer take their course through the retina into the vitreous body, then forward toward the crystalline lens. While a portion of these fluids now penetrates the equatorial portion of the lens, the larger quantity goes through the suspensory ligament and around and through (Ulrich) the iris into the anterior chamber. The aqueous humor is secreted by the anterior portion of the ciliary body and the iris. In the normal eye no fluid is secreted through the cornea (Leber), or, if any is secreted, the quantity is very small. The way by which the largest portion of the aqueous humor leaves the eyeball is through the iris angle; here it goes partially into Leber's venous plexus and partially into the lymph canals of the conjunctival and episcleral tissue, and of Tenon's space.

It seems, therefore, evident that an obstruction of the excretory canals will cause glaucoma. Such an obstruction may be due to an inflammation in the iris angle, which, as we saw, brings about an actual adhesion between Descemet's membrane and the periphery of the iris, with or without obliteration of Leber's venous plexus (Knies); or it may be due to entanglement of cell detritus in the meshes of the ligamentum pectinatum; or, finally, it may be due simply to the swelling of the ciliary processes, which will press the periphery of the iris against the corneo-scleral tissue (Priestley-Smith, Brailey, Weber). According to Priestley-Smith the size of the lens is, so to speak, too large for the eye in most cases. Thus accommodative strain may crowd the iris periphery against the cornea. Furthermore, the obstruction may be caused by the atrophy of the iris tissue and the consequent obliteration of the channel by which, in the normal eye, fluids pass directly through the iris (Ulrich). Some authors speak of an obliteration of the lymph canals near and in the optic-nerve entrance as the partial cause of glaucoma. Gifford has shown that there is a current backward in the lymph spaces accompanying the central retinal vessels.

The obstruction of the reflux of the venous blood from the eyeball may be due to an increased rigidity of the sclerotic (Stellwag, Arlt); to inflammation and consequent increased thickness of the sclerotic (Cusco); to fatty degeneration of the sclerotic (Coccius), all of which pathological changes will tend to compress the venous blood-vessels. Magni finds that the ciliary nerves are atrophic in cases of glaucoma. This atrophy of the ciliary nerves causes shrinking of the vitreous body and sclerotic, and stasis in the venous blood-vessels. This stasis, according to others, may be due to an infiltration of the tissue surrounding the veins, or to a proliferation of their endothelial coat.

All of these theories take glaucoma to be a disease due to a reduction of the area of the channels of excretion, and they consider all other symptoms of the disease, including inflammatory attacks, anæsthesia of the cornea, and excavation of the optic papilla, to be directly dependent on the increased intra-ocular pressure.

Most recently Schoen has advanced a new theory of glaucoma, which also refers the cause of the disease to mechanical conditions of the eyeball. Although it does not strictly belong among the "pressure theories," it may find its place here. He says that an overstrain of the accommodation is the etiological momentum in the development of all cases of primary glaucoma. This may act in two ways: by pulling the sheaths of the optic nerve forward (thus causing excavation), and by pressing the crystalline lens forward (thus producing glaucomatous increase of pressure). As long as all the fibres of the ciliary muscles act, glaucoma simplex will follow this overstrain. When the inner fibres of the ciliary muscles become insufficient as compared with the outer ones, the lens is pushed forward, and glaucoma, with increased pressure, is the result. The two modes can act combinedly in various ways. The pathological changes found in the ciliary body are due to subsequent inflammation.

The theories which consider glaucoma due to an affection of the optic nerve were inaugurated by Jaeger. He sees the direct cause of the disease in changes in the ring of blood-vessels which bring blood to the portion of the sclerotic surrounding the optic-nerve entrance, to the lamina cribrosa, and to the optic papilla (Haller's ring). He denies that the increased intra-ocular pressure is characteristic of the glaucomatous process, although it is an important symptom. Schnabel and Klein support this theory.

The theories which take glaucoma to be the result of a choroiditis, and assume that this choroiditis alone (without increase of pressure) would lead to the loss of function and excavation of the optic papilla, have found their most urgent advocate recently in Mauthner. He says: Glaucoma is an inflammatory process in the system of the ciliary blood-vessels,—a process which may concern the whole area of this system, or leave some portions of it free; an inflammatory process which (with the exception of the location of the glaucomatous halo) is distinct from others by the lack of formed elements in its products, and by the faculty of inducing a rapid atrophic process in the tissues involved. This inflammation is often combined with an increase of the intra-ocular pressure. This is less marked when the inflammation concerns only the area of the short posterior ciliary arteries that go to the choroid, but is hardly wanting whenever the area of the anterior ciliary arteries and long posterior ciliary arteries (ciliary body, iris, and cornea) is attacked; in this latter case the fluid secreted into the vitreous body is exuded from the inflamed ciliary body (Brailey). The increased intra-ocular pressure is not a constant symptom, and it is not the source of the functional trouble. This latter is caused by the fact that the inflammatory process of the choroid exerts its action upon the neighboring layer of the retina (the rods and cones) while the affection of the optic papilla, characteristic of glaucoma and due to the inflammation in the area of the arterial scleral ring, plays only a secondary or final rôle in the total ruin of vision.

When the glaucomatous inflammation suddenly attacks the area of the long posterior and anterior ciliary arteries (a kind of kerato-irido-cyclitis), we have the acute inflammatory glaucoma. The disturbance of vision is only proportionate to the dimness of the media; the function of the retina does not suffer from the sudden increase of the intra-ocular pressure. In exceptional cases the uveitis, which is the glaucoma, will suddenly attack the *whole* area of the ciliary blood-vessels; the attack, then, of course, includes the choroid. The function of the rods and cones may be thus suddenly (and usually forever) destroyed by the exudation; this is the case in glaucoma fulminans; or these organs may at least suffer considerably and lastingly; this is the case in glaucoma acutum inflammatorium.

Whenever the inflammatory process creeps slowly and in a chronic manner from in front backward, or *vice versa*, we have the glaucoma chronicum inflammatorium. In the former case the excavation will be developed at a late period only, while in the latter case the excavation will exist before any inflammatory changes appear in the anterior portion of the eyeball.

When the affection is a chronic choroiditis posterior, we have the glaucoma chronicum simplex; and the glaucoma acutum simplex is that rare form in which this posterior choroiditis appears acutely; a form of glaucoma, however, which is very soon followed by the anterior choroiditis in such a manner that the painless increase of intra-ocular pressure and blindness are soon succeeded by inflammatory changes in the anterior portion of the eyeball.

The writer may here state that it seems to him impossible to adopt such a theory, as the choroiditis on which it hinges does not seem to exist. Careful examinations of many glaucomatous eyeballs have not revealed the presence of inflammatory changes in the choroid which would be important enough to be taken as a cause of the series of symptoms constituting the disease which we call glaucoma. It seems to the writer that the theories which seek the cause of glaucoma in a mechanical obstruction of the outlets of blood and lymph fluids from the eyeball are the most plausible ones, and there can, it seems, be no doubt but that a number of different influences may bring about such an obstruction. That the once increased pressure can easily cause an excavation of the optic papilla in hyperopic eyes, at least, seems to be plain from Figs. 2308, 2309, 2310, and 2311.

In more recent years Richey and a number of followers have again brought forward an older theory, according to which glaucoma is said to be the result of uric-acid diathesis, and they seem to have strengthened their views by numerous observations of improvements and cures by careful treatment of the lithæmia.

Prognosis.—The prognosis of glaucoma, unless its progress is interfered with by therapeutical or operative measures, is absolutely bad.

Treatment.—In the medical treatment of glaucoma an important step forward has been made since the myotics, and especially the sulphate of eserine (physostigmine, Laqueur) and the muriate of pilocarpine have been found to reduce the intra-ocular pressure. The value of these remedies in glaucoma is, however, a rather limited one. They do not and cannot cure glaucoma, but by their tension-diminishing influence they act beneficially during the prodromal stage, and they may well serve to stave off a threatening attack of glaucoma. By the forcible contraction of the sphincter pupillæ, induced by the action of these remedies, the periphery of the iris is, as long as this is yet possible, pulled away from the ligamentum pectinatum and thus its obstruction may be partially or even totally abolished for the time being. These remedies are, furthermore, of value before and after an operation for this disease. When instilled into the eye they generally also ease the pain of an inflammatory attack.

A cure of glaucoma or, at least, an arrest of the process, is to be accomplished only by operative measures. Among these the iridectomy (von Graefe) as yet holds the first place. Its value is greatest in the acute inflammatory and then in the chronic inflammatory forms, least in the chronic simple glaucoma. An early iridectomy in a case of acute inflammatory glaucoma is likely to bring vision again up to the normal. If performed at a later stage it may not be able to restore more than a part, or even nothing, of the lost vision. In the chronic inflammatory form the iridectomy usually restores a part of the lost vision; the quantity of this, however, depends very much upon what pathological changes the optic papilla and the nerve fibres had already undergone at the time of the operation. In the chronic simple glaucoma the iridectomy generally arrests the progress of the disease, and may produce an improvement of vision, although it does so but rarely. On general principles we may state that the earlier the operation is performed the greater may we expect its effect to be.

It is as yet an unsettled question why an iridectomy will lastingly reduce the intra-ocular pressure, although the fact is undoubted. It seems to be most likely that the explanation lies in the fact that the removal of a piece of iris tissue not only lessens the quantity of the blood-vessels, and, therefore, of blood within the eyeball, but also takes away a part of the obstacle to the draining of the fluids from the anterior chamber. It has been stated by Exner that a direct communication between the arteries and veins, without intervening capillary network, would take place in the parts of the iris directly wounded by the iridectomy. The writer, when reporting his studies on the process of healing after an iridectomy, had occasion to state that he had never been able to see such a condition. Arlt, in his recent book on glaucoma, takes pains to say that the writer's statements in regard to this question are of no value, since he had not injected the blood-vessels. The writer's paper on the question, however, states plainly that he injected most of the animals experimented upon with Berlin blue, and for the truth of the matter it is necessary to state here again that he was, and is to this day, unable to verify Exner's observations.

A number of authors maintain that the scar in the corneo-scleral tissue is of more importance even than the excision of a piece of iris tissue (Wecker), and they consider this scar a means of continued filtration of fluids from the anterior chamber. No direct proof for this opinion has thus far been given, but there is no doubt that scar-tissue, when consolidated, is, as a rule, more compact than normal tissue. It would, therefore, seem that we have a right to expect an effect just opposite to the one here given as an explanation of the action of an iridectomy in glaucoma.

Whatever the explanation of the healing influence of an iridectomy in glaucoma may be, one thing is certain, that we have occasion to see cases in which a typically and *lege-artem* performed iridectomy has not been able to stay the progress of glaucoma, as well as cases in which a very imperfect operation has had the desired effect. This would seem to show that science will some day find a procedure which will supersede the empirical operation of iridectomy for glaucoma. At present, however, it is as yet the safest and the most satisfactory measure in our hands.

Based on the theory that the corneo-scleral or scleral incision necessary to perform an iridectomy was the main feature of this operation in glaucoma, and that the excision of a piece of iris tissue was wholly unimportant to the end in view, besides, of course, having other disagreeable features (Quaglino, Wecker, and others), simple sclerotomy, and either anterior sclerotomy or posterior sclerotomy have been proposed and introduced in place of iridectomy. The efforts which have been made to supersede the iridectomy by the sclerotomy have, however, failed. This failure is not only due to the danger arising from prolapse or from incarceration of the periphery of the iris in the corneo-scleral wound, but also to the fact that the combined experience of many observers has shown that this operation is insufficient, and especially so in the inflammatory forms of glaucoma. It may be performed with more success in chronic simple glaucoma, and in cases in which an iridectomy has not been able to cut short the progress of the disease altogether, and in which a second iridectomy has by some authors been advocated. It may, furthermore, be considered of value in cases of glaucoma absolutum, when the pathological changes of the iris tissue no longer allow of the performance of an iridectomy.

Several authors have tried to replace iridectomy by an operation which aims at cutting the ciliary muscle (Hancock) or the tendinous portion at its insertion into the corneo-scleral tissue. These procedures seem not only to be of doubtful value, but also to be fraught with danger from subsequent sympathetic ophthalmia. The latter objection has, however, also been urged against sclerotomy. The most recent procedure is excision of the superior cervical sympathetic ganglion as introduced by Jonnesco. This operation is still *sub judice*, having its ardent admirers as well as enemies. A careful critical paper on the subject by Ziehe and Axenfeld says that in all cases of glaucoma in which our present therapeutic measures have not sufficed, the extirpation of the cervical sympathetic is a justifiable and advisable experiment, although it does by no means afford help in every instance.

Aside from the operation, the general condition of a patient suffering from glaucoma ought to be attended to. He ought to be especially restrained from everything which may in his case be apt to act as an occasional cause for a glaucomatous attack. If there is—and this is the rule—an error of refraction or accommodation, or of both, it must be corrected. In fact it is claimed that careful attention to refractive errors as practised in this country has reduced the number of cases of glaucoma.

Glaucoma not always being easy to recognize, it will be always well to examine carefully, with regard to the possible presence of this disease, every patient who comes to his physician complaining of, and seeking relief from, neuralgia of the eye and head, combined with obscurations of sight and with nausea. *Adolf Alt.*

GLECHOMA. See *Labiatæ.*

GLEN ALPINE MINERAL SPRINGS.—El Dorado County, California. Back in the mountain fastnesses at a distance of seven miles from Lake Sahoe, and at an elevation of 6,700 feet above the sea-level, are Gilmore's Glen Alpine Mineral Springs and Health Resort. The wild, rugged gorge in which they are situated runs back from Sahoe a distance of some ten miles. It is diversified throughout its length with varied scenes of beauty and grandeur, and terminates abruptly in a glacial amphitheatre. The region is rich in exquisite flowers and ferns. "Those dimpling lakes, with the wild beauty of their surroundings are sufficient to enthrall the heart of him who visits them; but if he be devoted to the rod and reel he will find an additional charm in the swarms of speckled beauties which sport in the clear depths and rise to the glancing fly."

This region has been opened to the public with great labor and expense by the construction of a wagon road as far as Glen Alpine Springs, and mountain trails to all the lakes, including a path for the ascent of Mount Sallac, which rears its head 10,000 feet above the level of the sea, and commands a wide and magnificent view of the distant peaks and numerous lakes. Good accommodations for guests will now be found at Glen Alpine Springs. Analysis by Dr. Anderson:

ONE UNITED STATES GALLON CONTAINS:

Solids.	Grains.
Sodium chloride	21.17
Sodium carbonate	32.75
Potassium carbonate	Trace.
Magnesium carbonate	9.96
Calcium carbonate	45.09
Calcium sulphate	4.10
Ferrous carbonate	1.80
Alumina	1.43
Borates	Trace.
Silica	2.50
Organic matter	Trace.
Total solids	118.80

Free carbonic acid gas, 138.36 cubic inches.
Temperature of water, 39.6° F.

The water is very palatable and sparkling. Its action is gently aperient and diuretic, and the water is useful in dyspepsia and torpidity of the bowels as well as in renal and cystic disorders. It contains sufficient iron to give it important properties as a ferruginous tonic. *James K. Crook.*

GLEN ALPINE SPRINGS.—Sevier County, Tenn.

POST-OFFICE.—Newport, Cocke County. Hotel.

ACCESS.—Viâ Southern Railroad to Newport, Cocke County, thence by stage 12 miles west to springs.

These springs are located in a mountainous region, 3,000 feet above the sea-level. The usual charming scenery and exhilarating climate of the East Tennessee mountain district will be found here. The springs are four in number, and yield about sixty gallons each per hour. No analysis has been made, but the water is said to be chalybeate and very serviceable in debilitated and anæmic states, especially those arising from disorders of digestion and assimilation. Hay-fever patients are said to improve rapidly as a result of a sojourn at these springs. The improvements at the resort are by no means elaborate at present, but the location offers many attractions during the summer months to persons not afraid to grow strong by roughing it. *James K. Crook.*

GLEN SPRINGS.—Schuyler County, New York.

POST-OFFICE.—Watkins. Hotel and sanitarium.

ACCESS.—Watkins is situated on the Northern Central Railroad, between Elmira and Rochester. This road (a division of the Pennsylvania system) runs from Rochester to Baltimore, Philadelphia, and Washington. It connects at Rochester with the New York Central, West Shore, Michigan Central and other railroads, at Canandaigua with the Auburn branch of the New York Central, and at Elmira with the Erie and the Delaware, Lackawanna and Western Railroad. The Fall Brook Railroad also has a depot one mile and a half from Watkins. This beautiful and modern health resort and watering-place stands upon a broad plateau 300 feet above Seneca Lake, whose winding course it overlooks for nearly thirty miles. It is surrounded by pine forests and backed by an amphitheatre of hills rising in regular terraces to nearly 1,500 feet. At the foot of the hill, less than a quarter of a mile away, lies the village of Watkins, with its churches, shady streets, and lovely homes, while the entrance to the famous Watkins Glen and the landing of the Seneca Lake steamers are both within seven minutes' easy walking distance. Seneca Lake is one of the most remarkable bodies of water known. It is fed by deep springs, and has been frozen over only twice during the last century. For beauty of scenery and richness of coloring it has no superior, its shores are grand and picturesque, the sides thickly wooded in places, in others covered with fruit orchards and vineyards. This great body of water, nearly forty miles long and from two to four miles in width, exerts an unquestioned modifying influence on the atmosphere, tempering it in winter and cooling and freshening it in summer. A remarkable feature of this region is the great number of its sunny days during the fall, winter, and spring. The record for 365 days has shown that there were only 55 cloudy days, and 17 of those were in May. These features tend to make the location a very desirable winter as well as summer resort. The Glen Springs Park comprises sixty acres of woodland and lawn, about equally divided, and one can wander for miles over well-built walks, obtaining from almost every point grand and beautiful vistas of lawn, lake, forest, and glen. Within the park are bowling-alleys, tennis courts, croquet grounds, and golf links. Pleasant drives abound in every direction, while to those who prefer the water the fine, large steamers of the Seneca Lake Navigation Company, plying six times a day between Geneva and Watkins, afford every comfort and luxury. Good fishing is found in Seneca Lake, and within easy driving distance over good roads one can reach Keuka, Lamoka, Cayuta, and Little Lakes, all famous fishing resorts. The main building of the Glen Springs sanitarium, heated by steam and lighted by electricity and gas, consists of four stories and a basement, constructed in a substantial manner of brick and stone. The annex, a new building, has accommodations for one hundred guests. The two buildings are connected by a wide corridor enclosed in glass and heated in cold weather by steam. It affords ample space for exercise, and forms an excellent solarium during the winter months. These buildings are provided with all modern comforts and luxuries. On the grounds there are several large mineral springs which are used for drinking and bathing. The following analyses of the first four springs were made by Prof. S. A. Lattimore, of the University of Rochester. The fifth spring was analyzed by Prof. Charles F. Chandler.

Seneca Spring—Calcic.

One United States Gallon Contains:

Solids.	Grains.
Calcium carbonate	9.90
Calcium sulphate	.47
Magnesium carbonate	2.10
Sodium chloride	.12
Silica	.07
Iron oxide	Trace.
Total	12.66

The water is entirely free from organic matter. This spring is situated two hundred feet higher than the buildings. It flows about 4,000 gallons of water per hour, and is used in the buildings for general domestic purposes.

Vulcan Spring—Alkaline-Saline, Chalybeate.

One United States Gallon Contains:

Solids.	Grains.
Calcium carbonate	29.80
Magnesium carbonate	11.37
Iron carbonate	1.87
Sodium chloride	149.06
Alumina	Trace.
Silica	Trace.
Total	192.10

Carbonic acid gas, large quantities.

This is a clear, sparkling water, and issues from the rocks at a depth of 100 feet. It resembles the waters of Kissingen, and has diuretic, tonic, mildly aperient, and slightly alterative properties.

Salubria Spring—Muriated-Saline.

One United States Gallon Contains:

Solids.	Grains.
Sodium chloride	196.28
Calcium carbonate	19.68
Magnesium carbonate	.05
Silica	Trace.
Total	216.01

This spring issues from the rock at a depth of 250 feet, and resembles the class known in Germany as muriated (chloride of sodium) alkaline springs. It is somewhat similar to the waters of Vichy, Sachingen, and Bilin, but is more like those of Kissingen, Homburg, and Wiesbaden. The water has a stimulating effect upon the mucous membrane of the stomach and bowels and increases the flow of gastric juice and bile and promotes digestion and absorption. It has about the proper quantity of sodium chloride favorably to influence the process of osmosis. In large doses it is purgative.

Neptune Spring—Saline, Calcic, Iodo-bromated.

One United States Gallon Contains:

Solids.	Grains.
Calcium chloride	3,499.08
Magnesium chloride	635.67
Sodium chloride	6,368.33
Sodium iodide	Trace.
Sodium bromide	Trace.
Iron and alumina	Trace.
Total	10,503.08

This water constitutes a strong brine. It is quite remarkable for its large proportion of calcium chloride and its total freedom from calcium sulphate (gypsum). In its principal ingredients it resembles the brine springs of Michigan and the springs of Nauheim, Rehme, and Jaxtfelt. It may be classed as an iodo-bromated saline spring, and while not adapted for drinking purposes, is of great value for bathing. By charging the water with carbonic acid gas it becomes very similar to the Nauheim waters, and the treatment of glandular and rheumatic troubles, gout, lumbago, and sciatica, as well as the Schott method in chronic diseases of the heart, is carried out at Glen Springs. This water is also employed in the electro-chemical and electro-vapor baths, douches, sprays, etc. The spring is said to have its origin about 1,700 feet below the surface of the earth.

Deer Lick Spring—Alkaline, Saline, Chalybeate.

One United States Gallon Contains:

Solids.	Grains.
Sodium chloride	114.75
Potassium chloride	.23
Sodium bromide	.59
Sodium iodide	.04
Potassium sulphate	Traces.
Lithium bicarbonate	Traces.
Ammonium bicarbonate	1.08
Iron bicarbonate	1.73
Calcium bicarbonate	41.77
Magnesium bicarbonate	19.28
Alumina	.34
Sodium phosphate	Traces.
Silica	.64
Total	180.45

This water is clear and sparkling, without odor, and with a slightly astringent, mildly saline taste. Containing, as it does, besides chloride of sodium and iron, the rare ingredients of iodine and bromine (in combination), it may be ranked as a ferro-iodo-bromo-muriated spring. It is also rich in carbonic acid gas. It resembles in many respects the waters of Kreuznach, Hall, Duerkheim, and Krauenheit. It is an excellent drinking-water and, unlike many of the foreign iodo-bromated waters, may be taken as it flows without dilution. The Deer Lick water possesses tonic, alterative, diuretic, and mildly aperient properties. Tissue metabolism is promoted and the red globules of the blood are increased. Its physiological action fits it for use in anæmia, neurasthenia, chronic renal diseases, glycosuria, and chronic diseases of the uterus.

James K. Crook.

GLEN SUMMIT SPRINGS. — Post-Office. — Glen Summit, Luzerne County, Pennsylvania. Hotel.

Access.—Viâ Lehigh Valley Railroad, about 150 miles from New York and 125 miles from Philadelphia.

This attractive summer resort is on the summit of the

Nescopic Mountain, 2,000 feet above tide-water. The romantic scenery of the surrounding country and its easy accessibility, coupled with an excellent modern hotel furnished with all the recent improvements, have of late years served to bring the place into well-deserved prominence. The charming surroundings and pure, invigorating mountain air offer an enticing refuge from the toils and cares of city life during the hot weather. Numerous cases are cited of the apparent complete arrest of incipient lung disease after a few weeks spent here. The springs about Glen Summit are of the ascending variety, welling up along the lines of jointing in the Catskill formation from far down in the subterranean recesses below. The temperature of the water is acquired from the rocks at depths sufficient to be beyond the influence of surface temperatures, and is cold enough to cause an unpleasant chill to the hands when submerged for a few seconds. An examination, however, will show that these waters owe their value rather to their purity and palatability than to their chemical ingredients. The following analysis was made by Prof. W. H. Dean, chemist, of Wilkesbarre, in 1896:

ONE UNITED STATES GALLON CONTAINS:

Solids.	Grains.
Sodium chloride	0.23
Calcium sulphate	.20
Calcium carbonate	.20
Silica	.11
Iron oxide and alumina	.03
Free ammonia Nitrogen as nitrates Nitrogen as nitrites Albuminoid ammonia	.00
Loss on ignition	.33
Total	1.10

This shows a very pure and valuable water for domestic uses. Among other excellent pure-water springs in the neighborhood are the "Great Indian" Spring, yielding over 4,000 gallons hourly (if supplies the hotel); the "Twin" Springs, the "Bear" Spring, and the "Counterfeiter's" Spring. There are also other springs which have not been named. *James K. Crook.*

GLENN SPRING.—Tipton County, Tennessee.

POST-OFFICE.—Atoka. Cottages.

ACCESS.—Viâ Chesapeake, Ohio, and Southwestern Railroad (Mississippi Valley route) to Atoka; thence seven miles to springs.

This spring is situated under the shadow of Chickasaw Hills. It has quite an ancient reputation in Western Tennessee in the treatment of liver, kidney, and digestive disturbances. The spring is surrounded by a magnificent grove of trees, which lends a romantic charm to the neighborhood. It yields about ninety gallons of water per hour. The following analysis was made in 1880 by W. S. Lupton, analytical chemist:

ONE UNITED STATES GALLON CONTAINS:

Solids.	Grains.
Sodium carbonate	1.58
Calcium carbonate	9.64
Magnesium carbonate	7.10
Potassium carbonate	.05
Iron carbonate	.54
Potassium sulphate	.27
Calcium phosphate	.01
Sodium chloride	.16
Silica	1.38
Total	20.73

Carbonic acid gas, 14.64 cubic inches.

This is a very good antacid and mild diuretic water with ferruginous properties. *James K. Crook.*

GLENN SPRINGS.—Spartanburg County, South Carolina.

POST-OFFICE.—Glenn Springs. Hotel and cottages.

ACCESS.—From Spartanburg, a distance of 12 miles by the Glenn Springs Railroad; double daily service.

These springs are located in a charming section of the country, broken by granite and sandstone hills. The elevation is about 1,000 feet above the sea-level. Many improvements have recently been added, the hotel having been greatly enlarged and comfortable cottages built. Many additional improvements are under way, and when completed Glenn Springs will bid fair to compete with the leading spas of the country. The following analysis of the Glenn Springs water was made in 1880 by C. U. Shepherd, Jr.:

ONE UNITED STATES GALLON CONTAINS:

Solids.	Grains.
Magnesium carbonate	3.32
Calcium sulphate	91.50
Sodium chloride	2.21
Potassium chloride	.52
Total	97.55

This analysis is probably incomplete. We are informed that a more recent partial examination of the water showed the presence of lithia in considerable quantities. The water has been in use many years. Numerous well-known physicians of South Carolina attest to its virtues, especially in disorders of the alimentary tract, dyspepsia, diarrhœa, dysentery, hemorrhoids, etc. It is said to be very useful in functional uterine affections, dysmenorrhœa, amenorrhœa, leucorrhœa, etc., as well as in torpidity of the liver and biliousness. *James K. Crook.*

GLENOLA SPRINGS.—(Formerly Wayland Springs) Nottoway County, Virginia.

POST-OFFICE.—Jennings Ordinary. No accommodations at present. These springs are located in a fine undulating stretch of country, half a mile from Jennings Ordinary, on the Southern Railroad, and six miles from Burkeville Junction on the Norfolk and Western Railroad. The location is about 500 feet above the sea-level, and the climatic conditions are of a very desirable character. The average summer temperature range is 77° F., winter 38° F. The temperature of the water is 48° F. There are several springs in the neighborhood, only one of which has been chemically examined. The following analysis was made by Prof. M. B. Hardin, of the Virginia Military Institute:

ONE UNITED STATES GALLON CONTAINS:

Solids.	Grains.
Sodium carbonate	0.55
Lithium carbonate	.01
Magnesium carbonate	.26
Calcium carbonate	.70
Strontium carbonate	.03
Iron carbonate	.06
Manganese carbonate	Traces.
Potassium sulphate	.05
Potassium chloride	.09
Sodium chloride	.34
Sodium iodide	Traces.
Sodium nitrate	.11
Sodium phosphate	.01
Aluminum phosphate	.04
Ammonium nitrate	Traces.
Silica	1.92
Aluminum silicate	.20
Calcium fluoride (suspended)	Trace.
Titanium dioxide	"
Organic matter	"
Carbonic acid in the bicarbonates	.71
Total	5.08

Carbonic acid gas, 6.65 cubic inches.

This water is distinguished by the presence, in small but perceptible quantities, of the iodide of sodium. It may be ranked as an iodic-alkaline-carbonated water. The spring yields about thirty-eight gallons per hour the year round. Since its discovery, in 1883, it has been extensively used in cases of rheumatism, dyspepsia, and renal diseases. The location offers excellent advantages as a health resort. *James K. Crook.*

GLENWOOD SPRINGS.—Garfield County, Colorado.

POST-OFFICE.—Glenwood Springs. Hotels: The Colorado and numerous smaller hotels.

ACCESS—Viâ the Denver and Rio Grande and the Colorado Midland branch of the Atchison, Topeka and Santa Fé Railroad. (For climatic and topographical features of Glenwood Springs, *vide* vol. iii., p. 222.)

The following analysis of the waters at Glenwood Springs was made by Prof. Charles F. Chandler of New York.

YAMPA SPRING—MURIATED, SALINE, SULPHURETED.

ONE UNITED STATES GALLON CONTAINS:

Solids.	Grains.
Sodium chloride	1,089.83
Magnesium chloride	13.09
Sodium bromide	.56
Sodium iodide	Trace.
Calcium fluoride	Trace.
Potassium sulphate	24.04
Calcium sulphate	92.38
Lithium bicarbonate	.22
Magnesium bicarbonate	13.55
Calcium bicarbonate	24.37
Iron bicarbonate	Trace.
Sodium phosphate	Trace.
Sodium biborate	Trace.
Aluminum	Trace.
Silica	1.97
Organic matter	Trace.
Total	1,260.01

Carbonic acid gas is copiously discharged from the springs. Sulphureted hydrogen is discharged in perceptible quantity.

The temperature of the Yampa, the largest spring of the group, as taken by the writer late in October, was 124.6° F., and of the "Chicken-broth" or "Cocktail" spring, 126.4° F. The specific gravity of the former when cooled down to 83° F. was 1.013, and of the latter a trifle less. . . . That the waters here are strongly impregnated with sulphureted hydrogen is amply attested by the heavy deposit of sulphur crystals on stones seen in the springs, and on the surrounding sandstone walls. In the Yampa Spring the gas is in sufficient quantity to impart a decided bluish tinge to the water, rendering it slightly opalescent. The atmosphere immediately surrounding the springs is heavily charged with the escaping vapor. . . . The waters of the springs in flowing into the great swimming-pool are cooled to some extent by contact with the air and by evaporation, but the temperature is further lowered by an artificial cold-water geyser near the western end of the basin, supplied from a nearby mountain reservoir. An average temperature of 93° to 98° F. is thus maintained, and bathing may be indulged in the year round. Another interesting and unique feature of Glenwood Springs should not pass unnoticed. Across the Grand River from the Hotel Colorado, and two or three hundred yards upstream, is the entrance to a cave which extends for a considerable distance under the mountain. This cave has a natural temperature ranging from 105° to 110° F., and the atmosphere is saturated at all times with the vapor of water strongly impregnated with sulphur like that at the springs. After one has remained for a few minutes in the cave the surface of the body becomes bedewed with a profuse perspiration. Advantage has been taken of this ready-made Russian-bath vapor chamber, and a bath-house with the requisite adjuncts has been constructed at its entrance. The cave itself is lighted by electricity, and attendants are on hand to supply the wants of bathers either in the caverns or in the private rooms.

As we have thus seen, the waters at Glenwood, besides being saline and sulphureted, are highly thermal. Fuller data concerning their exact remedial value are desirable. During the writer's sojourn at the springs a considerable number of persons, some of them from distant points, were using the baths, but they were for the most part acting under their own guidance and were not under medical observation. As far as could be learned, however, the evidence is strongly in favor of the utility of the baths in cases of chronic rheumatism, gout, cutaneous and renal diseases. . . . In common with all hot baths, these waters are contraindicated in fatty degeneration of any important structure, in atheroma, aneurism, or structural heart trouble, and in the predisposition to pulmonary, cerebral, gastric, or intestinal hemorrhage.

James K. Crook.

GLIOMA.—The glioma is a tumor consisting of proliferated neuroglia (the supporting tissue of the central nervous system) and of blood-vessels which are accompanied by a small amount of connective tissue. As the neuroglia cells are derived histogenetically from the epithelium lining the neural canal, the glioma is a tumor of which the essential or characteristic part is of ectodermic origin.

The glioma is found exclusively in the central nervous system of which it forms the commonest tumor. It occurs most frequently in the cerebrum, although the cerebellum is also a favorite site; it is found less commonly in the spinal cord. In the cerebrum it is often limited to the white matter and adjoining central ganglia, or it may arise from the latter and extend to the neighboring parts. Sometimes it reaches across the median line from one hemisphere to the other. It is more common in early than in adult life.

As a rule gliomata are solitary, but cases of multiple tumors have been reported Although the new growth generally appears well defined, the periphery is rarely sharply limited because a glioma is not surrounded by a capsule but tends to spread by infiltration of the adjoining brain tissue; it does not simply shove it back. By invasion of portions of convolutions it may enlarge them and render them denser or softer than normal. Gliomata do not, except possibly in rare cases (authorities differ), extend through the meninges or affect the bones of the skull, although they may set up a localized adhesive meningitis over the tumor. A zone of softening and of œdematous swelling often occurs for a greater or less extent around the growth.

In general a glioma of the brain is round. It varies ordinarily in size from a pea to a walnut, but in exceptional cases may be as large as an orange. In the spinal cord a tubular form is more common, probably on account of the pressure exerted by the narrow canal in which the cord lies.

The color of a glioma generally does not differ greatly from the white matter of the brain; it usually appears gray or yellowish-gray and rather translucent; but the more cellular forms may have a pinkish or reddish-gray or even dark red color from the numerous blood-vessels present. Degenerations, necrosis, and hemorrhages often cause marked changes in color, at least within the areas affected.

The consistence varies between hard and soft, depending chiefly on the number of cells and the amount of intercellular substance present in a given tumor, but œdema may also play an important part.

Two chief varieties of gliomata are recognized, depending on the consistence of the growth; these are the *hard* and the *soft* gliomata, but these descriptive terms really represent only the extremes of consistence, and all intermediate degrees occur. The term *myxoglioma* has in the past been applied to an œdematous glioma, but is manifestly incorrect because mucin has not been demonstrated to be present. A glioma containing numerous blood-vessels is sometimes called *glioma teleangiectodes.*

Secondary degenerations and necrosis are very common, as shown by yellow areas and by cysts of softening; the latter may occupy a large part of the original growth; they may contain a clear, cloudy, or dark brown fluid. In consequence of the numerous blood-vessels present, especially in the more rapidly growing gliomata, large and small hemorrhages are not infrequent; occasionally such a hemorrhage may be the cause of sudden death. As such vascular forms usually are soft, a large part of the tumor may be destroyed, so that careful and even microscopic examination may be required to determine the origin of the hemorrhage.

A glioma is essentially a benign growth; it does not give rise to metastases, but is dangerous partly on account of the pressure it exerts, partly from the destruction of the nervous tissue which it infiltrates.

Histologically the picture presented by gliomata varies greatly. In those of which the structure most resembles normal neuroglia the tumor tissue consists of round or oval vesicular nuclei surrounded by a slight amount of protoplasm and of chemically differentiated fibrillæ which are not processes of the cells but are an intercellular fibrillar substance. Several methods for staining them have been published. As in normal neuroglia tissue, these fibrillæ do not start from or end in the cells to which they owe their origin, but simply touch or adhere to the surface of the protoplasm in passing. They are generally straight or moderately curved, solid, smooth, and of uniform size, although the separate fibrillæ vary considerably in thickness; they do not branch or anastomose. This type of glioma (Fig. 2316) is particularly prone to infiltrate the surrounding nervous tissue. The peripheral limit of its growth is even more difficult to recognize under the microscope than in the fresh condition. Moreover, this type of glioma closely resembles the secondary growth of neuroglia tissue (*gliosis*) which takes place when nervous tissue is gradually destroyed, and also always forms to some extent around gliomata. It bears the same relation to gliosis that in the mesenchymal tissue a fibroma does to the fibrous or scar tissue formed in the liver and other organs under analogous conditions. There is this point to aid in the recognition of a gliosis: the form of the part affected is preserved in its normal relations, but shrunken in size.

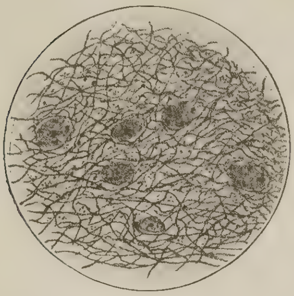

FIG. 2316.—From a Section of a Fairly Hard Glioma of the Small-Celled, Usually Infiltrating Type. The fibrillæ generally correspond in size to those of the normal neuroglia.

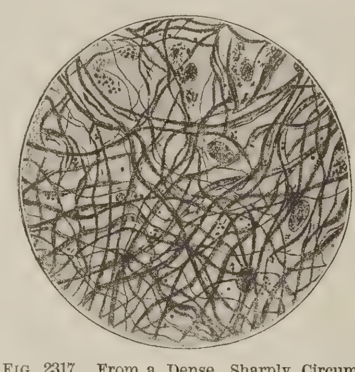

FIG. 2317. From a Dense, Sharply Circumscribed Glioma Containing Few Cells and many very Coarse Fibrillæ.

The density of this form of glioma depends chiefly on the relation between the cells and the fibrillæ; the more fibrillæ the greater the density. In one case studied the tumor (Fig. 2317) was very discrete in outline and dense to the touch; microscopically it contained few nuclei and great numbers of very coarse fibrillæ which could easily be distinguished from the fine fibrillæ of the gliosis surrounding the growth.

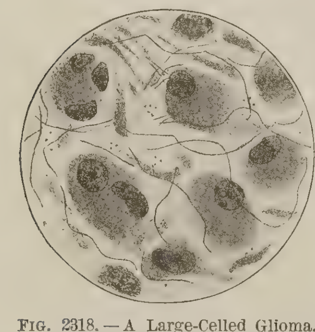

FIG. 2318.—A Large-Celled Glioma. The cells are often multinucleated, some have protoplasmic processes; the neuroglia fibrillæ are delicate.

In the cellular forms of gliomata (which correspond to the sarcomata of mesenchymal origin) the size of the cells in the different tumors varies greatly; large- and small-celled varieties are recognized. Whether differentiated fibrillæ are always produced by these rapidly growing gliomata is still an unsettled question. In a large-celled variety examined, in which mitotic figures were numerous, differentiated fibrillæ were fairly abundant in places (Fig. 2318).

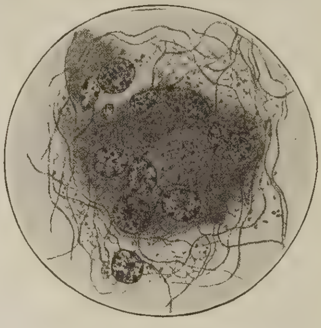

FIG. 2319.—From a Glioma Probably of Ependymal Origin. A clump of cells fused together and containing in their protoplasm differentially staining dots similar to those described by Weigert as occurring in the inner edge of ependymal cells and in the protoplasm of groups of epithelial cells lying near the neural canal.

To the above well-recognized types of gliomata another variety, never before described, must be added. It is as yet an unsettled question whether the ependymal cells lining the ventricles of the brain and the neural canal of the cord produce neuroglia fibrillæ; the relation of the ependymal cells to the neuroglia cells in post-embryonic life is therefore undecided. Weigert, however, has called attention to one peculiarity of ependymal cells: they each contain in the edge of the protoplasm lining the canal a small cluster of dots which stain by the differential methods for neuroglia fibres. In the cord just outside of the neural canal are often seen small clumps of epithelial cells in whose protoplasm similar differentiated dots appear. A very vascular tumor 4×5×3 cm., which hung from the roof of the fourth ventricle of the brain, was composed of cells arranged for the most part in clumps. The protoplasm of the cells was fused together; the nuclei, often six to a dozen or more in number, were arranged chiefly at the periphery. In the central part of nearly every one of these compound cells was a group of differentially staining dots lining a light staining circle in the protoplasm (Fig. 2319). Sometimes two or three clumps of dots were present. Similar groups of dots were found within single cells (Fig. 2320). There were also present in the tumor numerous small and large cysts (Fig. 2321) lined with epithelial cells in whose inner border occurred similar groups of dots. The so-called dots were not always round, but often appeared as short rods. Outside of the cells and cysts was a fine network of fine fibrillæ which stained differentially. This tumor would certainly suggest an origin from ependymal cells and the other cells mentioned above as occurring outside of the neural canal. It would also favor the view that at least some gliomata have their origin in congenital defects of development.

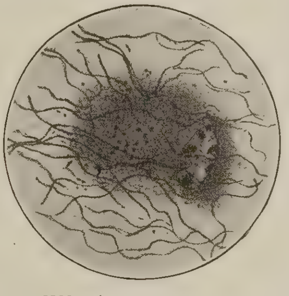

FIG. 2320.—(From same tumor as that shown in Fig. 2319.) A Single Cell Containing Similar Dots.

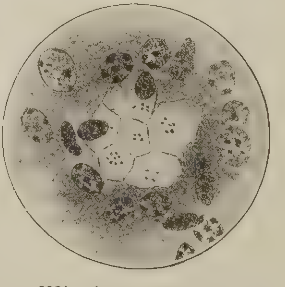

FIG. 2321.—(From same tumor as that shown in Fig. 2319.) The Bottom of a Small Cyst Showing the Dots in the Surface of Cells which do not Appear in the Section.

Gliomata of the retina have not been discussed because no one has yet shown by modern differential stains that they occur. The term *gliosarcoma* has been commonly applied to cellular gliomata; it can properly be applied only to a mixed tumor composed of rapidly proliferating neuroglia and mesenchymal tissues; it is extremely doubtful if such a tumor occurs. Another term that should be given up is *neuroglioma*. It should be applied to a new formation both of neuroglia tissue and of nerve cells. No evidence has yet been brought forward to prove that nerve cells in the central nervous system ever proliferate to form tumors. Nerve cells and nerve fibres often occur in gliomata in consequence of having been surrounded by the new growth. In certain large-celled gliomata some of the cells have protoplasmic processes and more or less resemble nerve cells, but they do not possess axis-cylinder processes or Nissl-granules; consequently they cannot be regarded as nerve cells.

The relation of glioma to syringomyelia will be discussed under the latter heading.

For the modern views on neuroglia tissue the reader is referred to Weigert's monograph, "Die Neuroglia," 1895. For a summing up of the neuroglia question to date, for the various differential stains for neuroglia fibres, and for complete bibliography see Huber, "Studies on the Neuroglia," *American Journal of Anatomy*, 1901, vol. i., p. 45. Consult also the article on *Neuroglia*.

GLOSSY SKIN. See *Hand and Fingers, etc.*

GLOTTIS, ŒDEMA OF. See *Laryngitis, Œdematous.*

GLOVES, USE OF, IN SURGERY.—Gloves have occasionally been used by surgeons at operations in order to protect the hand of the operator from foul discharges; but their general use to protect the patient from infective material introduced by the operator's fingers, has been developed in the last five years. The reason for this is the universally admitted fact that it is very difficult perfectly to sterilize the human hand. A secondary advantage of gloves lies in the saving of time and epidermis to the surgeon.

Various materials have been used to make surgical gloves. Wash-leather was one of the first, rubber cloth another; but as any thick glove is certain to make the fingers clumsy and blunt the sense of touch, such materials were found to be unsatisfactory. Gloves made of Lisle thread, and thin gloves of pure rubber have proved to be the most satisfactory, and these will alone be considered in detail.

Each material has its advantages. The cotton glove is cheaper than rubber, is more durable, is less easily torn, and is not slippery, a great advantage in some circumstances, as in tying ligatures, or in holding a slippery loop of intestine. Blood-smeared tools and fingers are slippery, and rubber increases this, while cotton does away with it.

On the other hand, the rubber gloves have certain advantages. Rubber is not porous, and hence no infective material can pass from the fingers to the wound through the glove if it is not pricked or torn. The tactile sense is better preserved through a thin rubber glove than through a thin cotton one. The very slipperiness of the rubber may be an advantage, as in thrusting the hand into the abdominal cavity. The chief point of difference, however, is the porosity of the cloth and the imporosity of the rubber. This makes the cotton more comfortable to wear, since the perspiration is not increased. The protection of the patient from infection is probably less perfect with the cotton gloves, especially if much fluid is used by the operator, or the operation requires much handling of wet tissues. In the ordinary dry operation, if the surgeon keeps his hands on the instruments and out of the wound as much as possible, the risk of infection must be a minimal one. If the cotton gloves become soiled they can be changed in a moment for others. In this way the risk of infection can be made still smaller.

Attempts have been made to render cotton gloves impervious to moisture by soaking them in various oils and other substances. The best results are obtained by use of a ten-per-cent. solution, in xylol, of paraffin of a low melting point. The gloves should be first dried in an oven, then immersed in pure xylol, and then for fifteen minutes in the paraffin solution. They are then taken out, dried, and sterilized by dry heat or steam. When soiled they may be washed with soap and water, dried, and again paraffined and sterilized. If cotton gloves are to be worn it is better to render the hands as nearly sterile as possible, before drawing them on, if the operation is such that the fingers must become wet.

Opinion is divided on the necessity of sterilization of the hands before operation, if rubber gloves are to be used. Theoretically this is not necessary, unless the glove is pricked or torn. In that case a new glove should be put on, or a thin rubber finger cot should be pulled on the affected finger. Some surgeons say that infection may take place in this way, and that therefore the hands should be disinfected before the operation. Even if this is done in a thorough manner, the gloves cause such an increase of perspiration, that the hands are certainly not sterile at the close of an operation, no matter what their condition may have been at its beginning. McBurney therefore advocates washing the hands simply with soap and water, drying them, and rubbing them with sterilized starch powder, to facilitate the putting on of the gloves. By avoiding the use of irritating antiseptic solutions, he says he is able to keep the skin of his hands in good condition, and thus to feel as well through the glove finger, as he could do without a glove if the skin of his fingers was harsh and rough.

The sterilization of rubber gloves is not so simple as that of the cotton ones, but it need by no means be so complicated as some of the directions imply. A simple and efficient method is as follows: Wash the gloves inside and outside with soap, hot water, and a little ammonia. Boil them for fifteen minutes in a one-per-cent. soda solution, taking care that they do not come into contact with any metal while in the sterilizer. Remove the gloves with sterile forceps and lay them in a sterile towel, which is then to be wrapped around them. It is not necessary to fill the glove fingers with gauze, nor to attempt to dry the inside of the gloves, as this necessitates some handling. If the hands are dry and are covered with sterile powder, the gloves can be drawn on without difficulty. This is a much better method than to fill the gloves with sterile water before putting them on. Water and perspiration will then continue to drip from the wrists at intervals during the operation, and the wound may in this way become contaminated.

A more complicated way in which to sterilize the gloves, but one by which they are kept perfectly dry, is the following: Wash the gloves on both sides with a one-per-cent. sodium-carbonate solution, rinse them in sterile water, and dry them over a flame. Dust them with sterile soapstone powder, wrap them in gauze or a towel, and sterilize them for two hours in a formalin oven.

There is no difficulty in having absolutely sterile clothing, water, sponges, towels, ligatures, sutures, instruments, and other utensils. The air and floor probably never cause infection. The skin of the patient must rarely do so, or stitch abscesses would be more common. The hands of the surgeon must therefore be held responsible for nearly all of the infection which arises in clean operative cases. In regard to the use of gloves McBurney naively remarks: "Those surgeons who already with naked hands have entirely satisfactory results certainly do not need rubber gloves. But I am sure that they will be useful to those who too frequently meet with imperfect results." The extent to which gloves have been taken up by the younger men as a routine surgical procedure in their operations, is a sufficient proof that their use will in a few years be recognized everywhere as a precaution which few careful surgeons will care to disregard.

Edward Milton Foote.

GLUCIN is the sodium salt of amido-triazin-sulfonic acid, and is obtained by the action of fatty aldehydes on the dye-stuff chrysoidin, with conversion of the condensation products into their mono- and di-sulfonic acids. Like saccharin, glucin is used as a sweetening agent in diabetes; but, while it is less sweet than saccharin, its taste is more like that of sugar. One part is equivalent to about one hundred parts of cane sugar. It is said not to interfere with the digestive functions.

W. A. Bastedo.

GLUTOID CAPSULES are gelatin capsules which have been hardened in formalin. They are made in three grades, capable of resisting the action of the gastric juice for from one and a half to twelve hours, and were introduced by Sahli for the conveyance of drugs which it is desired not to have set free in the stomach. As a stomach test, Fromme proposes the following: Potassium iodide is administered in these capsules, and if the iodide reaction in the saliva occurs within three and one-half to five hours there is good gastric motility and normal pancreatic digestion. The capsules are said to disintegrate readily in the pancreatic juice, but no statement is made as to the effect of the formaldehyde set free.

W. A. Bastedo.

GLUTOL, formacoll, formaldehyde-gelatin, or glycoform, is an odorless, coarse brownish-white powder, made by dissolving 500 gm. of gelatin or isinglass in water, adding twenty-five drops of formalin, and reducing to dryness in formaldehyde vapor. It is stable, indifferent, not liquefied or changed by heat or moisture, and can be sterilized. It is not of itself antiseptic, but, though tough and insoluble, it sets formaldehyde free and is absorbed when applied to raw animal tissues. It is said not to allow the formation of granulations, and to form a very hard clean scab. This, of course, must be watched lest it retain the secretions from the wound, or allow the collection of pus. In incised and lacerated wounds and abscesses, Foote (Vanderbilt Clinic, New York) has not succeeded in getting primary union, and the dressings were followed by pain lasting several hours, yet he considers it of much value. He uses it in the following manner: the skin is cleansed with soap and water, turpentine, ether and bichloride, cocaine is injected, a free incision is made, and pus and sloughing tissues are curetted away. The wound is then filled with glutol and a dry dressing applied. The glutol is soon absorbed so that the surfaces of the wound are not kept apart as by gauze packing. No drain is necessary, as the powder allows drainage by capillary action. It has not power to kill pus germs, but will control their development. Schleich, its introducer, Keen, Da Costa, and many other foreign and American surgeons have found it a valuable succedaneum for iodoform. Schleich sprinkles it over the surface line of sutures when operating.

W. A. Bastedo.

GLYCERIN.—Glycerin ($C_3H_8O_3$) is, chemically, an alcohol—propenylic alcohol ($C_3H_5(OH)_3$), and results from the decomposition of natural fats by alkalies. The United States Pharmacopœia recognizes under the title *Glycerinum*, Glycerin, "a liquid obtained by the decomposition of vegetable or animal fats or fixed oils, and containing not less than ninety-five per cent. of absolute glycerin." Glycerin can be obtained as a by-product in the making of lead plaster or of soap, but is derived in purest condition by acting on fats with water at a high temperature, under pressure. Under those conditions the fats break up into glycerin and fatty acids. Glycerin so prepared is known as *distilled glycerin*, and the famous Price's glycerin is of such kind. Glycerin appears as "a clear, colorless liquid, of a thick, syrupy consistence, oily to the touch, odorless, very sweet and slightly warm to the taste. When exposed to the air, it slowly abstracts moisture. Specific gravity: not less than 1.250 at 15° C. (59° F.). Soluble, in all proportions, in water or alcohol; also soluble in a mixture of 3 parts of alcohol and 1 part of ether, but insoluble in ether, chloroform, carbon disulphide, benzin, benzol, and fixed or volatile oils" (U. S. P.). On heating, glycerin undergoes some decomposition: boils at 329° F., and finally is wholly decomposed and dissipated.

In its medicinal relations glycerin is unique, because of the following combination of qualities: It is at once viscid, non-volatilizable, unalterable on exposure, antiseptic yet non-poisonous, and has an unusual range of solvent powers, dissolving bromine, iodine, sulphur iodide, the fixed alkalies, lime, tannic and other vegetable acids, many vegetable organic principles, such as salicin and santonin, sugar, gum, and pepsin, and very many inorganic salts. Physiologically glycerin, in concentrated condition, is somewhat irritant to very sensitive parts, probably because of abstraction of water from the tissues; but upon ordinary surfaces it is perfectly bland. Swallowed by the human subject in quantities of an ounce or more, glycerin produces no other effect than a very mildly laxative action; but experimentally administered to the lower animals it proves toxic, producing tetanus in the frog, apparently from direct action upon the muscular tissue (Amidon: *Archives of Medicine*, October, 1881), and varied signs of nervous derangement in rabbits and dogs, even to death by conjoint failure of respiration and heart action.

The uses of glycerin are, pharmaceutically, as a solvent, preservative, and sweet-tasting viscid addition to fluid preparations, or pill masses; and surgically, as an antiseptic, bland, and unalterable viscid application to wound surfaces and sores. Medically, glycerin has been used as a laxative in cases of hemorrhoids, as a preventive of flatulency, pyrosis, and the fermentation of the ingesta in the alimentary canal (Ringer and Murrell), and as a harmless sweetening addition to foods in cases of diabetes mellitus. A reputation which the substance once enjoyed, of tending directly to oppose the morbid process of diabetes, is now no longer credited. Glycerin may be given internally in quantities varying from a teaspoonful to a tablespoonful.

The United States Pharmacopœia makes official *Suppositoria Glycerini*, Suppositories of Glycerin. These suppositories are compounded of glycerin, with a little sodium carbonate and stearic acid, and each suppository contains 6 gm. (about gr. xciij.) of glycerin. They are used for the relief of constipation, but should not be employed habitually, for fear of irritating the bowel.

Certain solutions of substances in glycerin constitute pharmacopœial preparations called *Glycerites.*

Edward Curtis.

GLYCOSOLVOL is a diabetic remedy made by the action of oxypropionic acid on peptone, and by the action of sodium theobromine upon the zymogen of trypsin.

W. A. Bastedo.

GLYCYRRHIZIN. See *Licorice.*

GODBOLD MINERAL WELL.—Post-Office.—Summit, Pike County, Mississippi. Hotels and boarding-houses in Summit.

Access.—Viâ Illinois Central Railroad to Summit, thence a few minutes' walk to the well. This well-known chalybeate well is located in the suburbs of Summit, a village 108 miles northwest of New Orleans and 75 miles south of Jackson. The location is 420 feet above tide-water. The well has a depth of eighteen feet and a diameter of four feet. The supply of water is unlimited. The following analysis was made by J. H. Laster, chemist, of New Orleans:

ONE UNITED STATES GALLON CONTAINS:

Solids.	Grains.
Iron protochloride	11.42
Calcium sulphate	Trace.
Sodium chloride	1.73
Calcium carbonate	Trace.
Silica	"
Loss	.84
Total	13.99

The water is said to possess much value in the treatment of diarrhœa and dysentery and in disorders of the liver and kidneys. It is bottled and sold, but many persons visit the well in person for the purpose of drinking its waters. The water is almost a pure chalybeate, the remaining ingredients being practically inert.

James K. Crook.

GOERBERSDORF—This place is mentioned chiefly because it is the locality in which the renowned Brehmer Sanatorium – the oldest in existence, founded in 1854—is situated. The village of Goerbersdorf is located in the Southeastern part of Germany, in the province of Silesia, at an altitude of 1,840 feet. It is in the valley of the Steine, which runs from northwest to southeast, and is sheltered by densely wooded heights. The climate is not unlike that of the Adirondacks, for example, its main features consisting of "atmospheric purity, freedom from dust, dryness of soil, shelter against strong wind, and abundant sunshine." Its altitude is not sufficient to give it the character of an Alpine climate, though in a general sense it is a mountain climate. The season is an all-the-year-round one.

Here, nearly fifty years ago, Brehmer founded his famous sanatorium, the parent of all the others. Begun in a small way, it now consists of large and handsome buildings with several detached villas, surrounded by very extensive grounds. Meeting with much opposition at first, Brehmer, before he died in 1889, had the satisfaction of seeing his method adopted more or less closely in all systematic attempts to cure phthisis; other sanatoria established on the principles laid down by him; and more favorable results than had ever before been obtained in the treatment of the disease. To-day the Brehmer hygienic-dietetic treatment, with perhaps some modifications, is the best we have, when weighed by results.

Brehmer's theory of the underlying cause of phthisis was a disproportion between the heart and lungs, the latter relatively voluminous, the former small, with thin, flabby, feeble walls. Consequently he considered that the most important object in the treatment was to strengthen the heart, and methodic hill-climbing the best means for obtaining this result. For this purpose, in the park of about 300 acres surrounding the sanatorium, he constructed over nine miles of footpaths of gentle ascent, with frequent benches and pavilions for resting. Measured walks of measured steepness constituted at that time a fundamental principle of his treatment, and only the febrile cases and those with some contraindicating complication were exempt. The other sanatoria have modified this plan, and place the emphasis upon the *Ruheluft-Kur*, rest in the open air. This method is followed, to be sure, at Görbersdorf, but not to the extent that it is at Falkenstein and Hohenhonnef. At these latter it is the striking feature of the treatment.

The sanatorium building is a large gothic structure of brick, of very imposing appearance, in the midst of a beautiful garden; and besides the old and the new *Kurhaus* there are three annexes or villas. The internal arrangements are very extensive, consisting of a winter garden, conversation and reading rooms, large dining halls, various reception rooms, an imposing gothic staircase, and bedchambers hygienically arranged. One notices various suggestive maxims painted on the walls, like the following: "Wolle nur eins, und das wolle von Herzen" (Desire but one thing and that with all the heart). "Die lohnendste Arbeit für einen Kranke ist: gesund zu werden" (The labor which best repays a sick man is to get well).

Besides the sanatorium proper, there are two detached buildings of plainer construction, where patients are received at a reduced price. There is also a chemical and bacteriological laboratory, a meteorological observatory, and a medical library. The clientage comes from Germany, Russia, Hungary, Poland; and I found two patients from America. The supervision of the patient's life is most exact and continuous; every two weeks he is examined anew by the physician in charge, and is always under the observation of one or another of the physicians, all of whom, except the director, take their meals with the patients. Each is individualized in his treatment. As an illustration of the painstaking care, I noticed in the little reading library certain starred books, and on

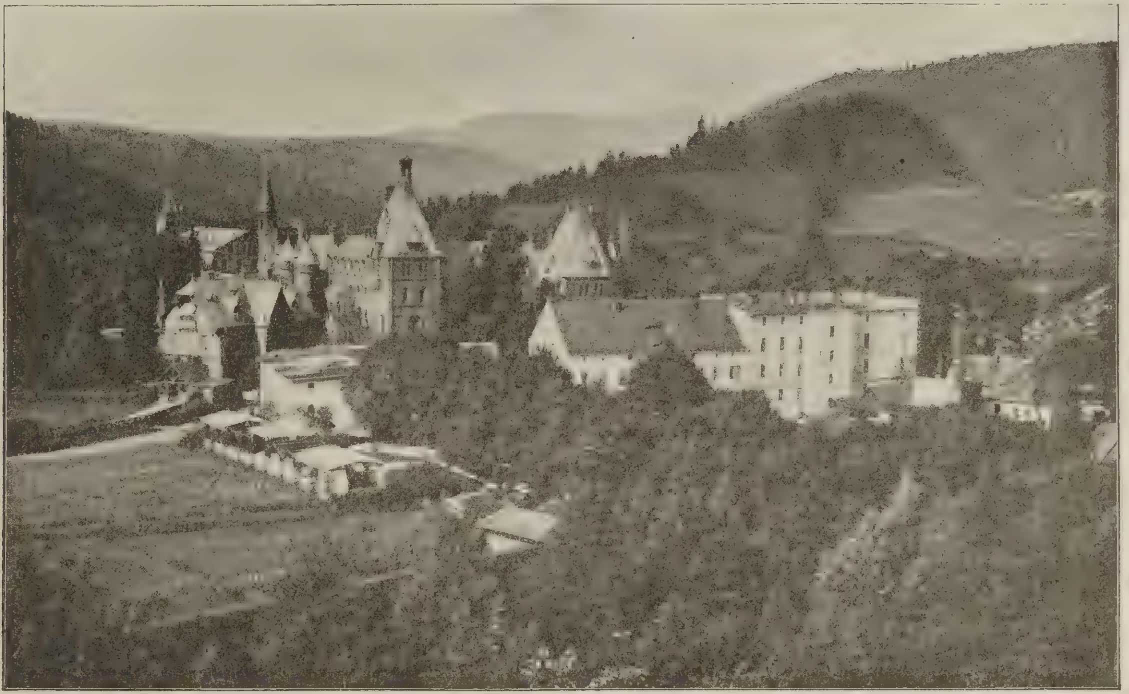

FIG. 2322.—Brehmer's Sanatorium at Goerbersdorf.

inquiry I found that they were of a rather exciting nature and were forbidden to those of nervous temperament as likely to produce a rise of temperature or some other unfavorable symptom. There are five meals a day, reinforced by milk. Kefir is prepared on the premises in large quantities and is much used, especially in gastro-intestinal troubles and in conjunction with alcoholic drinks for night sweats. Most of the patients use wine or beer. In fever milk is the principal diet, and as much as three litres in twenty-four hours is given a patient.

Hydrotherapeutics, as in the other sanatoria, is an important adjunct of the treatment in the form of simple bathing with acidulated water, the wet pack with massage, and cold douches. I was interested in watching the method of giving the latter. In a room adjoining the douche sits a physician at a table, with a watch provided with a second hand, and with the names of those for whom the bath is prescribed. The attendant informs the physician through a speaking tube when the patient is ready, and the doctor turns on the water (which he alone manipulates) for the specified number of seconds, as indicated in his list. When the douching is completed, the attendant throws a blanket about the patient and rubs him down. Only the stronger and convalescent patients are allowed this douche.

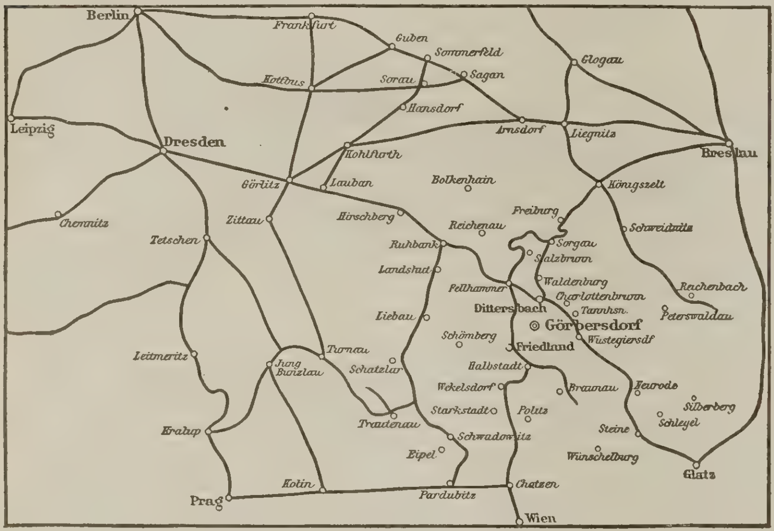

FIG. 2323.—Map Showing the Railroad Connections Between Goerbersdorf and some of the Chief Cities of Central Europe.

The sputum is deposited in shallow cuspidors containing sawdust, scattered about the building. Each patient also has a Dettweiler pocket spit-cup. The sputum is destroyed by burning.

A few minutes' walk from the Brehmer establishment brings one to Dr. Römpler's sanatorium, which is also extensive, accommodating about one hundred patients. Although not so imposing as Brehmer's, it is equally comfortable and complete, and, on account of the lighter character of the architecture, gives one a very pleasing and cheerful impression. In common with the other sanatoria, it possesses a fine winter garden, which is practically a great conservatory affording an extensive and beautiful view even to the horizon, and is the favorite lounging place for the inmates when the weather forbids outdoor life. The "Liegehalle" is in the second-story balcony with a glass roof, which seemed to me preferable to those on the ground floor. The extensive park is laid out with pleasant paths of varying grades (some protected) extending up to the richly wooded mountainside, with seats, terraces, and pavilions, which afford comfortable and picturesque resting places. The method of treatment is similar to that of the larger establishment; it comprises abundant alimentation, outdoor air (rest in the reclining chairs and walking in the paths of gentle ascent) and hydrotherapeutics.

Dr. Römpler's personality is most pleasing, which doubtless has much to do with the success he attains. He is a great lover of nature and inspires his patients with his enthusiasm for outdoor life. In a few words he well sums up the conditions of cure: "Upon the ability of the organism to *resist* depends finally the possibility of cure. To increase this power of resistance through gradual blunting of the susceptibility to irritation (hardening); through the improvement of the nutrition and quality of the blood; and, finally, through the avoidance of hurtful influences and through instruction and training for future guidance, is the principal problem of the phthisiotherapeutist."

The third sanatorium at Goerbersdorf is that of Dr. Weicker, which is a small one, and, as Dr. Weicker says, on the plan of a home rather than on that of a large institution, he and his wife living in the institution with his patients; and the method is essentially that of the others. It was originally founded by the Gräfin Pückler, under whose name it still stands. Dr. Weicker also has charge of a people's large sanatorium in Goerbersdorf, consisting of seven villas, which received 256 persons during the year 1896. It was established for working people who are members of the so-called insurance society for the disabled and aged; the expense being defrayed by the society, which allows each member a certain sum. The insurance societies of Germany of this nature are finding it to their interest to send their consumptive members to such an institution and have a certain proportion of them returned to their usual avocation, rather than support them indefinitely as invalids. Of 185 persons who were dismissed in 1896, 70.3 per cent. were capable of resuming their work; and for the three years from 1894 to 1896 inclusive, of those communicated with who were dismissed in these respective years as capable of resuming their work, 60, 71, and 89 per cent. respectively, still remained so at the beginning of 1897; so that from an economic point of view this plan of people's sanatoria is a profitable venture for the insurance societies.

Goerbersdorf is reached either viâ Breslau and Friedland, or from the station of Dittersbach on the Silesian Mountain railway. Either from Friedland or Dittersbach one has to ride four or five miles to the sanatoria. As to the results obtained at Brehmer's sanatorium, of 75,032 patients treated from 1876 to 1886, 26.6 per cent. were reported "cured and almost cured," of the first, second, and third stages of the disease collectively.

Edward O. Otis.

GOITRE.—(Synonyms: *Bronchocele, Struma, Derbyshire Neck, Kropf* [Ger.].) German writers apply the term "struma" solely to enlargements of the thyroid gland. Among English writers the word has a double meaning. It is used to indicate not only disease of the thyroid gland but also a tuberculous condition of the lymph nodes. Hence its use may lead to confusion.

The word "goitre" is probably a corruption of the Latin "guttur," the throat. Like many terms of popular origin it cannot be defined satisfactorily in scientific language. It is used rather loosely. It seems best to apply the term goitre to all enlargements of the thyroid gland. Wölfler, Orth, Kaufmann, and Ziegler use the word in this sense. Virchow, Murray, and Ewald attempt to restrict it to the benign thyroid tumors. If the use of the word is to be limited at all it would be better to designate as goitre that form only of thyroid tumor which occurs endemically or epidemically in certain regions of the world.

Historical Note.—The occurrence of endemic goitre is known to antedate the Christian era. That the disease abounded among the Alps was well recognized by the ancients. Juvenal asks—"*Quis tumidum guttur miratur in Alpibus?*" References to goitre by Greek and Roman physicians are few and indefinite. Paracelsus, who studied endemic goitre in the Duchy of Salzburg, was the first medical writer to treat of the subject in a satisfactory manner. In his work, which was based on personal observations, he indicated the relation of goitre to cretinism. Scientific inquiry in regard to goitre, according to Hirsch, may be said to date from the work of Malacarne, published toward the close of the eighteenth century.

Knowledge of the pathological anatomy of thyroid tumors began with the studies of Ecker, Frerichs, and Rokitansky. A little later Förster's monograph on the malignant tumors of the thyroid appeared. In 1867 Virchow published his classical description of the anatomical forms of goitre. Wölfler in 1883 finished his monumental work on the development and structure of thyroid tumors. Clinical knowledge of the subject has been greatly advanced by the work and writings of Lücke, Kocher, Ewald, Berry, and Murray.

In America, the first and only attempt at a systematic study of the distribution of goitre was made by Benjamin Barton, professor in the Medical School of the University of Pennsylvania, and was issued in 1800. The monograph was entitled "A Memoir Concerning the Disease of Goitre as it Prevails in Different Parts of North America." W. Gibson in 1820 published an able essay which included a study of the morbid anatomy and means of diagnosis of thyroid tumors.

In Dr. Osler's paper on cretinism published in 1893 he showed that endemic goitre no longer exists in those regions where, early in the last century, it prevailed extensively. The endemic disease has been studied in Michigan by Dock, and among the North American Indians by Munson.

Anatomy.—The thyroid (*glandula thyreoidea*) is a ductless gland, which consists of two lateral lobes connected by a middle portion, varying markedly in size, called the isthmus. The thyroid gland lies in front of the larynx and trachea, and is bound to them by fibrous bands so that it follows the movements of these organs in deglutition. The outer margins of the lateral lobes are anterior to the common carotid arteries. Sometimes a slender pyramidal process (*lobus pyramidalis*) projects upward from the middle of the isthmus to the hyoid bone. The lateral lobes (*lobus dexter et sinister*) measure 5 to 7 cm. in length, 3 to 4 cm. in breadth, and 1.5-2.5 cm. in thickness. The weight of the entire gland varies between 30 and 60 gm. (Orth). Weibgen found that the most active growth occurs between the eleventh and twentieth years. The average weight between the sixth and tenth years was 11.9 gm., between the eleventh and twentieth years 36.7 gm. The thyroid is slightly heavier in men than in women. It is relatively larger in the young than in adults.

Although a portion of the lateral lobes is developed from the fourth branchial clefts, the greater part of the gland arises as a diverticulum of the pharynx.

In the embryo the thyroid body consists of solid nests and strands of epithelial cells. Later these solid masses become converted into closed vesicles filled with colloid and lined with a single layer of cylindrical or cuboidal cells.

Wölfler holds that small nodules of embryonic tissue are normally present in the developed gland, and furnish the congenital *Anlage*, in the sense in which Cohnheim used that term, for the development of tumors. It is fully as probable, however, that these embryonic remains which Wölfler describes are in reality small adenomas.

His has described what he considers to be the rudiments of an excretory duct (*ductus thyreoglossus*) which extends from the thyroid to the tongue and opens at the site of the foramen cæcum. The finding of accessory thyroid tumors in the root of the tongue is certainly in support of this view, although Kanthack was not able to confirm the observations of His.

The thyroid vesicles range from 0.045 mm. to 1 mm. in diameter. The epithelial cells vary in size and shape. Sometimes in young individuals they have a cylindrical form, but usually they are cuboidal. Low, flat cells, according to E. Schmid, are seen chiefly in old age. On fresh examination colloid droplets and a varying number of fine and coarse granules can be demonstrated within the cells. The granules are most abundant near the free margin of the cell.

The viscid, homogeneous colloid substance present in the vesicles usually appears vacuolated in hardened specimens (see Fig. 2324). It takes nearly the same color with eosin as do the red blood corpuscles. Ernst has shown that colloid can be distinguished from hyalin by staining more deeply with fuchsin when treated with Van Gieson's mixture.

The origin of colloid has not been fully determined. It is probably a secretion of the epithelial cells. These have the characteristics of secreting cells. Virchow believes that the cells secrete a clear fluid into the vesicles, and that the colloid is formed from the fluid. Many histologists and physiologists hold to the view of Frerichs that colloid is formed within the cells or is the product of a specific transformation of the cells. They regard the process as partly secretory and partly degenerative. Reinbach holds that colloid in normal glands is a secretion, but the colloid in goitres is formed by the degeneration of the cells. He adduces little evidence in support of the latter hypothesis, and Müller is probably right in regarding the colloid substance of both normal and goitrous thyroids as a secretion and not a degeneration.

How the thyroid secretion enters the circulation is not known. The explanation of Biondi and Schmid that rupture of the vesicles occurs as a physiological event and thereby the colloid escapes into the lymphatics is improbable. The existence, between the epithelial cells, of ducts communicating with the lymphatics, as described by Hürthle, is doubtful.

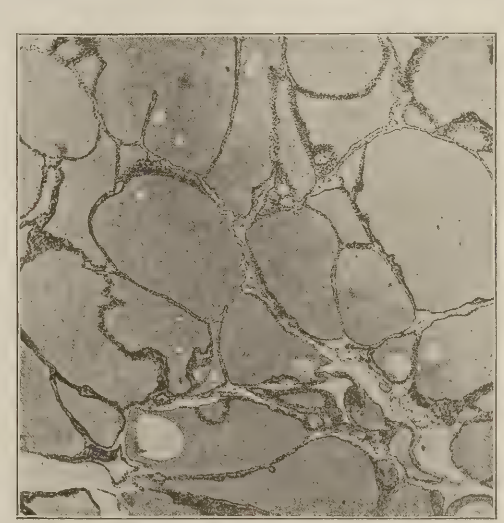

Fig. 2324.—Accessory Thyroid Tumor from Root of Tongue. The vesicles are filled with colloid and lined with low epithelium. (× 41 diam.)

A number of histologists have described colloid within the lymphatics of the thyroid, and Podack found it in lymphatics outside of the thyroid. The observation by

Zielinska of colloid in the capillaries, veins, and even in the arteries of the thyroid and by von Ebner in the vessels of the larynx, would seem to show that this supposed demonstration of colloid within vessels is due to an artefact possibly produced in removing the organ or in the process of hardening. It may be coagulated blood serum which sometimes simulates colloid in appearance. I have recently studied a specimen of syphilis of the testicle in which the veins were filled with a homogeneous hyaline material which presented exactly the appearance of the colloid of the thyroid. Fine projections of the hyaline material attached it to the walls of the vessels which gave the festooned border seen in thyroid vesicles. This observation suggests that the lack of apposition between the epithelium of the thyroid vesicles and the colloid mass is not due to the presence of a clear secretion between the epithelium and the colloid mass, but to a retraction of the latter.

The morphology of the epithelial cells and their relation to the abundant capillary network rather favor the view that the thyroid secretion passes without the intervention of lymphatics directly into the circulating blood.

The thyroid is an extremely vascular organ. Mayer estimated that it receives almost as much blood as the forearm. Sömmering calculated that the size of the thyroid arteries was relatively eight times greater than those of the brain. Both the arteries and the veins form large anastomoses upon the surface of the organ.

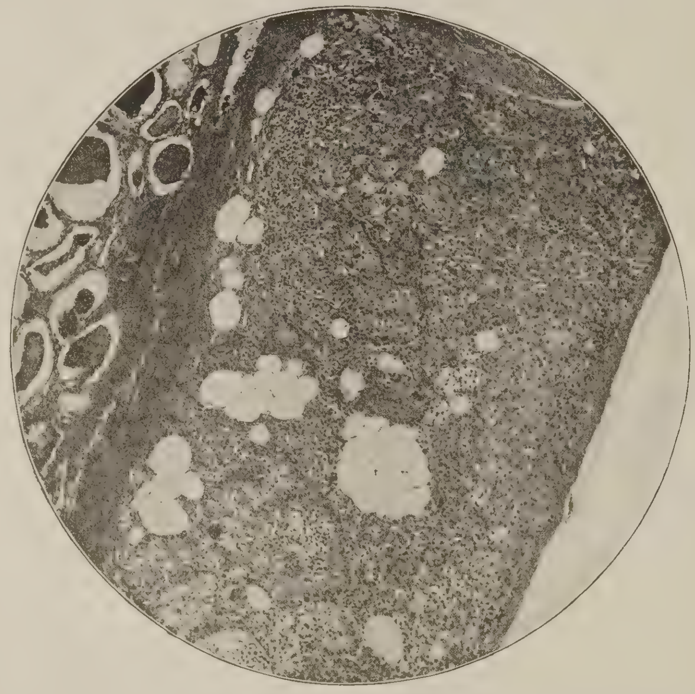

FIG. 2325.—Section Through a Parathyroid of Man. It is contiguous to the thyroid gland. The difference in structure between thyroid and parathyroid tissue is well shown. (× 85 diam.)

Horne in 1892, working under von Recklinghausen, described bud-like projections composed of proliferated endothelial cells on the inner wall of the arteries of goitrous thyroids. M. B. Schmidt found similar cell buds quite regularly in the small arteries of the healthy thyroid at all ages. They may involve the media as well as the intima. The significance of these nodules is not known. Ricker has suggested that they represent a temporary infolding of the wall and thus offer a morphological explanation for the great variations in the blood content of the gland. Years ago the idea was advanced that the thyroid was, in a certain sense, a safety reservoir to prevent an excessive flow of blood to the brain.

Accessory thyroids (*glandulæ thyreoidæ accessoriæ*) are not rare. They may occur anywhere from the root of the tongue to the middle of the thorax, but they are most frequently found in the neighborhood of the hyoid bone. Zuckerkandl found them anterior to the hyoid bone in fifty-seven out of two hundred cases.

Streckeisen distinguishes between the median and the lateral accessory thyroids. The former he divides into four groups: (1) the *prehyoid* which lie superior to the mylohyoid muscle; (2) the *suprahyoid* which lie between or within the geniohyoid; (3) the *epihyoid* which lie above the geniohyoid; (4) the *intrahyoid* which lie in the hollow or even in the substance of the hyoid bone. The lateral accessory thyroids are usually found in the neighborhood of the greater cornua of the hyoid.

Wölfler has observed accessory thyroids on the ascending aorta in children. In dogs they are commonly found in this situation. Piana states that aortic accessory thyroids were present in sixty-six per cent. of the dogs examined. In cats accessory thyroids are rare.

PARATHYROID GLANDS (*Glandulæ parathyreoideæ*).—These bodies were described first by Sandstroem in 1880. They are composed of solid masses of epithelial cells, and do not contain colloid. The parathyroids in man have been studied by Welsh, of Edinburgh. As a rule, there are two parathyroids on each side. Sometimes the distribution is irregular, so that one or more may be overlooked. Two glands may be intimately connected so that they appear, on superficial examination, as one gland. They vary in size, but most commonly measure about 6×3 ×1.5 mm. I have seen them 1 cm. in length, and Welsh states that they may measure 1.5 cm. They are thin, oval bodies which are moulded to the form of adjacent structures. Their characteristic color is yellow, admixed with red and brown. The yellow hue is due to clusters of fat cells lying between the masses of epithelial cells. This adipose tissue within the gland is well shown in Fig. 2325. The two parathyroids, according to Welsh, have a constant position in relation to each other. Welsh designates them as the *posterior superior* and the *anterior inferior*. The posterior superior parathyroid lies on the posterior wall of the pharynx or œsophagus at the level of the inferior border of the cricoid cartilage, just internal to the posterior margin of the lateral thyroid lobe. The position of the anterior inferior parathyroid is less constant. The parathyroids differ from the thyroids developmentally. They are formed earlier.

PHYSIOLOGY.—The thyroid secretes a material which is essential to the well-being of the body. Notkin's view that the thyroid serves to collect some toxic substance from the blood is interesting but improbable. The internal secretion into the blood appears to be specially concerned in producing metabolic changes in the central nervous system. In 1856 Schiff showed that complete extirpation of the thyroid in dogs resulted in the death of the animal. Some, however, recover, and in 1899 Katzenstein concluded as a result of his experiments that the thyroid is not essential to life. He probably overlooked the accessory thyroids that are so common, as Sultan (*Archiv für klinische Chirurgie*, 1901, vol. lxii., p. 620) found that total extirpation of the thyroid tissue always produces severe, characteristic, disease phenomena, and leads to a fatal issue.

If, in the dog, one lobe be removed, although no symptoms supervene, the other undergoes a compensatory hypertrophy. This was pointed out by Wagner. The remaining lobe does not always enlarge, so, as Halsted says, the microscope must be the criterion of hypertrophy. The microscopical changes have been described by Horsley and Halsted. The vesicles enlarge. Their lining membrane becomes folded and branched. The epithelium assumes a cylindrical form, and the colloid disappears. Beresowsky removed five-sixths of the thyroid in dogs. In addition to compensatory hypertrophy he observed actual regeneration with new formation of vesicles.

Edmunds found that if one parathyroid be left in the animal the other parathyroids and the entire thyroid might be removed, and yet the dog would live and no apparent ill effects follow. The parathyroid that is left shows signs of active growth, but it does not develop into thyroid tissue. This overthrows the old view of Gley that the parathyroids are immature thyroids. Edmunds observed that compensatory hypertrophy of the thyroid took place when the thyroid was left intact, if all the parathyroids were removed. Excision of a portion of the superior laryngeal and vasosympathetic nerves on one side and of the lateral thyroid lobe on the other side leads to great hypertrophy of the remaining lobe. It may weigh three or four times as much as normal. The increase in size is largely due to a growth of thyroid tissue between the vesicles (Edmunds).

The experiments of Vassale and of Moussu show that the thyroid and the parathyroid are different organs. It is probable, however, that they are functionally associated. The removal of the former produces trophic disturbances resembling those of myxœdema in man, and removal of the latter produces convulsive disorders and death.

Levin's work seems to indicate that the thyroid secretion acts upon mucin. He demonstrated that an intravenous injection of mucin which is fatal to animals deprived of their thyroids gives rise to no untoward effect in healthy animals.

The colloid substance of the thyroid gland has great physiological power. It contains phosphorus, and yet is not a nucleoproteid, neither is it allied to mucin. It belongs to the glycoproteids. The singular feature about colloid is that it contains iodine. This notable discovery was made by Baumann who isolated a substance to which he gave the name iodothyrin, and which Hutchinson showed is found in the colloid substance. It contains all of the phosphorus and the greater part of the iodine. Oswald, in 1899, obtained from the complex iodothyrin the simpler body thyreoglobulin, which de Cyon and Oswald (*Pflüger's Archiv*, 1901, vol. lxxxviii., p. 199) claim is the active principle of the thyroid secretion. Baumann estimates that every gram of the thyroid of man contains 1 mgm. of iodine. Gideon Wells has shown that the human thyroids obtained in Chicago contain four times as much iodine as the glands of individuals living in the goitrous regions of Germany. The thyroid of newly-born children is free from iodine. The accessory thyroids may be richer in iodine than the thyroid gland proper (Gley, Mendel).

GEOGRAPHICAL DISTRIBUTION OF ENDEMIC GOITRE.—In certain districts, widely scattered over the globe, a goodly proportion of the inhabitants are affected with enlargement of the thyroid. This peculiar form of thyroid tumor is known as endemic goitre.

Early in the last century the disease prevailed in New England and in New York State. Dorr, writing in 1806, mentioned a number of New England towns in which goitre was very common. In 1893 Osler reported that the disease no longer existed in these towns. In many towns of Vermont it was especially prevalent. Dorr states that in Chester one-half of the inhabitants were affected. Osler found that goitre is now rare in Alabama, although it was common in 1854, and it is also interesting to note that the disease has gradually disappeared from those parts of Virginia where it was formerly endemic. Barton states that in 1798 bronchocele prevailed to such an extent in Pittsburg that out of fifteen hundred inhabitants no less than one hundred and fifty had the disease. The number of cases gradually declined, and in 1825 Denny wrote that no new cases had occurred since 1806.

As both Hirsch and Osler complain that they have been able to learn nothing of the occurrence of endemic goitre in Massachusetts, I have made inquiries of physicians in various parts of the State, especially of those connected with the hospitals for the insane. I have not been able to discover a single focus of the disease in the State.

Dock has found that goitre prevails in all parts of Michigan, but particularly in the northern section. The southern portion of the lower peninsula also contains many cases. Dock asserts that the disease exists in parts of Ohio and Indiana, and still more in the States bordering on Lakes Michigan, Superior, and Huron.

In 1895 Munson published his observations on the occurrence of endemic goitre among the Indians of the United States. A century before Barton called attention to the frequency of the disease among the Indians of New York State. Munson found goitre most prevalent in the southern part of Montana. It is common on the single reservation in Wyoming, and on the reservations of Utah, Idaho, and Colorado, situated on the western slope of the Rocky Mountains. It abounds in the western portion of the Dakotas, especially in the region of the Black Hills. The district examined includes a total of 18,182 Indians, made up of various tribes, and from this number were reported 764 cases of goitre, which is over four per cent. Munson states that the disease is frequently seen among the Chippewas of Minnesota, and is especially prevalent among the Menominees of eastern Wisconsin. "With the exception of a single reservation in Southern California, goitre is unknown throughout Washington, Oregon, western Utah and Idaho, California, Arizona, and New Mexico, although this region contains a comparatively dense Indian population."

In the Province of Quebec (Osler) and the Island of Montreal (Adami) endemic goitre occurs. It is still more common near Lake Ontario in the Province of Ontario. Osler mentions the extraordinary prevalence of this affection in the Kingston Insane Asylum, where in 1893 there were 288 cases of goitre among 600 patients.

In England endemic goitre is especially common among the Derbyshire Hills, hence the name Derbyshire Neck. It exists in the Pennine range in the North. Morris in 1895 stated that he had seen fifty cases among a population of two thousand in the Chiltern Hills. The greatest centres in Scotland are in the Lowlands and in and around the Lothian Hills (M'Kenzie).

A glance at the map prepared by Bircher shows in a striking manner the association of the disease with the mountainous countries of Europe. In Switzerland it is very prevalent. Bircher found that in some parts of the cantons of Freiburg and Berne eighty or ninety per cent. of the recruits were goitrous. In Italy the disease is common on the southern side of the Alps. It also exists in Savoy, in the Black Forest, and in Styria. The departments of France chiefly affected are those occupying the regions of the Alps, the Pyrenees, the Central Plateau, the Jura, and the Vosges. The disease has diminished in France, especially during the last fifty years, yet it is estimated that there are now between 375,000 and 400,000 goitrous people in that country (Mayet). The distribution of the disease throughout Europe is much the same as it was several centuries ago.

In Asia endemic goitre exists in the Himalayas, in the hilly districts of China, and in Siberia.

A great zone of goitre begins in Mexico and extends with increasing intensity through Central America and South America as far as Chili, and "forms a region of the disease worthy to be named besides those of the Alps and the Himalayas" (Hirsch).

ETIOLOGY OF ENDEMIC GOITRE.—Goitre is said to occur in endemic, epidemic, and sporadic forms. The term "sporadic" in this connection is unfortunate and misleading. It implies that the cause of the scattered cases of thyroid enlargement which are found everywhere is the same as that of endemic goitre. Like other glandular organs the thyroid may be the seat of a variety of new growths. The etiology of these tumors will probably remain obscure until more light has been thrown on the formation of tumors in general. In Massachusetts endemic goitre does not exist, and yet I have been able to collect in Boston over fifty specimens of thyroid tumors which have been removed during the past few years. These would be classified as "sporadic" cases, and yet the evidence is all opposed to the view that they were caused by the same agent that produces the endemic disease.

The cause of endemic goitre is not known. There seems to be little doubt that it is an infectious disease; but the *contagium vivum* has not been discovered.

Epidemic outbreaks of goitre may occur. With rare exceptions they have developed in districts where endemic goitre existed. Nearly all the cases have been observed in France. The epidemics have always been sharply localized. Most of them have been in barracks or boarding-schools. At Clermont-Ferrand fifty of the seminary pupils were attacked within a few days.

St. Lager in 1868 stated that he could number no less than 378 authors and 42 different views of the causation of the disease.

The geological formation has been held by some recent writers to be of importance in the genesis of the malady. Bircher concluded, as a result of careful study, that it occurred only upon the marine deposits, especially of the Palæozoic, Triassic, and Tertiary periods. He held that volcanic rocks, the crystalline rocks of the Archæan group, chalky sediments, and those of the Jurassic formation, as well as all fresh-water deposits, were free from goitre. Kocher in 1889 pointed out that it existed on the rocks exempted by Bircher, and Dock has shown that in America goitre is found on the Laurentian, the drift, and many intermediate formations.

For a detailed account of the various theories and the evidence adduced in support of them Hirsch's "Handbook of Geographical and Historical Pathology" should be consulted. His conclusion is so reasonable and so well stated that I give it in full: "The absence of results to all these inquiries about the genesis of goitre and cretinism—inquiries which have extended to every influence perceptible to the senses that could be brought into the consideration of the question before us—warrants, I will not say compels, the conclusion that in these diseases we have to do with a specific agent, *a veritable morbid poison*, and that endemic goitre and cretinism *have to be reckoned among the infectious diseases.* This doctrine finds a certain support in two things: on the one hand the fluctuations in the amount of the sickness, which we have had frequently occasion to notice, and for which there is no sufficient explanation to be found in the states of the atmosphere or of the soil or of hygiene; on the other hand, the epidemic outbreaks of goitre, for which the theory of infection, as Saillard, Viry and Richard, Thibaud, and other French military surgeons have recognized and said, is hitherto the only one that affords an explanation, and an explanation that accords most nearly with the facts of the case."

The infectious agent is probably conveyed through the drinking-water. The water of certain wells is known to cause goitre, and there are some in Switzerland whose water Kocher found had invariably produced goitre in the children who drank of it. The water is rendered harmless by boiling. There are noted goitre wells in Europe to which young men wishing to avoid enlistment resort. In a few weeks goitres develop which are large enough to exempt them from military service.

Dock noted that a very large proportion of all the cases in Michigan had used well-water. In Ludington goitre became much less frequent when lake-water was substituted for well-water. Singularly enough, according to a statement made by Dr. Hurd, the reverse is true at the Kingston Insane Asylum, Ontario. There, the patients developed goitre when the water of the River St. Lawrence was substituted for well-water.

Numerous attempts have been made to show a causal relation between certain micro-organisms and goitre. Klebs detected some minute animal or vegetable structures, which he called "naviculæ" from their shape, in the water of goitrous wells. Rüdel was not able to find these peculiar organisms. Bircher found diatoms and other micro-organisms in water from districts where goitre is prevalent.

Kocher discovered that water from goitrous wells is characterized by the large number of bacteria it contains. Tavel compared goitre-water with that of wells known to be harmless. Both were pure upon chemical analysis, but the former contained more bacteria. One bacillus isolated from two goitrous waters produced hypertrophy of the thyroid when inoculated into guinea-pigs. Experiments with this bacterium upon dogs yielded negative results. Lustig and Carle claim that a bacillus with definite characteristics is constantly present in water known to induce goitre.

Grasset in 1898 described a hæmatozoon, somewhat similar to the parasite of malaria, in the blood of goitrous individuals. M'Kenzie has not been able to confirm Grasset's observations.

Adami thinks that if micro-organisms cause the malady they do so indirectly, by forming injurious products in the water. The disease would then be regarded not as an infection but as an intoxication.

Endemic goitre is more common in women than in men. In England the proportion is from 7 to 1, to 44 to 1 (Murray). It usually develops at or before puberty. Hausleutner said that it rarely, if ever, occurred after the fortieth year; but we now know that cases may occur in older people.

In goitrous localities the lower animals are frequently affected, especially dogs and horses. Dock saw in a short time one day in Calumet, Michigan, six goitrous horses.

CONGESTION.—Vascular disturbances of the thyroid are favored by the richness of its blood supply. A transient enlargement occurs under a variety of conditions. There seems to be a definite connection between the sexual functions and the thyroid gland. Prof. Milnes Gaskell has shown that in the primitive vertebrate—the human progenitor—the sexual organs lay in intimate relation with the thyroid. Freund's careful investigations would seem to prove that a physiological enlargement occurs during menstruation and pregnancy. Transient swelling is also a consequence of parturition. Lange examined over three hundred pregnant women and confirmed Freund's observations. He does not agree with Freund, however, that the swelling is due simply to congestion. As reduction followed the administration of thyroid extract Lange maintains that the condition is due to a hypertrophy of the glandular elements.

It is also claimed that defloration is accompanied by an enlargement of the thyroid. If this be true there is a scientific basis for the ancient custom,* still followed in the East, of testing a bride's virginity by measuring the circumference of her neck before and after the marriage-night.

Sexual excitement in women and in animals is said to produce an engorgement of the thyroid. I have been told of a case in which a physician measured his wife's neck immediately after coitus and found a definite increase in the size of the thyroid. Berry says that one of his patients insisted that sexual excitement was always followed by temporary enlargement of his goitre, usually sufficient to cause dyspnœa.

In girls enlargement of the thyroid is common at puberty. Schönlein, Friedreich, and Heidenreich described it as a special type of goitre, the *struma antemenstrualis.* The swelling is probably due to hyperæmia or congestion. A connection seems to exist between thyroid enlargement and chlorosis. Ewald in Berlin, a nongoitrous locality, has been struck with the frequency of goitre in chlorotic girls. Capitan has called attention to this association. He thinks chlorosis is sometimes dependent upon abnormalities in the thyroid gland. Hayem in thirty-five subjects of chlorosis examined within a short time found goitre twenty-nine times.

---

* "*Non illam genitrix orienti luce revisens hesterno poterit collum circumdare filo.*" Catullus, *Epigram 1.*

A case of acute enlargement of the thyroid in mumps has come under my notice. The patient was a student in the Harvard Medical School. A few days after the onset of the disease a swelling of the thyroid was observed, which continued to increase for several days. The gland was neither painful nor tender. There was slight dyspnœa. It remained enlarged for about two weeks. The case appears unique. There is no reference to this complication of mumps in the "Index Catalogue of the Surgeon-General's Library."

Alfred Stengel recently reported an interesting case of acute non-inflammatory thyroid enlargement. It was probably the result of congestion.

HYPERTROPHY.—When a portion of the thyroid is removed the remainder undergoes a compensatory hypertrophy. This type of hypertrophy is known to occur in man and it has been produced experimentally in animals by Ribbert, and Beresowsky. Berry relates a case in which symptoms of cachexia thyreopriva, which appeared after a supposed complete thyroidectomy, disappeared upon the development of a small tumor at the site of the operation. Either a bit of the goitre, fortunately not removed, or an accessory thyroid, had undergone compensatory hypertrophy and assumed the function of the normal thyroid.

It is possible that many of the thyroid enlargements in which the histological structure resembles that of the adult normal gland, and which I class as simple adenomas, are, in reality, examples of hypertrophy. Wölfler has attempted to separate the hypertrophies from the simple adenomas. The former (*Hypertrophia parenchymatosa et hypertrophia gelatinosa* Wölfler) are produced by an increase or enlargement of the normal vesicles or an increase in their contents, the latter (*adenoma gelatinosum*), he holds, are developed from embryonic remains. But as different writers (Birch-Hirschfeld, Orth, Weichselbaum, and Kaufmann) have stated, this distinction is not practical.

CONGENITAL GOITRE.—In goitrous districts congenital thyroid enlargement is frequent. Among 642 cases of goitre in children at Berne, Demme found 53 in which the disease was congenital. Usually the goitre is small, Virchow pointed out that it might readily be overlooked owing to its high situation in the neck. It frequently lies in close relation with the hyoid bone and may extend behind the pharynx and cause severe dyspnœa or even suffocation. Congenital goitre is not uncommonly associated with enlargement of the thymus (Virchow, Bednar).

The tumor may be very large. Hecker reported a case in which the goitre in a child who died at birth from asphyxia weighed 41.6 gm. Probably the largest congenital goitre on record is the one cited by Demme, which weighed 102 gm. In the museum of St. Bartholomew's Hospital is a huge congenital goitre. A photograph of the specimen appears in Mr. James Berry's recent work "Diseases of the Thyroid Gland."

Thyroid tumors have been found in embryos. Danyau described one in a fœtus of five and a half months. It formed a mass the size of a hen's egg and weighed 46 gm. The normal weight of a thyroid at this period never exceeds 1 gm.

Congenital goitre is rare in regions free from the endemic disease. Abt lately observed a case in Chicago. The child died at birth. The tumor was the size of a walnut and involved the entire gland.

Congenital goitres may have the structure of a normal fœtal thyroid and are then regarded as examples of hypertrophy (Spiegelberg, Fröbelius, Wölfler). Colloid cysts sometimes of large size have been observed. Congenital goitres are found in animals also (cattle, horses, goats, sheep, and dogs). For a comparative study the monograph of Pflug should be consulted.

Large goitres may offer a mechanical obstruction to the delivery of the child or they may cause face presentation.

BENIGN TUMORS—*Classification.*—Virchow's division of benign goitres into the following anatomical varieties is usually adopted: hyperplastic, fibrous, colloid, cystic, and vascular. This classification is based entirely on the macroscopic appearances. Wölfler attempts to classify them according to their mode of origin. His explanation of the mode of origin of the different types of thyroid tumors, however, is not convincing, and is largely hypothetical. The genesis of thyroid tumors will probably remain obscure until the general laws governing the formation of tumors are understood.

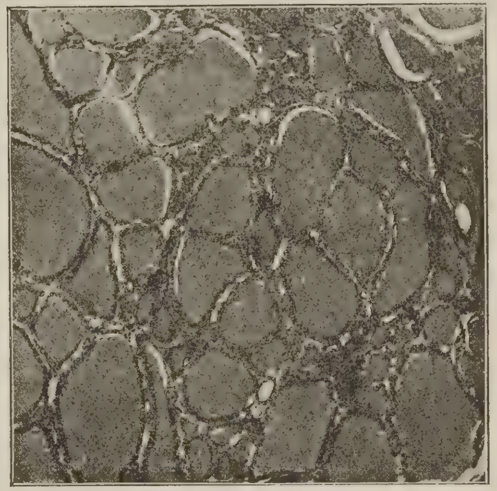

FIG. 2326.—Simple Adenoma of the Thyroid. (× 61 diam.)

As a classification is needed for the study and diagnosis of thyroid tumors, and as neither system at present in use is satisfactory—Virchow's, because it deals only with the naked-eye variations, and Wölfler's, because it is complicated and artificial—the attempt has been made to arrange these tumors into groups according to their histological structure. To this end I have read the objective descriptions of thyroid tumors given in the literature and have personally examined many specimens.*

There are three primary types of benign adenomatous thyroid tumors. All of these would be classed by Virchow as hyperplastic or parenchymatous goitres. They can be diagnosed with certainty only by microscopical examination.

1. Simple adenoma.
2. Fœtal adenoma.
3. Papilliferous adenoma.

The vast majority of all cases are of the first type. The third is the most rare.

Simple adenoma (Fig. 2326).—It is composed of vesicles of various size filled with colloid. The structure resembles closely that of the normal adult thyroid. The epithelium lining the vesicles may be low and flat (Fig. 2324) or it may be cuboidal (Fig. 2326). In the intervesicular tissue similar cells are sometimes seen arranged in solid masses or forming small rosettes. These are probably areas of undeveloped thyroid tissue.

The simple adenoma may be confined to one lobe, or it may appear as a diffuse growth involving the entire gland or form a distinctly encapsulated tumor. Although usually single, multiple simple adenomas do occur (Fig. 2327). The consistence is moderately firm. The cut surface is usually smooth and homogeneous, reddish-brown to reddish-yellow.

---

* I am indebted to Dr. W. F. Whitney, curator of the Warren Museum of Harvard University, Dr. J. H. Wright, director of the Clinico-Pathological Laboratory of the Massachusetts General Hospital, and Dr. F. T. Fulton, pathologist to the Rhode Island Hospital, for the use of their collections.

Secondary changes are common. The colloid frequently becomes increased in amount. The walls of adjoining distended vesicles rupture or are atrophied by pressure, and cysts are formed. Thus the tumor becomes changed into a *colloid goitre* (Fig. 2328). With continued production of colloid these cysts may reach a large size, and the tumor is then spoken of as a *cystic goitre*. The cysts may be single or multiple. Their contents are frequently tinged with blood or contain modified blood pigment. I cannot agree with Bradley, however, that the cysts are usually hemorrhagic in origin. Müller states that in the colloid goitre the capillaries are diminished in number. The intima of the arteries is usually thickened and the elastic tissue is degenerated (Jores).

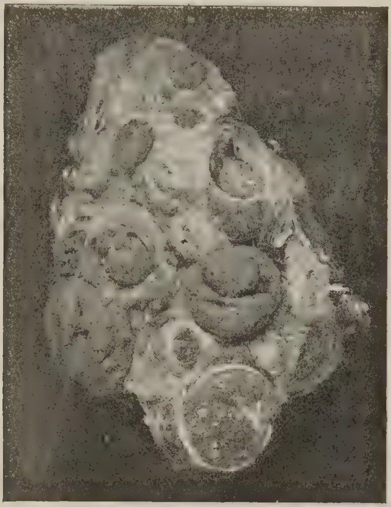

FIG. 2327.—Multiple Simple Adenomas of the Thyroid Gland. (Natural size.)

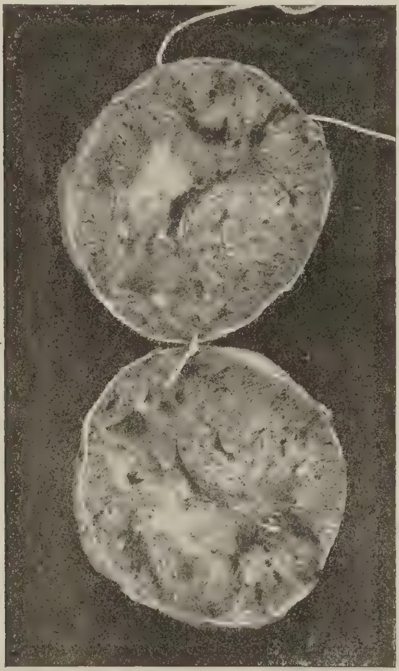

FIG. 2328.—Colloid Goitre. The vesicles are greatly distended with colloid forming small cysts; the largest are 0.5 cm. in size. The colloid in some of the cysts is tinged with blood. (Natural size.)

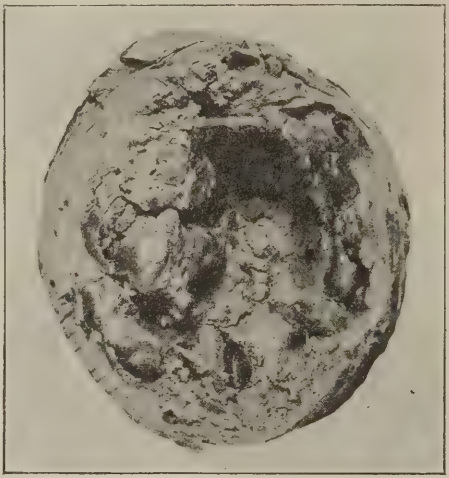

FIG. 2329.—Fibrous Goitre which has Undergone Central Softening. The cyst measures 5 cm. in diameter, and has a shaggy lining composed of necrotic tissue. (Warren Museum, No. 9721.) (Reduced.)

The stroma varies greatly in amount. It may form broad areas or bands of fibrous tissue, or the tumor may be largely converted into fibrous tissue and form a *fibrous goitre*. The vesicles are shrunken and separated by wide areas of fibrous tissue (Fig. 2330). The overgrowth of fibrous tissue is probably secondary to the degeneration and atrophy of the glandular tissue. This fibrous tissue, usually dense and sclerotic, is prone to undergo hyaline degeneration. Gutknecht pointed out that large cysts are sometimes formed by the softening of this degenerated fibrous tissue. A good example of a fibrous goitre that has undergone central softening is contained in the

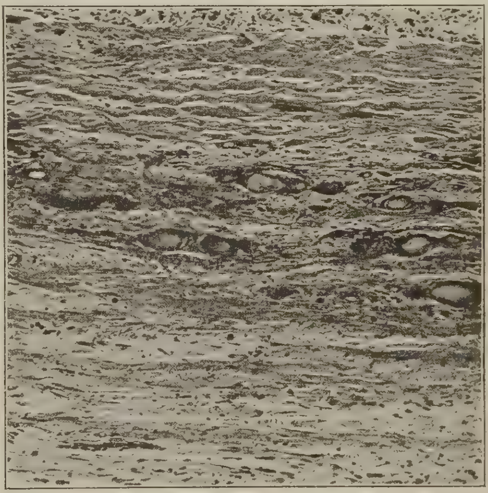

FIG. 2330.—Fibrous Goitre. It is composed of dense hyaline connective tissue. A few atrophied vesicles containing colloid are seen. (× 86 diam.)

Warren Museum (Fig. 2329). This unilocular cyst measures 5 cm. in diameter. Its wall, which is 1.5 cm. in greatest thickness, is formed of dense, hyaline fibrous tissue. Fig. 2330 is a section of the wall. These cysts of softening usually contain a turbid fluid composed of cellular and fatty detritus, broken-down red blood corpuscles, polynuclear leucocytes, blood pigment, calcium oxalate, and cholesterin crystals.

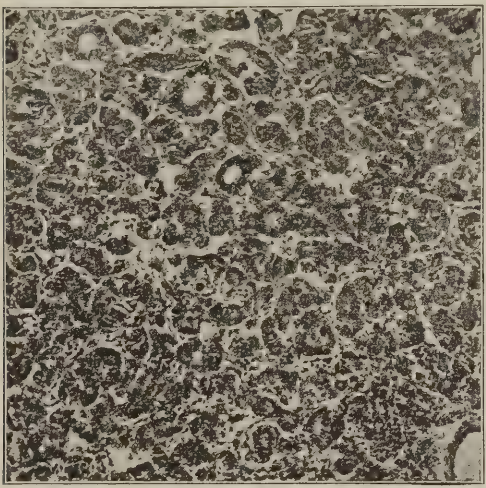

FIG. 2331.—Fœtal Adenoma of the Thyroid. The cells are arranged in solid masses and in circles surrounding small spaces. No colloid. Stroma very vascular. (× 85 diam.)

Lime salts are commonly deposited in the walls of old cysts. Large calcified plates may form. I have seen a cyst about 5 cm. in diameter the wall of which was entirely calcified. Bone has been found in the same situation. Lücke reported two cases in which there was typical bone formation with bone corpuscles and medullary spaces.

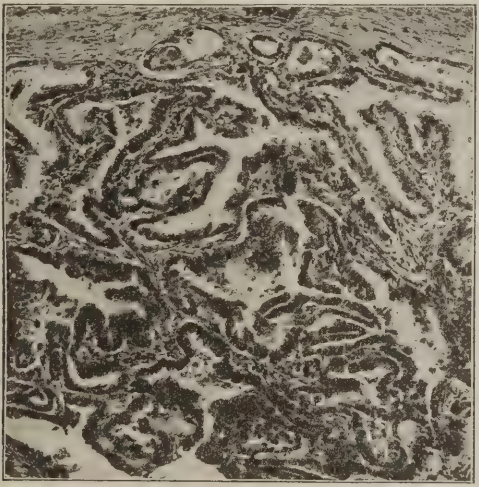

FIG. 2332.—Papilliferous Adenoma of the Thyroid. Branching processes, consisting of a connective-tissue framework covered with columnar epithelium, lying within a cyst. (× 73 diam.)

Extensive amyloid infiltration of the vessels has been observed by Friedreich, Virchow, and others. The entire tumor may assume a waxy appearance, hence the term *waxy* goitre applied by Beckmann.

Fœtal Adenoma (Fig. 2331).—The structure resembles that of the fœtal thyroid. The cells are arranged in solid columns and in circles surrounding small spaces. There may be a few vesicles, but there is little if any colloid. Occasionally the tumor is not sharply circumscribed, but usually it is provided with a definite capsule. The stroma is generally scanty, but is sometimes moderately abundant, and may be the seat of a mucoid degeneration (*Adenoma myxomatosum*, Wölfler). In size fœtal adenomas vary from a few millimetres to four or more centimetres, and are usually multiple, grayish-

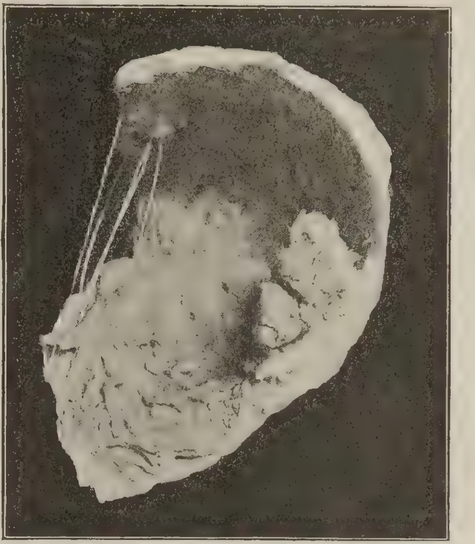

FIG. 2333.—Papilliferous Adenoma Developing from the Wall of a Thyroid Cyst. (Natural size.)

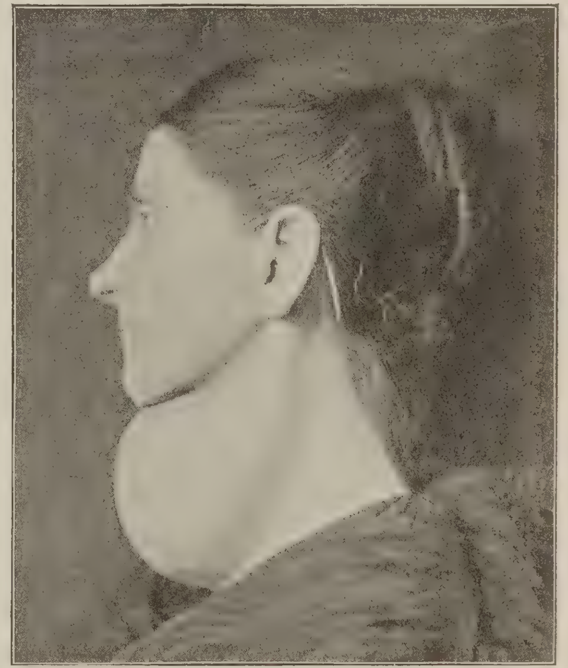

FIG. 2334.—Papilliferous Adeno-cystoma Successfully Removed by Dr. F. B. Lund at the Boston City Hospital. (Reduced in size.)

white or reddish in color, and of soft consistence. Often they are very vascular. They generally develop at the time of puberty (Wölfler).

Papilliferous Adenoma (Fig. 2332).—There are two types: (*a*) the papilliferous adenoma which develops from the walls of old cysts; (*b*) the true cystoma which closely resembles the papilliferous adeno-cystoma of the ovary. This important class of thyroid tumors lies on the border-line between the benign and the malignant growths.

Wölfler was the first to study them carefully; but all his cases were examples of papilliferous epithelial ingrowths from the walls of preformed cysts. Such a tumor is pictured in Fig. 2333. The second type of papilliferous growth is shown in Fig. 2335. It is a very rare form. I have not found it described in the literature. My collection includes two cases, which are quite similar in appearance. The one photographed in Fig. 2334 was successfully removed by Dr. F. B. Lund at the Boston City Hospital. It was surrounded by a fibrous capsule. It will be described by Dr. H. C. Low in the Medical and Surgical Reports of the Boston City Hospital, 1901. Dr. Low has searched through the museums of the London hospitals, which are rich in thyroid tumors, but has not found a single example of this type.

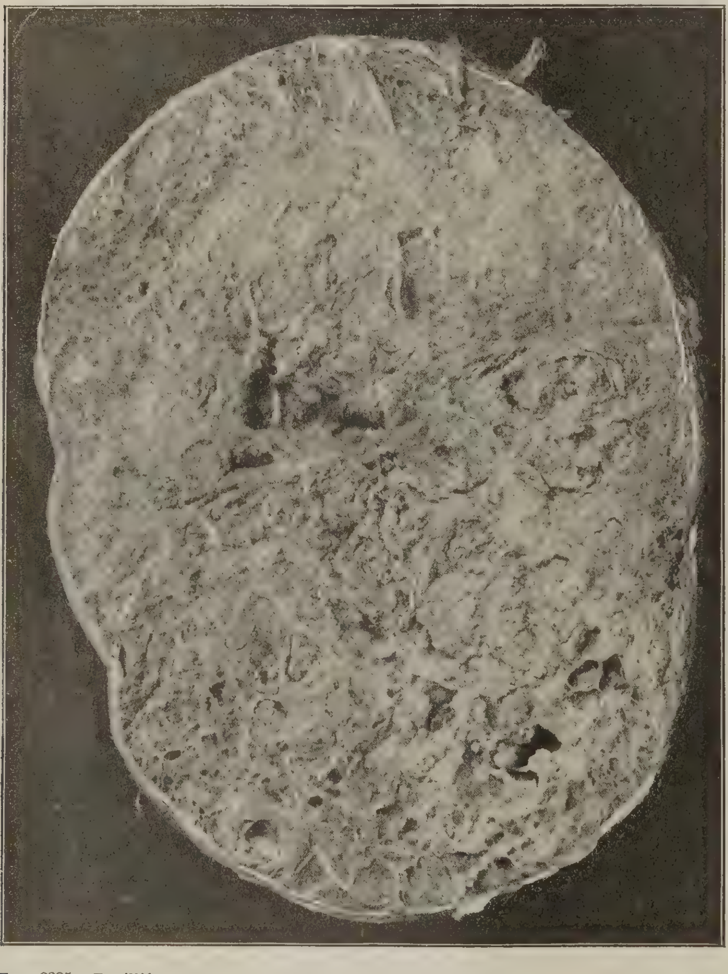

Fig. 2335.—Papilliferous Adeno-cystoma. (Natural size.) There are dendritic ingrowths into cystic spaces. The appearance of the tumor before removal is shown in Fig. 2334.

The papilliferous tumors consist of branching processes lying within a definite cyst or cystic spaces. The growth is composed of delicate connective-tissue stalks covered with cuboidal or columnar epithelium. There is rarely any colloid formation, but occasionally a vesicle is seen containing colloid. The stroma may undergo mucoid degeneration. Sometimes the tumors assume malignant properties and invade the surrounding tissues. In a papilliferous growth which developed on the inner wall of a cyst (Fig. 2333) I have seen numerous mitotic figures. Just as the fibrous wall of ovarian cysts frequently prevents the extension of adenocystoma into the peritoneal cavity, so in this thyroid tumor the wall of dense fibrous tissue acted as a barrier to prevent the infiltration of the neighboring structures.

The coalescence of simple colloid cysts may give rise on naked-eye examination to the false impression of papilliferous intracystic growths.

Goitres have frequently a rich blood supply. Fœtal adenomas are especially vascular. The term *vascular goitre* is frequently used. I agree with James Berry that the term is a bad one and should not be employed. He says: "If it be intended to signify a goitre composed mainly of blood-vessels, then it is a name for what probably does not exist, for there is no evidence of the existence of any such goitre."

Morbid Anatomy.—The size of thyroid tumors varies from small nodules, 1 cm. or less in size,* to masses as large as a man's head (Alibert, Keser). Such monstrous enlargements are, however, very rare, and probably are seen only in regions where the endemic disease abounds. In this country the endemic goitres are of small size and would attract little attention in Switzerland. The thyroid tumors that I have examined in Massachusetts have rarely measured more than 8 cm. in diameter. The tumor depicted in Figs. 2334 and 2335 is one of the largest in my series. The tumors generally occur singly, but they may be multiple. There is not uncommonly a diffuse enlargement of the entire thyroid, but usually one lobe is affected. The right is more frequently involved. Brunet seeks to explain this predisposition on the ground that the venous outflow is normally more impeded from the right lobe than from the isthmus or left lobe. Tumors from the isthmus are rare. A photograph of a specimen in the Warren Museum is shown in Fig. 2336.

The thyroid growths which develop anteriorly are visible on inspection even when they are of small size. Tumors growing posteriorly from the lateral horns may produce pressure symptoms before their existence has been discovered. They may form *retro-œsophageal goitres* which frequently escape detection.

Adami performed an autopsy on a woman who died quite suddenly from dyspnœa. She had suffered from previous paroxysmal attacks supposed to be asthmatic. Adami found that the trouble was due to a localized enlargement of the thyroid.

Large tumors sometimes fill up the space between the chin and the sternum. Huge pendulous goitres have been described which projected over the front of the sternum to below the level of the xiphoid cartilage, and instances are on record of goitres that have reached as low as the waist (Alibert). In a case published by P. Bruns the weight of the tumor produced lordosis in the cervical and kyphosis in the thoracic region of the spine. The tumor measured 70 cm. in greatest circumference. These enormous goitres are probably always cystic. The pendulous goitres are connected with the thyroid by a band of parenchymatous or connective tissue which carries blood-vessels.

---

* I have seen a discrete nodule, with the structure of a fœtal adenoma, which was only 2 mm. in size. Wölfler would probably regard it as an embryonic rest.

Tumors developing from the tip of a lateral lobe may appear in the submaxillary region near the angle of the jaw. The nature of these *submaxillary goitres* and their connection with the thyroid has often remained unrecognized. Tumors of the isthmus lie in the median line in front of the trachea. Those arising from a lateral lobe by pushing the trachea to one side may also take up a position in the middle of the neck.

The substernal and intrathoracic goitres form an important class. They are usually connected with the lower part of *the lateral lobes* or *the isthmus.* Some thyroid tumors grow down behind the sternum into the anterior mediastinum. The substernal goitre is the *goître plongeant* of the French. They are a very dangerous class of tumors. Owing to their situation they frequently cause severe dyspnœa by pressure on the trachea. Sometimes they become visible only during expiration, sometimes they lie entirely behind the sternum. A peculiar form of substernal tumor is the "wandering goitre" described by Wölfler. The tumor in his case did not rise and fall during respiration, but at times it actually changed its position. It was a small tumor, and when it migrated into the thorax it could be neither seen nor felt, but it produced severe dyspnœa by pressure on the trachea and circulatory disturbances by pressure on the right innominate vein. Reuter had a somewhat similar case. The tumor developed from the right lateral lobe. Upon coughing it rose above the sternum.

McWhinnie described a goitre which descended behind the sternum as low as the bifurcation of the trachea. Retrosternal goitres, as a rule, however, do not extend so deeply into the thorax and are not so large as those that grow beneath the clavicle. The latter may attain an enormous size and greatly compress the lung. Dittrich found a large thyroid cyst nearly filling the right pleural cavity. Above the cyst was thyroid tissue. The right lobe of the thyroid gland was missing.

These intrathoracic growths arise as follows: 1. Thyroid tumors may grow downward into the chest. 2. Tumors may develop from thyroids which are situated abnormally low in the neck. Kocher has introduced the term "thyreoptosis" for a condition analogous to other splanchnoptoses. 3. Tumors may arise from congenital prolongations downward of the thyroid gland (Krönlein). 4. Tumors may develop from accessory thyroids.

The first mode of origin is the most common (Braun). Usually a parenchymatous pedicle, it may be a thin one, connects the tumor with the thyroid gland. The connecting band may disappear or become converted into fibrous tissue. Then the genesis of the tumor cannot be determined. It seems wise, however, as Wölfler says, to classify all thyroid tumors which are not connected with the main thyroid, without regard to their genesis, as accessory goitres. No suspicion may be held that a tumor from the pleural cavity is thyroidal in nature until microscopic examination has been made. Virchow cites such a case. These accessory thyroid tumors situated within the pleural cavity are of course rare. Osler and F. A. Packard have reported cases. Reference has already been made to Dittrich's famous case.

Accesory thyroid tumors of the neck may develop from any of the accessory thyroid glands which are so common in the neighborhood of the main thyroid. They are usually found near the hyoid. Rokitansky and Sir James Paget first described them in the middle of the last century. One case has come under my notice in the post-mortem room of the Boston City Hospital. It was a simple adenoma measuring 2.5×2×1.5 cm. situated above and to the left of the thyroid and 1 cm. from it. There is no other case in the pathological records of the hospital. Pollard found a papilliferous adenoma of an accessory thyroid of the neck.

Intralaryngeal thyroid tumors are very rare; Paltauf reported a case in 1891. The tumor was situated under the right vocal cord. On post-mortem examination it was found to be composed of thyroid tissue and to be connected with the thyroid gland. Baurowicz in 1898 collected eight cases in which tumors composed of thyroid tissue had been observed within the larynx and trachea, and added one of his own. He thinks these tumors arise from the thyroid and are enabled to grow into the trachea owing to a congenital defect in the wall. Bruns, however, has described a tracheal tumor which originated from an accessory thyroid in this situation.

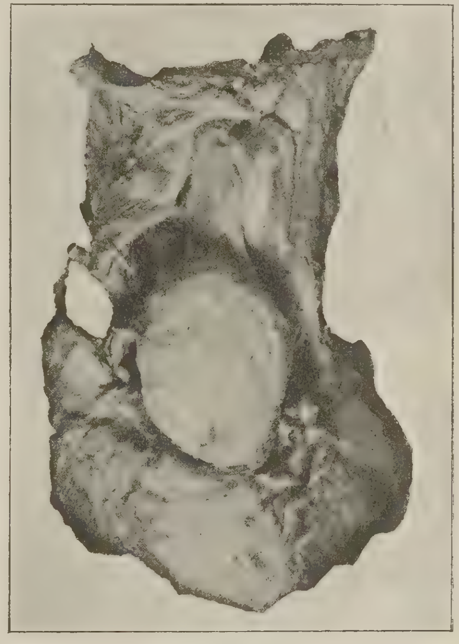

Fig. 2336.—Tumor of the Isthmus of the Thyroid. It extends upward as far as the lower border of the thyroid cartilage. (Warren Museum, No. 7,747.) (Slightly reduced.)

Accessory thyroid tumors occur in the base of the tongue. I have collected eleven cases from the literature,* and there is an unrecorded case in the Warren Museum. It is a nodule 1.5 cm. in size, and was removed by Dr. S. J. Mixter. In 1892 Dr. J. C. Warren presented a case before the American Surgical Association. These tumors have also been studied by Butlin, Wolf, and Watson. They are usually 2 to 3 cm. in diameter. Nearly all the cases have been in women. In Wolf's case the tumor produced great dysphagia.

Symptomatology and Diagnosis.—It is usually not difficult to determine whether or not a tumor of the neck is connected with the thyroid. The thyroid is closely bound to the larynx, and moves with it during deglutition. It must be remembered that any tumor or swelling connected with the outer surfaces of the larynx or trachea may present this sign. Berry tells us that a lipoma attached to the thyroid cartilage was mistaken by Sir Morell Mackenzie for a thyroid cyst. It moved with

---

*Theisen (*Albany Medical Annals,* October, 1901) reported a case of a tumor at the root of the tongue which he regarded as an accessory thyroid. It cannot, however, be included in the list as the structure of the tumor was not determined.

the larynx. Tumors thus simulating growths of the thyroid are, however, very rare.

A very large goitre may fail to move during deglutition. Either the bulk of the tumor may prevent the movements of the larynx or the tumor may become united to neighboring structures so that its position is fixed. The latter is frequently the case with malignant neoplasms.

The shaking or tilting of large thyroid tumors during deglutition is stated by Berry to be almost as valuable a sign as the rising of the tumor.

Dr. Osler reported a case of lymphosarcoma of the deep cervical glands which involved the thyroid and simulated goitre.

A tumor of the thyroid usually displaces the sternomastoid muscle outward and forward, while other tumors of the neck which might be mistaken for goitre generally push this muscle to the inner side (Berry).

The position of the carotid artery is an important aid in diagnosis. Bronchoceles push the artery backward and outward. The reason is plain. The thyroid gland is situated to the inner side and slightly anterior to the carotid sheath. Mr. Jonathan Hutchinson, in a recent clinical lecture on a case of tumor of the neck, laid special stress upon the position of the carotid, which was in front of the growth, in distinguishing it from goitre.

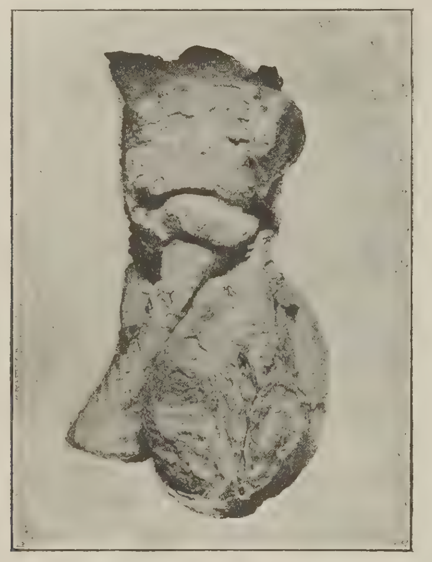

FIG. 2337.—Trachea Displaced and Compressed by a Tumor of the Left Lobe of the Thyroid. (Warren Museum, No. 7,979.) (Slightly reduced.)

The internal jugular frequently is carried forward and may lie in front of a thyroid tumor. The carotid artery and jugular vein thus become widely separated. The position of the jugular is due to the traction of the veins which pass to it from the thyroidal plexus (Lücke).

Pulsation transmitted to the tumor from the carotid artery has led to the mistaken diagnosis of aneurism. Guttmann stated that in the goitres of Graves' disease there is an arterial murmur over the tumor which is not present in other forms of goitre. George Dock says he has not seen a case of simple goitre in which there was a murmur. James Berry, however, reports cases in which loud murmurs were audible over the tumor, and further states that a well-marked bruit is not uncommon.

The consistence of benign thyroid tumors varies greatly. The simple adenomas are usually soft. Tense cysts and fibrous goitres may be very hard, and goitres infiltrated with lime salts are, of course, hardest of all. Beck has called attention to the Roentgen rays as a means of diagnosing calcified goitres. In dealing with suspected cystic growths, tapping gives the surest means of diagnosis. Strict attention should be paid to asepsis, and care taken to avoid blood-vessels.

Pressure on the large veins of the neck produces obstruction to the venous circulation and roaring in the head, vertigo, deafness, etc., may result. These symptoms are rare.

Pressure on the recurrent laryngeal nerve may lead to paralysis of a vocal cord. A subclavicular goitre may produce numbness or pain in the arm by pressure on the brachial plexus. Involvement of the cervical sympathetic is rare.

The trachea is frequently displaced to one side, and lateral compression is common (Fig. 2337). Rose taught that the tracheal rings were often atrophied and softened; subsequent investigators have failed to confirm his observations. The stenosis of the trachea may be marked. Extreme lateral flattening gives the trachea very much the shape of a sword scabbard. The brassy cough due to compression of trachea or bronchus is well known and characteristic. Dyspnœa is the most common symptom of goitre. It is usually the result of direct pressure upon the trachea.

Compression of the œsophagus leading to dysphagia is not common. It occurs especially in those rare cases in which a prolongation of a goitrous gland extends behind the pharynx and œsophagus, or between the trachea and the œsophagus. I have seen a goitre which nearly encircled the larynx and trachea. There may be a marked inward bulging of the pharyngeal wall caused by the thyroid tumor. Edwards records a case of acute thyroid enlargement in which the dysphagia was extreme and death partly due to starvation.

A simple goitre does not produce constitutional symptoms. Walter Edmunds states that cases of goitre which present symptoms other than those due to pressure are really examples of Graves' disease.

The diagnosis of intrathoracic goitre is very difficult. Kocher in his latest article (*Archiv f. klin. Chir.*, 1901, vol. lxiv., p. 454) gives the following signs:

1. Patients have a strongly marked dyspnœa, out of all proportion to the relatively small struma in the neck. The dyspnœa may take the form of a constant air-hunger or of intermittent attacks of suffocation.

2. The trachea is pushed to one side, much farther than can be explained by the tumor of the neck. Indeed, it can happen that the trachea is pushed to that side on which the cervical portion of the thyroid appears enlarged.

3. The tumor in the neck is not definable below; on the other hand, one feels a distinct resistance on pressing the fingers deep into the thoracic aperture, and this resistance is often accompanied by a heaving pulsation.

4. The portion of the tumor in the neck can neither be deeply pressed into the thorax nor pulled upward. The trachea and larynx also are less easily drawn upward than normal.

5. There are signs of pressure upon the great veins of the neck, indicated by stasis which finds no satisfactory explanation in the tumor demonstrable in the neck. The cervical veins fill from below if one empties them, by pressing the blood out with the finger, and the veins of the arm no longer empty, in marked cases, when the arm is elevated. Headache, dizziness, tinnitus, epistaxis, and loss of memory may direct attention to the stasis in the cerebral veins.

6. Paresis of the recurrent laryngeal nerve is not uncommon, and quite often there is paralysis of the sympathetic of the same side with retraction of the optic bulb, slight ptosis, a narrow palpebral fissure, and myosis.

Birch-Hirschfeld found at a necropsy an intrathoracic goitre which had given rise to the symptoms of a severe cardiac neurosis.

Dulness on percussion is rarely elicited over intrathoracic goitres (Braun).

COMPLICATIONS.—In cysts of no other organ is there such a tendency to *hemorrhage* as in those of the thyroid

(Berry). Serious or fatal results may follow. Dr. Osler records a case in which death was due to hemorrhage into a large bronchocele. The cyst had ruptured, and the blood had infiltrated the surrounding tissues and extended beneath the sternum into the anterior mediastinum.

Rupture of a cyst into the trachea or larynx may lead to sudden death from suffocation.

Inflammation of a thyroid tumor may occur. The term "strumitis" is applied to an inflammation of a goitrous gland, while "thyroiditis" refers to an inflammation occurring in a normal gland. The former is the more common. The infection is usually secondary to primary infection elsewhere. Strumitis and thyroiditis occur more frequently in association with typhoid fever than with any other disease. Metastatic inflammation of the thyroid may take place in pyæmia, puerperal fever, pneumonia, and other infectious diseases. It is also said to be associated with rheumatism and malaria.

Tavel made a bacteriological examination in eighteen cases of strumitis. All but three were secondary infections. Streptococcus pyogenes was the micro-organism most frequently found. Diplococcus lanceolatus, Staphylococcus pyogenes, Bacillus typhosus, and Bacillus coli were also isolated, usually in pure culture. In the three primary cases no bacteria were demonstrable. Treatment of goitres by injection has not infrequently been the cause of strumitis.

The inflammations terminate in resolution, abscess formation, or gangrene. Abscess formation is the most common.

Strumitis can be recognized by the usual signs and symptoms of inflammation of the external parts. A rapid increase in the size of the thyroid occurs. The other important symptoms are dyspnœa, dysphagia, and fever. Pain is frequently severe. There is localized congestion and œdema of the surrounding tissue, and the tumor may become adherent to the overlying skin, but a thyroid abscess rarely opens externally.

An abscess may rupture into the œsophagus, or more commonly into the trachea. Sir James Paget describes a case in which a large suppurating thyroid cyst burst into the pharynx and produced suffocation.

Treatment.—Some of the simple adenomas (parenchymatous and colloid goitres of authors) can be cured by medical treatment. The most favorable cases are those occurring in the young. All the fœtal and papilliferous adenomas, as well as the majority of simple adenomas, require the surgeon's knife for their removal.

If the patient is suffering from an endemic goitre he should leave the affected district. A residence at the seaside is said to be most beneficial. In a locality where goitre abounds the drinking-water should be boiled as a prophylactic measure.

The medical treatment may be local, general, or specific (organotherapy). The local treatment consists of the use of ointments and injections. The red iodide of mercury ointment is recommended. It should be rubbed into the skin over the tumor daily until the skin is tender. After a few days the procedure should be repeated. Exposure of the skin to the sun's rays after the ointment has been applied favors the remedial action.

Some authorities strongly recommend treatment by injections; others strongly condemn it. Injections of iodine should not be employed, as suppurative inflammation has frequently followed its use. Iodoform may be used, but strict aseptic precautions should always be taken. Mosetig-Moorhof recommends the following emulsion: iodoform, 1 part; ether, 7 parts; olive oil, 7 parts. Inject about ♏ xv. once every five or eight days. Frey treated sixty-five cases by this method with no untoward results. Nicholas Senn advocates injections of a five-per-cent. solution of carbolic acid, repeated once or twice a week.

Many internal remedies have been recommended. Most of them are useless. Iodine is probably the most valuable. It may be given as potassium iodide in doses of gr. v.–xx., or as tincture of iodine in doses of ♏ v.–x. two or three times a day (Murray). Ferrand, Gautier, and others have called attention to the particular susceptibility of goitrous individuals to iodism. Kocher states that he has had a number of patients brought to him with a diagnosis of acute thyroidismus when their symptoms were entirely due to iodine poisoning.

Phosphorus is highly lauded by Kocher. Experimental studies show that administration of phosphorus causes a notable increase in the iodine content of the thyroid.

It is still an open question whether thyroid extract yields any better results than iodine. Kocher thinks not. Bruns, Angerer, Murray, and others obtained striking results in some cases. Improvement is common, cure is rare. Reinbach fed thymus gland with almost equal success. Murray (*Edinburgh Medical Journal*, 1900, vol. viii., p. 113) administers dry thyroid in doses of three or more grains two or three times a day, or the liquid extract in doses of ♏ xv. In cases in which operation is deemed advisable he recommends treatment by thyroid extract for two or three weeks. The reduction in size of the goitre and superficial veins makes its removal less difficult.

Treatment of Strumitis.—An ice-bag should be applied to the gland in the early stages of the disease. The bowels should be cleared by a dose of calomel. If an abscess forms it should be incised without delay.

Malignant Tumors.—Both primary and secondary tumors of the thyroid are very rare. Cooper in 1819 wrote that cancer of the thyroid never occurs. Walshe estimated the frequency of thyroid to other cancers as 1 to 1,000. Tanchon found among 9,118 cases of cancer only 8 in which the thyroid was involved. Cancer of the thyroid occurred 11 times in 7,700 autopsies (Chiari). Malignant disease of the thyroid is more common in goitrous districts than elsewhere. Lücke observed 10 cases in two years in Berne.

Cancer is more common than sarcoma. The relative frequency of cancer to sarcoma, judging by collected statistics, is as three to one.

Lartigau (*Am. Jour. of the Med. Sci.*, August, 1901) collected fifty-five cases of primary sarcoma of the thyroid. It is a disease of the old rather than the young. Few cases occur under forty years. The earliest age was eleven years. It is more frequent in the male than in the female (Morf).

The round-celled sarcoma is the most common. Ten of the forty cases collected by Morf were of this variety. Spindle-celled, mixed-celled, and alveolar sarcomas occur.

The tumors may vary in size from a small nodule 1 or 2 cm. in diameter to a mass the size of a child's head. They have a smooth or slightly lobulated contour, and on section are usually pale, smooth, and translucent. Their consistence is soft and homogeneous. They are more vascular than the carcinomas. In the majority of cases they have originated in the right lobe (Lartigau).

Sarcoma of the thyroid ordinarily grows more rapidly than carcinoma. Death usually occurs within a year (Lücke). It is often induced by compression or infiltration of the trachea or œsophagus.

Metastases were present in forty-five per cent. of the cases of sarcoma collected by Morf. The cervical lymph nodes are most frequently involved in sarcoma as well as in cancer. Secondary growths in the lungs and bones are common. The great vessels of the neck may become infiltrated. Wölfler records a case in which the tumor invaded the internal jugular and extended downward through the left innominate and superior vena cava into the heart.

About one hundred and fifty cases of primary cancer of the thyroid have been recorded. The majority of these have been published within recent years. Hinterstoiser found fifty cases in the records of Kundrat's Pathological Institute at Vienna. In 1899 Poncet published forty-seven cases which he personally observed in Lyons, a city in which endemic goitre is commonly seen.

The size and appearance of the carcinoma vary greatly. In the majority of cases the tumor has been of small size. The thyroid gland is sometimes actually diminished in size. Before the growth has infiltrated the surrounding tissues it may closely simulate a benign encapsulated tumor.

Various types of cancer occur. The *papilliferous adenocystoma* may take on a low degree of malignancy and would then be classed as a cancer. Cases of this nature have been described by Barker and Wölfler.

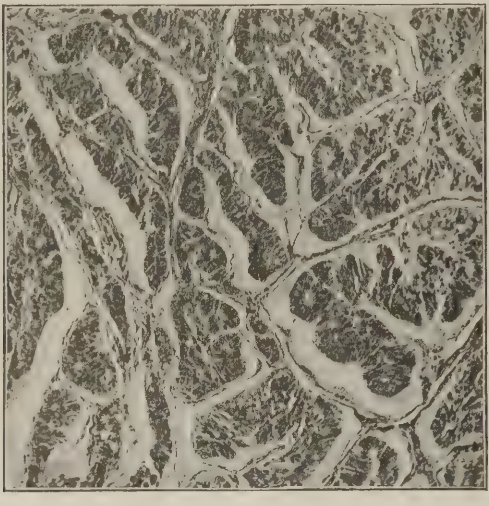

FIG. 2338.—Cylindrical-celled Carcinoma of the Thyroid. Acini filled with high cylindrical epithelium; no colloid present. (× 86 diam.)

A rare but interesting form is the *cylindrical-celled carcinoma.* The high cylindrical-celled adenomas probably are always malignant, although in places their histological structure may not suggest it. Fig. 2338 is from a cylindrical-celled adenoma that invaded the trachea.

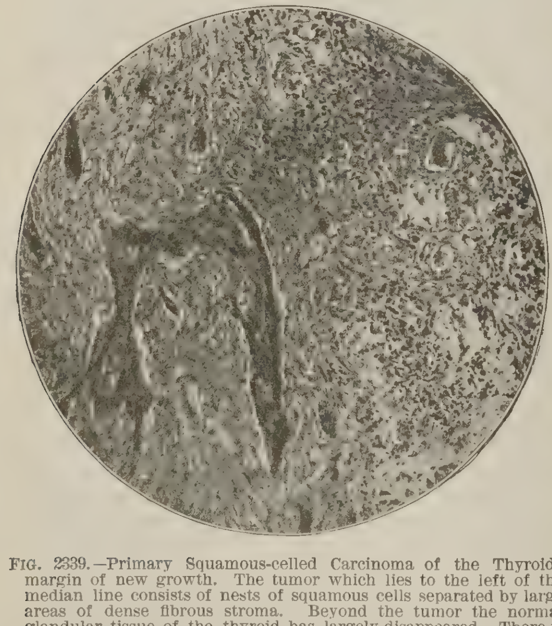

FIG. 2339.—Primary Squamous-celled Carcinoma of the Thyroid; margin of new growth. The tumor which lies to the left of the median line consists of nests of squamous cells separated by large areas of dense fibrous stroma. Beyond the tumor the normal glandular tissue of the thyroid has largely disappeared. There is marked infiltration with lymphoid cells. One shrunken vesicle filled with colloid is distinctly seen. (× 86 diam.)

The *squamous-celled* is also a rare but well-recognized form of primary thyroid carcinoma. It has been described by Forester, Lücke, Kaufmann, and Wölfler. Fig. 2339 is from a case that was examined by Dr. J. Homer Wright, of the Massachusetts General Hospital. It is held that this peculiar tumor originates from the remains of the branchial clefts which are enclosed within the thyroid.

Housell has collected twelve cases of benign thyroid tumors that formed metastases. I have found two other cases in the literature. The original tumor as well as the secondary growths in all the cases had the structure of simple adenomas. Metastases in the bones have been a constant occurrence, and they usually form pulsating tumors. The first case was studied by Cohnheim. The thyroid tumor was of moderate size, and there were metastases in the bones, lungs, and bronchial lymph nodes. A nodule of the original tumor projected into the lumen of a small vein. Riedel, and Oderfeld and Steinhaus (*Cent. f. allg. Path. u. path. Anat.*, 1901, vol. xii., p. 209) have described cases in which the thyroid gland was normal. The latter hold that normal thyroid tissue may grow into blood-vessels, and the epithelial cells swept along in the current form metastases in the bones. Christiani (*Jour. de phys. et path. Anat.*, 1901, vol. iii., p. 22) has demonstrated the great vitality and viability of thyroid tissue.

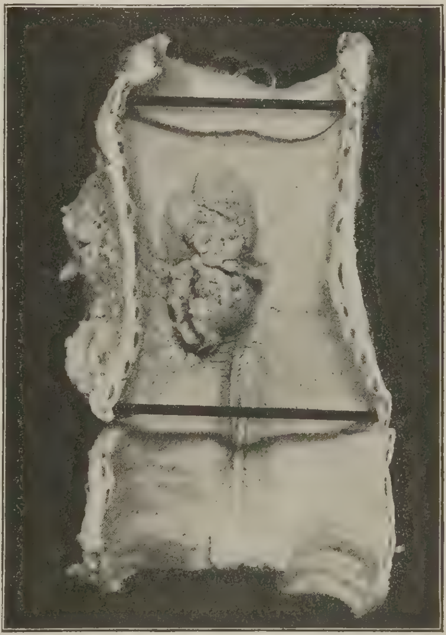

FIG. 2340.—Carcinoma of the Thyroid which has Invaded the Trachea and Formed a Button-like Nodule which Projects into the Lumen. (Warren Museum, No. 4,892.) (Natural size.)

SYMPTOMATOLOGY AND DIAGNOSIS.—Clinically it is difficult to distinguish between sarcoma and carcinoma. The latter usually are of smaller size and develop more slowly.

The malignant tumors develop rapidly. Pain is an early and important symptom. It is usually severe and radiates to the head or shoulders. Tenderness on pressure is often present. Fever is the rule. Enlargement of the lower cervical lymph nodes is strong evidence of the malignant nature of the thyroid tumor, provided strumitis can be ruled out. Immobility of the tumor does not occur until the capsule of the thyroid has been penetrated and the tissues of the neck are infiltrated. Hence it is a late sign. Kaufmann considers thrombosis of the veins of the neck one of the most reliable signs of malignant tumors.

Penetration of the trachea is common. An elevated nodule, sometimes of considerable size, is found projecting into the lumen. It is usually situated about 2 cm. below the cricoid. Fig. 2340 is from a specimen in the Warren Museum of the Harvard Medical School. The patient entered the Massachusetts Hospital suffering from extreme dyspnœa, hoarseness, and some dysphagia. Dr. Knight examined the larynx and found paralysis of one posterior crico-arytenoid muscle, and made out an obstruction of the trachea. The dyspnœa continued until death occurred two days later. The autopsy was performed by Dr. Fitz. A tumor mass the size of a small lemon connected with the thyroid was found. The growth extended through the anterior wall of the trachea projecting into the lumen to such an extent as to reduce the calibre fully two-thirds. The œsophagus was so compressed as barely to admit the little finger.

A peculiar chronic inflammation of the thyroid which closely simulates an infiltrating tumor has been described and studied by Riedel, Tailhefer, and Berry. A number of cases have been reported within the past five years.

Treatment.—Early and radical operation offers the only hope of cure.

Tuberculosis.—Although rare, tuberculosis of the thyroid is more common than is generally stated. Chiari found the thyroid was involved at autopsy in seven out of one hundred cases of tuberculosis. Roger and Garnier (*Arch. gén. de méd.*, 1900, vol. iii., p. 385) assert that while tubercles rarely develop, a sclerosis of the gland is a constant feature of chronic tuberculosis of the lungs or elsewhere.

Syphilis.—Swelling of the thyroid is common in the early stages of syphilis. Engel-Reimers found the gland enlarged in fifty per cent. of the cases. Gumma is extremely rare. The few instances that have been recorded were nearly all in children, and usually associated with severe visceral manifestations of the disease. For details in regard to syphilis of the thyroid the monographs of Fürst and Küttner may be consulted.

Echinococcus Disease.—Berry has collected twenty-two cases. A single cyst has usually been found. The tumor when large may be very irregular in shape. The symptoms are those of an ordinary goitre. Dyspnœa is usually present. There is a tendency to spontaneous suppuration. Diagnosis can be made only after microscopical examination of the cyst contents. The aspiration of a clear, limpid, colorless fluid is suggestive (Berry). The demonstration of hooklets or scolices confirms the diagnosis. The known association of urticaria with hydatid led Lannelongue to make the correct diagnosis. Perforation into the trachea has caused suffocation in a number of instances. *Joseph Hersey Pratt.*

GOITRE AND CRETINISM.

—Definition.—Cretinism is a peculiar type of mental and physical degeneracy, either congenital or developing in childhood, due to absence or disturbance of the function of the thyroid gland. An individual afflicted with cretinism is called a cretin.

Etymology.—The etymology of the word cretin is shrouded in obscurity. It seems that the word originated as a colloquialism in the Canton of Wallis in Switzerland. Esquirol (quoted by Demme, "Ueber den endemischen Kretinismus," Berne, 1840) derives the term from an old word *cretine*, an inundation (Anschwemmung), and connects it with the marshy character of many cretin districts. There is, however, no proof of such a derivation. According to Fodéré, the word comes from *chrétien*, a Christian, the term, "bon chrétien," having formerly been applied to the cretin, on account of his contented disposition. Another interpretation, according to which the word is also derived from chrétien, is based upon the fact that cretins were popularly believed to be elected Christians, and were considered holy, inasmuch as they were supposed to fulfil the lofty function of expiating in their unhappy lot the sins of their fellowmen. According to Gross ("Ueber die Ursachen des endemischen Kropfes und des Kretinismus." Inaugural Dissertation, Tübingen, 1837), the word comes from *Christiani* (spelled *Chrestiani* by Tertullian), because the Romans looked upon the converts to Christianity as fools and imbeciles. Celsus also spoke of the Christians as a society of slaves and idiots. Some have traced the term cretin to a word *cretina*, meaning stupid or silly. According to Ackermann, cretin comes from a Romance word, *cretira*, a creature. Others have derived it from *creta*, chalk, on account of the chalky complexion of the cretins. This derivation finds some support in the German colloquial word for cretin; viz., *Kreidling*, from *Kreide*, chalk.

Nearly every locality has its special name for cretins. In Austria they are known as Trotteln or Gacken; in Germany, as Kretins or Kreidlings; in German Wallis, as Gauche, Tampe, or Nollen; in French Wallis, as Crétins, or as Marrons, on account of the dark color possessed by some; in Salzburg, as Fexen, Trepped, or Trutsched; in Würtemberg, as Dackel, Dippel, Tralle, or Simpel; in the Pyrenees, as Cajots or Capots; in Piedmont, as Pazzi;

in Italy, as Gavas, Totolas, or Cristiani; in South America, as Bovos or Tontos. In Latin writings the word Christiani is generally employed.

Synonyms of Cretinism.—The synonyms of cretinism are infantile myxœdema, cretinoid idiocy; in French, idiotie avec cachexie pachydermique, pachydermie crétinoide.

Historical.—According to the Sardinian Commission's Report, the first mention of a cretin occurs in the fifteenth century. Demme (*loc. cit.*) says that the first reliable mention is in the writings of Peter van Foreest, a Dutch physician who lived from 1522 to 1597 (P. Foresti: "Observat. et curat. opera omnia," Francof.). A contemporaneous reference is found in the writings of Felix Plater (1536–1614) (F. Plateri: "Observat. in hominis affectibus plerisque," Basle, 1614). A description of the cretins of Wallis also occurs in the writings of Giosia Scentero (about 1574) (quoted by Gross, *loc. cit.*). One of the most graphic descriptions dates back to the eighteenth century, and is that of Horace Benedict de Saussure, the famous Alpine traveller, and the first to scale Mont Blanc ("Voyage dans les Alps," four volumes, 1779–96). The first real scientific work on the subject is that of Ackermann ("Ueber die Kretinen, eine besondere Menschen-Abart in den Alpen," Gotha, 1790). In the nineteenth century cretinism formed the theme of many writers, and the literature is now almost unlimited. Particular mention should be made of the reports of the Sardinian and French Commissions, and of the article on cretinism by Baillarger and Krishaber in the "Dictionnaire des Sciences médicales." Among the most important articles of recent date are those of Ewald, Osler, Kocher, Klebs, and Murray. An interesting picture of the cretin communities in France is to be found in Balzac's magnificent novel, "The Country Doctor."

Distribution.—Cretinism may occur in any part of the world, but there are certain limited districts in which it is an endemic disease affecting a large percentage of the population (endemic cretinism). Isolated cases of the disease (sporadic cretinism) have been observed in many widely separated places that are far removed from foci of endemicity. It is, indeed, probable that if the characteristics of the disease were universally known, some cases would be found to exist in nearly every large community.

Several observers have noted conditions in the lower animals suggestive of cretinism: thus, Müller (*Würzburg med. Zeitschr.*, 1860) speaks of cretinoid changes, particularly of the bones, in calves; and Eberth ("Fötale Rachitis und ihre Beziehung zu dem Kretinismus," 1878), of the condition in calves and puppies.

There is one very interesting feature connected with the endemicity of cretinism, namely this: cretinism is endemic in the same localities in which goitre prevails as an endemic affection. This, as we shall see, is a fact of tremendous importance in the study of the pathogenesis of the disease.

Endemic Distribution.—Cretinism is endemic in certain parts of Switzerland; in the Valais, Tarantaise, Maurienne, and in the upper valleys of the Rhone. In Germany, the foci are Würtemberg (2 cretins per 1,000 population. Schmid, *Correspondenzbl. d. ärtzl. Landesver.*, 1886), the Black Forest, and Alsace; in Austria, Salzburg (1 to 139, according to Wallmann, *Wiener med. Jahrbücher*, 1863, vol. i., p. 120), Galicia, and the Kärnthner (1 to 110) and Styrian Alps (1 to 116); in France, the Pyrenees, the Vosges, and the French Alps; in England, according to Murray ("Diseases of the Thyroid Gland," Part I., 1900), the upper valleys of the Pennine Range, the north of England, the neighborhood of Allston, Stanhope, and Kendal. In these places goitre is also endemic. Formerly (Morris, *Medical Times*, 1847, vol. xvii., p. 257), cretinism was strongly prevalent in Chiselborough, in Somersetshire; but it has died out. There are also said to be foci in Scotland and in Spain. In some portions of the Caucasus (the valley of the Zschomarski and Swanetia) (Witke, *Münchener medicinische Wochenschrift*, 1896, p. 292) cretinism prevails endemically. According to Kandaratski (Congress der russ. Aerzte, 1899), goitre and cretinism are widespread throughout Western Russia, which has many marshy districts. In Asia the disease is found in certain parts of the Himalayas, in Thibet, in Turkestan, and in Tartary. As to the occurrence of the affection in Africa, very little is known. According to Blumenbach (quoted by Gross, *loc. cit.*), the disease is found in Madagascar. In South America we find it prevalent in parts of Brazil and along the slopes of the Cordilleras. No foci of endemic cretinism exist in North America at the present time (Osler, *American Journal of the Medical Sciences*, 1893). Goitre formerly prevailed in this country, and is yet endemic in Eastern Ontario, where even the lower animals suffer from it. Demme, in his American travels, found many cases of goitre, especially in Pennsylvania, about Pittsburg, in the valleys of the Allegheny, Monongahela, and Ohio rivers, and in New York; but he saw no cretinism.

Endemic cretinism is confined to certain altitudes, being most common between the elevations of 1,300 and 2,000 feet; it is hardly ever found above the level of 3,000 feet. Its homes are not the tops of the mountains, but the dark, sheltered valleys and clefts, through which course the mountain streams.

The occurrence of goitre in dogs, hogs, cats, cattle, and antelopes has been demonstrated; but as to the existence of cretinism, little is known, with the exception of the brief reference made above.

Etiology and Pathogenesis.—As stated in the definition, the cause of cretinism is absence or disturbance of the function of the thyroid gland (athyroidism, dysthyroidism, hypothyroidism). This applies both to the endemic and to the sporadic form of the disease. The proofs of the thyroidal theory, as we may call it, are as follows:

1. The most constant lesion in cretinism is that involving the thyroid gland. In the case of the endemic form, there is generally goitre; in the sporadic, the gland is either atrophic or absent.

2. *The occurrence of operative cretinism*, that is, the development of the cretinoid state after the removal of the thyroid gland. Küster (quoted in the Report of the Committee on Myxœdema, Transactions of the Clinical Society, 1888, No. 21, Supplement) extirpated the thyroid gland in a fourteen-year-old boy. Thereafter, the lad's growth was arrested, so that he always retained the characteristics of a boy of that age. Kappeler (*ibid.*) performed total thyroidectomy in a boy twelve and a half years old, who afterward did not grow, and developed some of the symptoms of myxœdema. Intelligence, however, was preserved. Kocher (*ibid.*) removed the entire thyroid from a child aged six, with the result that the physical symptoms of cretinism developed, although the mental symptoms remained in abeyance. Costengo (*Riv. Ven. di Sc. med.*, vol. xx., No. 2) reports a case of total thyroidectomy in a boy. Nine years after the operation the patient was a complete cretin. In a case reported by Sulzer (*Deutsche Zeitschrift für Chir.*, 1893) a goitrous thyroid was removed from a boy twelve and a half years old. Within five years typical cretinism had developed. On the appearance of a new thyroid, the boy improved, and within four years had regained all that he had lost. It was found that a piece of the gland had been left behind, and that it did not begin to grow until eight years after the operation. Palleske (*Deutsche medicinische Wochenschrift*, 1895) removed the thyroid from a girl of thirteen, who three years afterward was a typical cretin. Other cases are reported by Grundler (*Beitr. zur klin. Chir.*, 1883, No. 1), Julliard, Lancereaux, and Dolega (cited by Hofmeister, *Beiträge zur klin. Chir.*, 1894). Schmid (*Berliner klin. Wochensch.*, 1886, p. 509) removed the thyroid gland *in toto* from a boy fourteen years old, who afterward developed typical cretinism. He had absolutely no memory, and did not grow after the operation. Brian and Sargnon (*Gaz. hebdom. de Méd. et de Chir.*, 1898) report the case of a man thirty years old, who was in a moderate cretinoid state, and had a

goitre. This was removed by operation; within one year later complete cretinism had developed.

3. *Animal Experiments.*—The removal of the thyroid gland in young, growing animals, if the animals survive any length of time, is generally productive of an arrest of growth, and a state comparable to cretinism in man (Hofmeister, *loc. cit.*). The majority of animals die if the whole gland is removed, whether it be done in one or in two operations. In some experiments made by W. S. Carter and myself, this was the invariable result. Eiselsberg, however ("Ueber Tetanus im Anschlusse an Kropfoperationen," 1890), found that if only four-fifths of the gland are removed, the animals survive, and subsequently develop a myxœdematous state. It must be admitted that not all experimenters have been able to produce the same results. Munk, for example (Sitzungsberichte der königl. preuss. Akademie der Wissensch., 1888, No. 40) was never able to produce myxœdema or cretinism in apes by thyroidectomy. The animals all died with tetanic symptoms. The most suggestive experiments are those made more recently by Eiselsberg (*Langenbeck's Archiv*, 1895, vol. xlix.). He removed the thyroid from two lambs when they were about a week old. At the end of six months they weighed 10 and 14 kgm., respectively, while the control animals weighed 35 kgm. The disturbances were general, and involved the brain functions as well as the skeleton. Similar results were obtained in four goats and in one pig. One goat, however, developed in a normal manner, probably owing to the possession of an accessory thyroid gland.

4. *Therapeutic Results.*—The use of thyroid-gland extract in the treatment of cretinism has brought about remarkable results. It is true that these have been more brilliant in the case of sporadic, than in that of endemic cretinism; but it has not been systematically tried in the latter, and there are other factors of influence in the development of the disease. The successes obtained are, however, a strong confirmation of the view that cretinism is consequent upon disturbance or absence of the thyroid function.

The relation between the thyroidal changes and the development of cretinism is not definitely understood. The subject involves a consideration of the physiologic function of the thyroid gland, and that is not in place here. Suffice it to say that in the opinion of most authorities the thyroid gland produces a substance that acts as an antidote or antitoxin to certain toxic products of daily metabolism. Where the neutralization occurs is a matter of doubt, some holding that it takes place in the thyroid gland, and others that it takes place in the blood. If the toxins are not antagonized, they remain in the body and exercise a deleterious influence, primarily upon the nervous system, but also on the skeleton and other connective tissues. If the individual is young, the result will be an arrest of both physical and psychical development.

Normally the antitoxic action of the thyroid gland begins to be exercised early in life—according to Kinnicut (*Medical Record*, 1893), between the sixth and the eighth months of fœtal life. Failure of development (aplasia), imperfect development (hypoplasia), and morbid conditions in later life (such as atrophy, fibroid change, calcareous infiltration, acute inflammation, and goitre in all its forms), are the pathologic conditions that rob the body of the benefits conferred by a functionating thyroid gland.

Relation to Myxœdema.—The studies of English physicians, particularly Ord, Horsley, and Murray, have conclusively demonstrated that there is an intimate relationship between cretinism and myxœdema. Etiologically, the two affections are identical, in that their basis is a morbid condition of the thyroid gland; symptomatically, they also have considerable in common. The differences which they present are due to the fact that cretinism begins in childhood, at a time when the growing system is most impressionable to deprivation of the thyroidal influence; while myxœdema is the same disease developing after the body has reached its growth. Thyroid treatment produces beneficial results in both.

If it be accepted then as proved, that cretinism is due to absence or disease of the thyroid body, the next question to arise is, "What influences bring about the morbid condition in the gland?" The cause of its absence, poor development, or goitrous state, in sporadic cretinism, we do not definitely know. A number of reasons have been assigned: consanguinity of the parents, conception during alcoholic intoxication, fright during pregnancy, tuberculosis, and a neurotic taint; but the frequency of these conditions compared with the rarity of cretinism indicates that they possess little real importance. A study of embryologic pathology may throw light upon the subject. In rare cases, as in the one reported by Shields (*New York Medical Journal*, 1898, vol. ii., p. 476), the disease has followed upon an acute thyroiditis, undoubtedly of infective origin.

In the case of endemic cretinism, our knowledge is less meagre, although still far from complete. The fact that endemic cretinism and endemic goitre are in a large measure coextensive in distribution suggests a relationship between the two. At present, this relationship is interpreted as being that of a common causation: goitre and cretinism, it is believed, are due to the same cause. This view dates back to the early part of the nineteenth century, and was advocated by Fodéré ("Traité du goître et du crétinisme, precédé d'un discours sur l'influence de l'air humide sur l'entendement humain," Paris, an. viii., 1800), Gross (*loc. cit.*), Baillarger and Krishaber ("Dictionnaire des Sciences médicales, 1re série," vol. xxiii.), and Virchow. The common cause, nearly all observers agree, is to be found in the drinking-water. Goitre and cretinism always grow less frequent in affected localities when the water supply is changed. Thus, Bircher states that 59 per cent. of the school children of Rapperswyl, in the Swiss Canton of Aarau, had goitre in 1885. The town then made a change in the water supply, obtaining it from beyond the Aar, from a goitre-free district; and the percentage fell rapidly to 44 per cent. in 1886, 25 per cent. in 1889, and about 11 per cent. in 1895. In contiguous communities, living under identical conditions with the exception of the water supply, goitre and cretinism may prevail in one and be absent in the other. Thus, the Bozel district in the Tarantaise had, in 1848, 1,742 inhabitants, of which 900 had goitre and 109 were cretins, and a number semicretins. The St. Bon district, which is only a short distance away, using a different water supply, had no goitre and no cretinism. Upon the advice of the Sardinian Commission, Bozel changed to the St. Bon water, with the result that in 1864 there were but 39 goitres and only 58 cretins.

An active discussion has been waged upon the question as to the constituent of the water bringing about goitre and cretinism. It is known that only water from the soil, not rain or snow water, produces these disorders. At first, certain minerals—for example, gypsum—derived from the particular geologic formation in which the goitre streams have their source, were believed to be the active agents; but the occurrence of endemic goitre in localities the waters of which have an entirely different mineralization, makes this view untenable. The favorable influence exercised by iodine upon goitre led to the theory that the waters of goitrous districts were deficient in this substance. Against this not unreasonable supposition is the fact that goitre may and does exist in valleys the streams of which are rich in iodine—as the valleys of the Po, Aosta, and Isère—and may be absent where the water is free from iodine.

From this dilemma an escape was found in the assumption that the efficient agent in goitrogenic waters was a *contagium vivum*. This hypothesis is now generally adopted, Ewald in particular having strongly defended it; but it is not new, and was long ago expressed by Alexander von Humboldt, Troxler, Virchow, and Hirsch —to be sure, in pre-bacteriologic language. Demme and Gross had assumed the existence of a miasm which arose in the vapors of the marshes. Baillarger and Krishaber (*loc. cit.*) had also come to the conclusion that the goitrogenic substance was organic, although they did not go so far as to make of it a living substance. The fact that the boiling of the water renders it innocuous is one of the strongest arguments in favor of the modern theory. What the substance is, still remains a mystery. It may be bacterial, although no definite organism has been isolated. Tavel (quoted by Kocher, *Deutsche Zeitschrift f. klin. Chir.*, 1892, vol. xxxiv., p. 556), in a beautiful, clear stream in a goitrous district, found thirty-three varieties of plant life, although he was not able to prove definitely that any one of them was the sought-for cause of goitre.

Whatever the cause may be, it is not long-lived in the body. Goitre increases only as long as the infected water is drunk, and it may even disappear if the individual afterward consumes a pure water. Immunity to goitre may exist in goitrous localities. According to Kocher, persons who pass the tenth year in such a locality without the development of goitre, will usually remain immune. Whatever the nature of the morbific agent, it seems to expend itself upon the thyroid gland; and in the end it is the disturbance in the function of that organ that brings about cretinism.

There are, however, certain predisposing causes:

1. *Locality.* Endemic goitre occurs especially in sheltered, damp, and imperfectly aired valleys.

2. *Geologic Formation.* Goitre and cretinism are most common in sections characterized by marine sedimentary rocks, particularly those of the Paleozoic Era (Devonian, Silurian, Carboniferous, and Dyas), the Triassic, and the Tertiary. McClelland, in his Himalayan studies, found goitre most common in places in which the soils were rich in lime and magnesia, there being one goitre in every thirty-three, and one cretin in every thirty-two persons.

3. *Social Condition.* Endemic cretinism prevails among people eking out a meagre existence under unfavorable conditions. The influence of such conditions has been proved indirectly by the lessening of goitre and cretinism as such communities become more affluent and more civilized, the water supply remaining unchanged. Wallmann (*Wiener med. Jahrb.*, 1863, vol. i., p. 120) also considered despotic government a factor in the production of cretinism. There was an opinion, found not uncommonly in older writings, that cretins were the relics of an ancient, inferior race of human beings—an hypothesis that has, of course, no proof whatever.

4. *Consanguinity.* Inbreeding and consanguineous marriages are an important factor in the perpetuation of cretinism.

5. *Heredity.* When the parents are goitrous, even if the thyroid disease is slight, the children are very apt to develop cretinism; and this is particularly true, as indicated in the preceding paragraph, if the parents are related.

The Sardinian Commission found that of 3,613 fathers of cretins, 962 had goitre, and 51 were cretins; and of 3,652 mothers, 1,281 were afflicted with goitre. But that heredity is not of controlling moment is proved by the fact that, given good surroundings, the descendants of goitrous parents may develop normally, although they do not always do so. Goitre does not, however, of necessity bring about endemic cretinism; for in Ontario goitre is, according to Osler, quite prevalent, but cretinism is unknown. Goitre also formerly prevailed in Pennsylvania and New York (Demme, Gross), but cretinism was rare or unknown. Regarding Canada, however, while endemic cretinism does not occur, sporadic cretinism is by no means uncommon; and Macphedran (*Canada Journal of Medicine and Surgery*, 1898, vol. iv., p. 275) was able to collect no less than seventeen cases.

General Features.

Nothing is more characteristic than the physiognomy of a typical cretin. There is, moreover, a remarkable uniformity in the appearance of all persons afflicted with this disease, so that the characteristic individuality of normal human beings is largely obliterated. To such an extent is this the case that older writers, as already mentioned, considered cretins to be the remains of a degenerate aboriginal race.

The typical cretin is short of stature—a stunted, dwarfish being, with a large head resting almost upon the shoulders or sinking forward upon the chest. As a rule, the hair is short, coarse, and abundant, though sometimes long and silken, and grows well down over the low forehead. The skin is pale, thick, dry, rough, at times scaly, and has a tendency to form thick folds or waddles. The face is stupid, expressionless, and repulsive. The eyes gaze vacantly, seldom fixing objects. The nose is short and thick, with a deep-lying root and flaring nostrils. The mouth is large; the lips are thick and fleshy, and constantly open, permitting the swollen tongue to protrude and the saliva to drool. The teeth are few in number, large, wide apart, and badly formed. The ears are fleshy, pale, often deformed, and usually stand out. Sometimes they are small and grown flat to the head. A short, thick neck, at times deformed by the presence of a goitre, joins the head to the thorax. The latter is disproportionately short, flattened irregularly at the level of the lower end of the sternum, and often scoliotic and kyphotic; it is usually smaller in circumference than is normal. The breasts in female cretins are either not developed at all, or are very large and pendulous. The abdomen is protuberant and inclined to hang downward; often a hernia, either umbilical or inguinal, is present. Lordosis is common. In both sexes the genitalia are usually small and infantile, with absence of hair in the pubic region, but in rare cases the external organs of generation are excessively developed. The extremities are short, fleshy, and grooved by deep furrows; the feet and hands are large; the nails roughened. Often there is a tendency to bow-leg or knock-knee. Many cretins cannot walk; some cannot even stand unless supported.

Intellectually, the cretin, as a rule, presents a degree of degeneracy that is on a par with that of his body. His wants are confined to the most rudimentary desires, such as hunger and thirst; and to these, even, he gives expression in ways that are intelligible only to those that are constantly about him. Speech he usually has not, and is able only to make monotonous, inarticulate noises, and does not employ gestures. If he speaks at all, his voice is shrill and unpleasant. He remains in all respects a helpless child, and often wears, even at two-score years or more, the garb of childhood.

In the foregoing I have given a brief sketch of the cretin in his worst estate—the type that Maffei calls plant-men (Pflanzenmenschen), on account of their purely vegetative existence. The picture is not overdrawn, and characterizes wellnigh the majority of cretins; but there are many in whom the disease does not reach such a profound degree, and in every locality in which the disease is endemic there are gradations, from the fully developed to the mild type—so mild, indeed, that only a few features of the disease remain. These slight cases are termed cretinoid.

Age.—Cretinism may be congenital; that is, it may be present at birth. In such cases the child rarely lives any length of time; indeed, it is often still-born. More frequently the disease develops some time after birth: in the endemic type, between the fifth and the eighth months; in the sporadic, after the second year, or later. The condition usually reaches its height at the age of fifteen years, and remains stationary after the twentieth year. According to Ord (Medico-Chirurgical Transactions, 1878), cretinism never develops in a child that is healthy up to its sixth or seventh year. Operative cretinism naturally begins after the operation, if that be done within the period of growth. The duration of life is generally short, especially in the sporadic form, in which the fourth decade is rarely attained. In endemic cretinism, subjects sometimes reach the exceptional age of seventy, or even one hundred years. Tuberculosis seems to be rare in cretins.

Sex.—Endemic cretinism is more common in the male sex. In sporadic cretinism there seems to be a decided preponderance of females. I have collected from the literature 93 cases of the sporadic type. The sex was mentioned in 86; of these, 48 occurred in females, 38 in males. Osler, in the American cases, only a few of which are included in my list, found the difference in favor of the female sex even greater; 35 females to 23 males.

FEATURES OF THE DISEASE IN DETAIL.

A. SOMATIC FEATURES.—1. *General Skeleton.*—The cretin is almost never of the normal stature of persons of his age; in the majority of cases indeed, his height does not exceed that of a child of three or four years. Maffei (quoted by Kocher, *loc. cit.*) found 22 out of 25 cretins to be less than 4.5 feet (140 cm.) in height; several were even less than 3 feet tall (95 cm.). Macphedran (*Canadian Journal of Medicine and Surgery*, 1898, vol. iv., p. 275) found the height in 9 cretins to vary from 26 to 55 inches. I have tabulated the heights of 28 cretins, ranging from four to fifty-three years of age, and found the average to be 96.6 cm. (38⅗ in.).

There is a disproportion among the different parts of the body. At times the arms are very long; the hands, large; the fingers, short; the nails, broad, flat, short, and brittle. The lower limbs are crooked, and there is often a backward extension of the knees. The clavicles are thin, delicate, and slightly curved. The hair is coarse, dry, and abundant; often reddish in the sporadic form, and chestnut-color in the endemic. There is usually no pubic or axillary hair, but sometimes a considerable hirsute growth is noted between the scapulæ. Fatty tumors are found above the clavicles, and occasionally between the shoulder-blades, but only in the sporadic, not in the endemic, type. Umbilical and inguinal hernias are common features. As already mentioned, the genitalia are small; but in some instances (Friedreich, "Ueber die äusseren Geschlechtsorgane der Kretinen in Iphofen," 1828) the male sexual organ reaches an enormous length, the testicles being in proportion, and usually very hard. Puberty, if it occurs at all, is late in appearance, sometimes, as in Wagner's observation (Medic.-chir. Centralblatt, 1893, 245), at the fortieth year. The cretin's skin is dry, harsh, and brownish or pale ashen in color. The veins of the chest are prominent, and there is often, as Bramwell ("Atlas of Clinical Medicine," vol. i., p. 16) has noted, a venous mottling of the legs. Eruptions are common in the sporadic form. The body temperature of cretins is nearly always subnormal.

The Head.—The head is unduly large, with a flat top and a prominent occiput. (Bulldog-like is the comparison made by some writers.) The circumference is, however, not so large as might be expected from the general appearance of the head, the average in twenty cases being 51 cm. (20⅗ in.); at times there is actual microcephaly. The fontanel and sutures remain open very long, although sometimes they close early. The shape of the head varies. It is usually brachycephalic in endemic cretinism and dolichocephalic in the sporadic type. The head is often so heavy that it cannot be held up by the weak neck muscles. The forehead is low, the supraorbital ridges are prominent, the eyebrows thin, the eyelashes short and few in number. The eyelids are swollen. The eyes are usually open, but sometimes half closed from ptosis. Many cretins have pronounced squint. Lachrymation is common, from occlusion of the lachrymal duct, and there is often well-marked epicanthus. The nose is retracted, short, and homely, with large, flaring nostrils. The upper jaw is usually unduly prominent, while the lower recedes. The lips are thick and fleshy (macrocheilia), and at times there is a pinkish flush upon the cheeks. The naso-labial folds are indistinct. The mouth is always open, and the breath offensive. There is constant drooling of saliva. The tongue is large, swollen, and in advanced cretinism protrudes from the mouth (macroglossia). The teeth appear late, and the milk teeth generally persist throughout life, second dentition being rare. The teeth are subject to early decay, and are always badly formed and of large size. The palatal arch is generally high and narrow. The neck is short. The thyroid gland as a rule cannot be felt in sporadic cretinism, and was absent at autopsy in nine out of ten cases collected by Bramwell (*loc. cit.*).

I have analyzed 88 cases of sporadic cretinism recorded in the literature with reference to the condition of the thyroid gland. There was no thyroid demonstrable in 44; there was no goitre, or the gland was normal in 9; goitre existed in 7; and no mention was made of the gland in 27. Osler, in his cases, a few of which are embodied in my table, found goitre present in 7, the gland normal in 12, and small in 2; it was not felt in 16, and not mentioned in 20. In one case of cretinism on which I had an opportunity to make the autopsy, the thyroid gland was absent. In endemic cretinism the thyroid is not only present, but is, as a rule, the seat of goitrous change. Wagner (*loc. cit.*) gives the frequency of goitre as high as ninety per cent.; others generally find a lower percentage. Among 20 cretins, Bircher found 15 with goitre, the thyroid not being palpable in one, and being normal in 4. Regarding the statement that the gland is normal, it must always be remembered that it is difficult to determine merely by palpation the condition of a thyroid gland. Cretinism is always worse in non-goitrous persons than in those having goitre.

Fleshy lipomatous masses are found above the clavicles and between the scapulæ, but only in sporadic cretinism. During wasting diseases and before death, these tumors generally atrophy.

Circulatory System and Blood.—The heart sounds are weak; the pulse is slow and feeble. The blood has not been carefully studied in endemic cretinism; and with regard to the sporadic form, the reports are also meagre. Koplik (New York *Medical Journal*, 1898, vol. ii., p. 84), in a female cretin one month of age, found the hæmoglobin ranging from 85 to 53 per cent.; the red blood corpuscles numbered 4,200,000, and the white cells, 10,000. In another case, an infant of nine weeks, presenting a typical cretinoid appearance, the hæmoglobin was 105 per cent., the red corpuscles numbered 3,000,000, and the white cells 13,500. After a short treatment with thyroid gland, the hæmoglobin sank to 55 per cent. In a case reported by Mendel (*Berliner klin. Wochenschrift*, 1896), the red cells were 4,700,000, the white cells 30,000, the differential count showing: polymorphonuclear cells, 58 per cent.; lymphocytes, 33 per cent.; eosinophiles, 5 per cent.; transitional forms, 4 per cent. Osler (*American Journal of the Medical Sciences*, 1893), in one case, found anæmia, leucocytosis, and poikilocytosis; and in another, absence of leucocytosis. Phillips (Transactions of the Clinical Society, 1885) reports finding in one case slight anæmia and no increase in the number of leucocytes. Garré (cited in *Virchow-Hirsch's Jahresbericht*, 1890, 341), in a female cretin of twelve years, found 3,900,000 red corpuscles, 5,730 white, and 63 per cent. hæmoglobin. In a female cretin twenty-six years old, Routh (Proceedings of the Medical Society of London, 1884, vol. vii., p. 309) found the red cells 86 per cent. of the normal; the hæmoglobin, 77 per cent.; and the relation of the white to the red cells as 1 to 250, showing a decided leucocytosis. From these blood studies, it is apparent that cretinism—at least, the sporadic form—is accompanied by anæmia, manifesting itself in a decided reduction of the red corpuscles and a diminution in the hæmoglobin; sometimes the red corpuscles present alterations in form. The leucocytes seem to be increased in the majority of cases, without any noteworthy alteration in the proportion of the different elements; in some instances, however, there is no leucocytosis. A thorough study of the blood—both of its cellular and of its liquid elements—is a distinct desideratum.

Digestive Tract.—The drooling of saliva and the thick, protuberant tongue have been mentioned. The appetite of the cretin is usually voracious, and he bolts his food. Constipation is generally present. In extreme types of the disease the bowels are moved involuntarily. In the terminal stages diarrhœa sets in, and may be the cause of death.

Genito-urinary Tract.—The sexual sense is usually absent. Puberty is rarely attained; and if so, not before the age of twenty-five, and sometimes as late as forty. Menstruation, if it occurs at all, is scanty and irregular. Cretins are generally sterile. The size of the external genitalia varies; as a rule, they are infantile; exceptionally, as already mentioned, very large. The urine is normal, but small in amount. In one case Ord (*Lancet*, 1893, vol. ii., p. 1113) estimated the quantity of urea, and found it to be 0.4 per cent. Urinary incontinence is the rule in typical cretins.

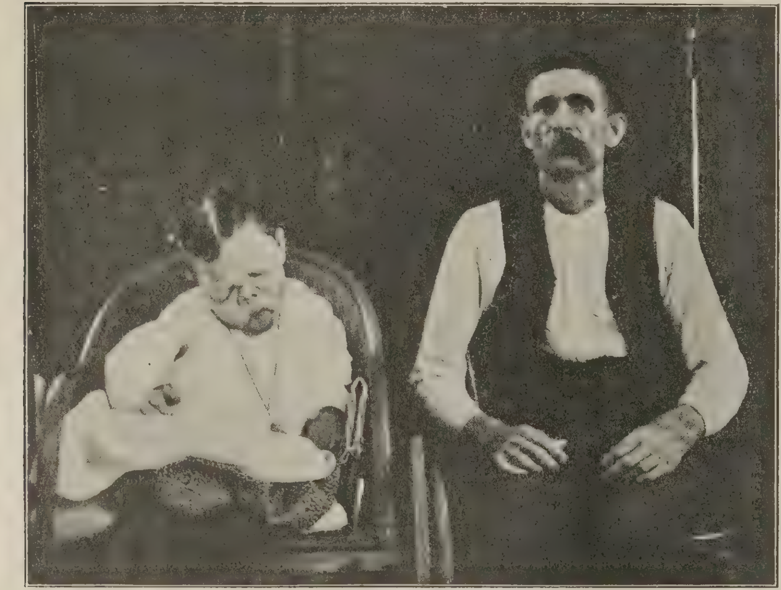

FIG. 2341.—Bartine Mills, a Cretin, about Thirty-three Years Old, formerly in the Philadelphia Hospital. The man beside him was his voluntary caretaker for many years.

B. MOTOR PHENOMENA.—On account of the short legs and large bodies, the gait of cretins is of a peculiar, grotesque, waddling character. Many can progress only by pushing a chair; some cannot even stand. The use of the hands for delicate movements is limited in varying degrees. Often the cretin cannot even feed himself. Regarding the reflexes, the statements in the literature differ considerably. Some have found the tendon reflexes normal; others, the knee jerks increased, and the abdominal, cremasteric, and other superficial reflexes, unaltered. Mayer (*Revue médicale de la Suisse romande*, 1883, 523) found a diminution in the faradic excitability of the muscles.

C. SENSORY PHENOMENA.—All the special senses are blunted, particularly that of hearing, complete deafness being a common feature. Some have attributed the low intelligence in part to this deafness. As to its cause, Wagner (*loc. cit.*) suggests that it is due to a myxœdematous swelling of the mucous membrane of the middle ear.

Hitchmann (*Wiener klin. Wochenschrift*, 1898, 655) has made a study of the eye conditions in 58 cretins. Lesions of that organ were, on the whole, rare. He found epicanthus in 12 and myxœdema of the lids in 56. Chronic catarrhal conjunctivitis was common, and was either an accidental condition, or due to disturbance of the tear duct. Eczema of the lids was frequent. Strabismus was found in but 1 case, senile cataract in 2, and posterior capsular cataract—due to prolapse of the retina—in 1. The retina was normal in 42. There was conus, with a downward axis, in 5 cases, which is a high percentage, as ordinarily this is found but 27 times in 1,000 cases. In one case there was beginning gray degeneration; and in 2, increased pigmentation of the choroid and retina. Nystagmus is sometimes present.

Touch, pain, and temperature sense, like the more highly specialized functions, are also greatly dulled.

D. PSYCHIC PHENOMENA.—I have already stated that cretinism presents all gradations from the most profound amentia and idiocy to mere feeble-mindedness, or even to a fair state of mentality. The majority of cretins are dull, apathetic, silent, unteachable, and incapable of work, and have to be cared for like infants. A few, particularly in endemic cretinism, are able to do light tasks, run errands, etc. Cretins, as a rule, are good-natured but jealous, and are not emotional; at times, however, they have violent outbursts of animal fury, or pass into states of deep depression. In rare instances, they present delusions or are maniacal; and Kraepelin refers to one case in which paresis existed. Convulsions have also been observed. In exceptional instances some one faculty will be extraordinarily developed, as, *e.g.*, the musical memory.

PATHOLOGICAL ANATOMY.—The general characters of the skin, hair, and nails have been described. A peculiar feature to which I might again allude is the gelatinous infiltration of the skin (cachexia pachydermica), which is particularly marked in sporadic cretinism. According to Beach, it is due to an excess of mucin in the subcutaneous tissue. In nearly all autopsies an absence of subcutaneous fat has been noticeable. Fatty tumors are found above the clavicles in sporadic cretinism.

With regard to the skeleton, I have already spoken of the shortening of the bones and the peculiar external features of the skull. The cause of the skeletal characteristics has been a subject of much dispute, but it is now proved that the fundamental defect is a delayed ossification of the cartilages. There is a retardation in the formation and growth of the centres of ossification, in the transformation of the epiphyses into bone, and in the disappearance of the epiphyseal discs. Eventually, if the individual lives long enough, ossification may be accomplished; but it is common to find, as did Dolega ("Beiträge zur pathol. Anatomie u. allgem. Pathologie," 1890, vol. ix., p. 488), in a cretin twenty-eight years of age, that the sutures remain open and that the epiphyses persist in their cartilaginous state. These facts also explain why cretins may continue to grow until the third or fourth decade of life.

Periosteal osteogenesis shows no constant characters; it may be normal, or it may be excessive. Sometimes there is a projection of the periosteum between the epiphysis and diaphysis, such as was observed in Dolega's case, but this is not the rule. Little is known of the condition of the bone marrow. In the only case in which it is mentioned—that of Langhans (*Virchow's Archiv*, 1892, 128)—the marrow was fatty. The case was that of a cretin fourteen months old.

In two fœtuses presenting cretinoid characteristics, Virchow ("Gesammelte Abhandlungen," 1856, 969; also in Verhand. d. phys.-med. Gesellschaft, Würzburg, 1856, 199) found synostosis of the spheno-occipital sutures—of the so-called os tribasilare—and concluded that this was an important feature in cretinism; one probably responsible for the arrest of growth in the other parts of the skeleton. Normally the sutures of the os tribasilare do not disappear until the twelfth or thirteenth year. There is, however, a general belief among authorities at the present day that the disease found in the fœtuses described by Virchow was not a form of cretinism, but a condition somewhat analogous, yet different in its essence, known as *chondrodystrophia fœtalis*, about which more will be said later. In true cretins there is no premature ossification of the sphenobasilar sutures.

The foramina for the cranial nerves and blood-vessels are often small, including the foramen magnum; sometimes, however, they—especially the latter—may be of normal size. Wormian bones are frequently present along the sutures.

In shape the skull, as has been stated, may be either dolichocephalic or brachycephalic. Shortening of its base is one of the most constant features of the cretinic skull. The root of the nose is depressed and prognathism is marked. Allen (New York *Medical Journal*, February 2d, 1895), in a supposedly cretinic skull, found projection of the occiput, and such a union of the parietals with that bone that a conspicuous depression was formed between them, giving rise to a shape of the head called "cat head."

Histologically the osseous changes are but little known. They can be satisfactorily studied only in juvenile cretins, and autopsies upon them are rare. Langhans (*loc. cit.*) found that in his case the cartilage cells were small and spindle-shaped; in places they were abnormally disposed, being longitudinal to the axis of the rows of cells. Sometimes, also, the rows were interrupted. The marrow spaces showed irregularities, being often very large and widely separated in the youngest portions of the bones, and exhibiting shortening of the bony trabeculæ.

The Brain.—An interesting pathological change is enlargement of the pituitary body, which, however, is not constant. It was noted by Boyce and Beadles (*Journal of Pathology and Bacteriology*, 1893) and by Packard and Hand (*American Journal of the Medical Sciences*, September, 1901). Langhans (*loc. cit.*) found the brain and cord normal, but in the peripheral nerves he observed dilatation of the lymph spaces of the endoneurium and perineurium. The dilated spaces, besides having fine fibrillæ, contained unilocular and multilocular vesicular cells, which seemed to have originated from the endoneurium. There were also peculiar cylindrical or spindle-shaped, solid structures, probably the result of degeneration of the connective tissue.

Thyroid Gland.—The condition of the thyroid gland, to which allusion has been made upon page 393, is of great interest. In sporadic cretinism it is usually absent; when present it is small and atrophic. In such cases the acini are smaller than normally, are devoid of colloid, and often are surrounded by thick bands of fibrous tissue. The blood-vessels, as in the case of Packard and Hand (*loc. cit.*), may show advanced calcareous infiltration of their walls. In endemic cretinism the gland is usually goitrous; sometimes, however, the thyroid is not demonstrable in the neck, but at autopsy a retrosternal goitre or one behind the sterno-cleido-mastoid muscle may be found.

The enlargement of the tongue is usually due to a lymphangiomatous condition of the organ. The viscera, in general, show no characteristic changes. Beach found an increase in the fibrous tissue; and in a case examined by myself the liver was the seat of an enormous number of cavernous angiomata and the hepatic cells were deeply pigmented.

Differential Diagnosis.—But little need be said regarding the differential diagnosis of cretinism. The endemic form usually presents no difficulties; and the sporadic in its fully developed state is also easily recognized. Occasionally it is necessary to distinguish between cretinism and *dwarfism* (nanosomia). In border-line cases the distinction may be impossible; but ordinarily we find that the dwarf does not present the typical skeletal changes nor the myxœdematous condition of the skin. There are likewise no real deformities: the large tongue is absent; and the psychic defects, so prominent in cretins, are not a feature of dwarfism. It may be difficult to distinguish between cretinism and that form of idiocy known as *Mongolian idiocy*. There are, however, mental differences that are of help in the diagnosis. The cretin is dull and apathetic; the Mongolian idiot, though stupid, has a smiling countenance, and is more or less vivacious and observant. The œdematous condition of the skin and the fatty tumors are also absent.

Under the term *infantilism*, several writers have described a condition of under-development, the individual retaining the characteristics of childhood at a period when these should have disappeared. The secondary sexual characters in particular fail to develop. Infantilism may be, and usually is, general, but according to Hertoghe ("Die Rolle der Schilddrüse bei Stillstand und Hemmung des Wachstums und der Entwicklung," from the French by Spiegelberg, Munich, 1900), it may affect single features, as the voice, the hair, the genitalia, etc. Brissaud considers infantilism an attenuated form of cretinism.

A few words must be bestowed upon the subject of so-called *fœtal rickets*, which by some is considered a form of fœtal cretinism. Few diseases are honored with so many high-sounding names as this. Besides being called fœtal rickets, it is known as cretinoid dysplasia, pseudorhachitism, chrondritis fœtalis, micromelia chondromalacica, achondroplasia, and chondrodystrophia fœtalis. Without going into the details of the affection, which are out of place in the present article, the following statements may be made:

1. The disease is not a form of rickets.

2. It has very little in common with cretinism, differing from the latter in certain essential points:

(*a*) In its period of development: it begins during fœtal life, and the child is generally still-born or dies early. Cretinism rarely begins before from the fifth to the eighth month.

(*b*) The thyroid gland is usually normal.

(*c*) It may occur anywhere, and is not more frequent in the foci of endemic cretinism than in other places.

(*d*) Although the osseous changes present no fundamental difference, there is in chondrodystrophia a sclerosis of the diaphysis which is absent in cretinism.

3. The essential feature of chondrodystrophia fœtalis is a disturbance in the development of the primordial cartilage, characterized by irregular growth of the cartilage cells with defective formation of the cellular rows. Regarding the cellular proliferation itself, it may be deficient, the cells being spindle-shaped in their hyaline matrix, or it may be excessive, or the cells may form groups lying in a soft, glassy matrix. These three types of abnormalities correspond with three types of the disease: chondrodystrophia hypoplastica, chondrodystrophia hyperplastica, and chondrodystrophia malacica.

4. Periosteal osteogenesis is not, as a rule, disturbed. Occasionally it is in excess of the normal.

5. An almost constant feature is the penetration of a periosteal process between the epiphysis and the diaphysis.

6. There is a sclerosis of the marrow, especially of the ends of the bones.

7. Ossification of the sutures of the os tribasilare is common, but not constant.

8. The dystrophy leads to a stunting of the growth, particularly of the lower limbs; hence the middle of the body is not at the umbilicus, but much higher—near the ensiform cartilage.

It is not impossible, however, that chondrodystrophia, although anatomically differing from cretinism, may like the latter be due to hypothyroidism.

Treatment.—The treatment of endemic cretinism is primarily a matter of broad public hygiene and sanitation. As the drinking-water is chiefly at fault, the first effort should be directed to its improvement. Whenever possible, water should be secured from a goitre-free district, the advantages accruing from such a change being truly remarkable. To one famous instance of the kind—that of Bozel—I have referred on page 391. When an entirely new water supply is unobtainable, an attempt should be made—of course, this is then not a matter for municipal performance, but of household initiative—to provide cistern water, which, it has been shown, is not goitrogenic, and, hence, not cretinogenic. Sedimentation of the water seems also to rob it, to a large extent, of its noxious properties; but boiling is the surest way to render it innocuous. In addition to giving attention to the water supply, amelioration of the general social conditions of the afflicted community must be sought, by preventing intermarriage, diversifying the industries, shortening the hours of work, improving the food supply, widening the streets, and modernizing the sewage system.

In sporadic cretinism remarkable results have been achieved by the so-called substitution treatment, *i.e.*, the substitution for the deficiency in the activity of the thyroid gland of either the gland itself, obtained from animals, or preparations made from it. It is unnecessary to dwell upon the development of this treatment, although it forms an interesting chapter in the history of medicine. The father of it, as at present practised, is G. R. Murray, of Newcastle-on-Tyne; although the value of the gland in the treatment of conditions dependent upon absence or disease of the thyroid body had previously been recognized both by Bircher and by Horsley. They, however, had recommended the implantation of the gland—a method not devoid of danger. At the present day numerous preparations of the thyroid are on the market. Some represent the gland in a dried state—the so-called desiccated thyroid; others are glycerin or ethereal extracts in liquid or solid form. As a rule, the gland from the sheep or the calf is employed, but that of the hog also seems to be efficacious. Attempts have been made to isolate the active principle and to use it instead of the extract or the gland itself. Different investigators, however, have isolated different substances, each claiming that his is the active principle; thus, there are Baumann's thyroiodin, Notkin's thyreoprotein, Fränkel's thyroantitoxin, and Hutchinson's colloid. The active principle seems to contain iodine.

The dose of thyroid is more or less arbitrary and varies with the preparation. It is well to begin with small doses (for example, a minim of the liquid or a grain (0.06 gram) of the solid extract nightly), increasing the dose with care. The younger the cretin, the more brilliant are the results; but there is no period, except, perhaps, extreme old age, at which it is not wise and proper to make a trial of the remedy.

Under the treatment a wonderful change comes over the entire system of the individual. There is a growth in height and a diminution in the general bulk of the body; a disappearance of the œdema of the skin, of the swelling of the tongue, and of the fatty tumors; a rise in body temperature; an improvement in the condition of the bowels; and a very striking increase in the intelligence. There is in the beginning, as pointed out by Thomson (*British Medical Jonrnal*, 1893, vol. ii., p. 677), a slight tendency to muscular debility, connected with the tremendous change in bodily metabolism; but this soon disappears.

If the thyroid medication is too active, symptoms of intoxication—so-called hyperthyroidism—may develop. These are tachycardia, pains in the limbs and elsewhere, slight fever, and diarrhœa.

Under thyroid treatment the diet should receive some attention. The use of meat should be restricted, and the food should be largely vegetarian in character.

A number of cretins that were under thyroid treatment have succumbed with astonishing rapidity to infectious diseases, such as diphtheria, typhoid fever, etc. Whether the thyroid medication had in any way lessened the patients' resistance to these is a fair question, but one which cannot as yet be definitely answered. The benefits obtained from the treatment so far outweigh any possible disadvantages that the latter need scarcely be given a thought.

In order that the beneficial effects of the thyroid treatment may not be lost, it is necessary to continue the administration of the drug throughout the patient's life. The lowest efficient dose should be determined, and then kept up uninterruptedly.

Specific medication with thyroid gland, which has been of such signal benefit in sporadic cretinism, has, so far, not met with striking success in the endemic form. The reasons for this are manifold. In the first place, the method has not been tried upon any large scale; secondly, the causes underlying the endemic cretinism continue; and thirdly, the majority of cretins were at a comparatively advanced age when the treatment was begun. It would seem advisable to administer the substance in a more or less routine way, as is done with quinine, for instance, in malarious districts, and thereby to aid the hygienic factors which have been mentioned. In any case the earliest manifestations of the cretinoid condition should be a spur to the use of thyroid preparations. Unfortunately, the state of civilization in cretin and goitre communities is, as a rule, so low that the people are slow to accept benefits, even if they do not actively resist them. To them applies the saying of Goethe: "Die Menschen wollen zu ihrem Glücke gezwungen sein."

I have referred to border-line cases that seem to bridge the chasm between idiocy and cretinism, and between dwarfism and cretinism. In them, as well as in infantilism, it is proper to make a test of thyroid treatment. A beneficial effect is proof that in the given case some of the elements of cretinism were present.

David Riesman.

GOITRE, EXOPHTHALMIC. See the APPENDIX.

GOITRE. (SURGICAL.)—In the treatment of goitre, surgical measures may become necessary, because internal medication has failed to stop the growth of the tumor or to relieve dyspnœa or other severe symptoms; or an operation may be resorted to, merely to free the patient from a disfiguring tumor.

External applications have little effect upon a goitre. The reports of success from the application of iodine in some form or other, or from the use of electricity, have been too few and too scattered to count for much.

Injection.—Many surgeons have reported excellent results from the treatment of goitre by injection, but on the other hand not a few deaths have been reported, so that one should be careful in advocating the use of injections. Since the perfection of the operative treatment, and the greatly diminished mortality of the operations performed for goitre in the last few years, the field for injection has been much limited. There will still be instances, no doubt, in which patients will absolutely refuse an operation, or in which on some other account a surgeon will be justified in injecting a goitre with iodine or iodoform; but such injection should be made with a clear understanding of its danger, and, it is hardly necessary to add, under strict aseptic precautions. Even then there is danger from hemorrhage and embolism.

Besides the tincture of iodine which has been most generally employed for injection, carbolic acid, alcohol, arsenic, and ergotin have been tried, but they are less effective than iodine, and do not decrease the danger of this method of treatment. Iodoform is the only substitute which has found many friends. It should be mixed with ether and olive oil in the proportions of 1 part of iodoform to 7 parts each of ether and oil. When the mixture turns brown it contains free iodine, and should be discarded.

To lessen the risk of hemorrhage, the hollow needle should be separately introduced. When it is seen that no blood escapes from it, the syringe should be attached, and ten or fifteen drops of the chosen mixture slowly injected. The resulting pain is sometimes very great, but lasts only for a few moments. The effect upon the gland is more or less marked according to circumstances. There may be an initial swelling, followed in a few days by more or less shrinking. Usually ten or twenty treatments will be required. These may occur at intervals of three days or more according to the amount of reaction. Parenchymatous goitre is best suited to treatment by injection, and this is the type of the disease which is most benefited by internal remedies. If the treatment is successful, there will in a few days be a distinct shrinking of the gland apparent to the eye and finger, and also capable of demonstration by measurements of the neck.

Operation.—Many operations have been advocated for the relief of goitre. Three of them have proved their worth and may be spoken of as classical. They are partial resection, enucleation, and ligation of the thyroid arteries.

Removal of the whole gland was formerly practised, but has been pretty nearly given up on account of the fact that acute or chronic "cachexia thyreopriva" follows in twenty-five per cent. of the cases. The acute form of this trouble is marked by tetanic symptoms which may terminate in speedy death. In the more chronic form surgical myxœdema develops, and this too may increase in severity till the patient succumbs. Hence total thyroidectomy, except for malignant disease, may be considered an unjustifiable operation. Partial resection is rarely followed by symptoms of tetanus, and when they do occur they are light and usually transitory.

Before any operation is performed upon a goitre, the patient should be prepared with all possible care. The difficulty of carrying out perfect asepsis so near to the mouth, the proximity of the tumor to important vessels and nerves, and above all the risk of sudden and severe hemorrhage, make the operations upon the gland much more serious than they appear at first sight to be. True, the mortality is small when a single surgeon operates upon a long series of patients, Kocher, for example, having reported a mortality of much less than one per cent.; but under ordinary circumstances a mortality of five per cent. may be expected.

Choice of an Anæsthetic.—Some surgeons advocate the use of ether, some of chloroform, and some prefer to use cocaine or some other local anæsthetic. The last plan possesses one advantage, namely, that the patient by speaking can demonstrate that the recurrent laryngeal nerve is not injured. A local anæsthetic should be chosen in cases of goitre accompanied by severe dyspnœa.

Incision.—A transverse incision is now generally preferred, as it well exposes the tumor, and leaves a scar in the direction of the wrinkles of the neck, and therefore not a conspicuous one. In case of a very large or deep-seated swelling, Kocher employs an angular incision, extending transversely on the level of the thyroid cartilage, from the sterno-mastoid muscle to the median line, and then bending downward to the sternum if necessary. This incision avoids the complete division of the sterno-laryngeal muscles.

Partial Resection.—When the skin incision has been made, and all superficial veins have been divided between ligatures, the muscles which lie in the way must be divided or drawn to one side, and the superficial fascia which overlies the true capsule of the gland must be divided and retracted. Beginning then with the upper and lower poles of the gland the surgeon carefully separates it from the surrounding tissues, placing ligatures around arteries and veins, and gradually dislocating the gland—as fast as it is freed—toward the median line. It is very important that every vessel should be clearly seen before it is clamped or ligated. If this rule is followed, the recurrent laryngeal nerve, which is closely associated with the inferior thyroid artery, will not be injured. Sudden hemorrhage should be controlled by compression, not by hasty clamping. The gland is often intimately attached to the trachea, and it is therefore better to leave a small portion of it behind, rather than to risk injury to the nerve by too violent attempts at removal. Hemorrhage from the substance of the gland, either where the isthmus is divided or elsewhere, may be controlled by cauterization or by ligature. The divided muscles are to be sutured. If the wound is deep, it should be drained for a couple of days.

The amount of gland tissue to be left depends a good deal on the shape of the goitre. If only one side of the gland is affected, the other is naturally left. If both sides require removal, enough gland tissue should be left to equal in bulk at least one-fifth of a normal gland. This tissue should be left at the poles of the gland, preferably about the inferior thyroid arteries, so as to reduce the risk of injuring the recurrent laryngeals.

Enucleation.—If a goitre is due to the development of distinct nodules within the thyroid gland, these may be enucleated. The ease with which this procedure may be carried out depends largely on how free these nodules are. Sometimes they may be shelled out from the surrounding gland tissue, almost as readily as non-inflamed tuberculous glands from their fibrous coverings. At other times the enucleation, on account of close attachment of the nodules, becomes virtually a partial resection. In such cases bleeding may be very troublesome, while on account of the depth of the holes which remain infection is more likely to follow in any case of enucleation than in a partial resection. Moreover, recurrence of the goitre is said to be more frequent after enucleation than after partial resection. Previous treatment by injection makes enucleation very difficult. There is little danger of injury to the nerves or jugular veins during enucleation. The skin incision is the same as that for partial resection.

Ligation of the Thyroid Arteries.—By the ligation of the thyroid arteries a certain amount of atrophy of a goitre may be accomplished. The superior artery is easily found through an incision along the median border of the sterno-mastoid muscle. The inferior may also be reached through this incision; but an easier method is to make a transverse incision situated far enough backward to allow the sterno-mastoid muscle to be drawn forward out of the way. The thyroid axis can be reached in this manner, and the inferior thyroid separated and tied near its origin.

Exothyropexy.—Jaboulay and a few other surgeons have succeeded in bringing about atrophy of a goitre by dissecting the enlarged gland sufficiently free to allow it to be brought into the wound, there to remain until healing by granulation shall have taken place—*i.e.*, for from three to eight weeks. Of the first sixty-five patients so operated upon four died, so that the operation is not without danger, and on account of its other obvious disadvantages it has not been generally taken up.

The two operations, therefore, which are most valuable are enucleation and partial resection; the former for isolated cysts and solid tumors, and the latter for diffuse and adherent goitres and all rapidly growing ones, since it best provides against recurrence.

Edward Milton Foote.

GOLD.—So far as determined, the action of gold upon the animal system resembles that of mercury more nearly than that of any other of the well-known heavy metals. Locally, soluble gold salts are powerfully irritant, and, constitutionally, gold compounds affect nutrition. In therapeutic doses they tend, like mercurials, to improve nutritive tone, but in poisonous quantities to derange it, with the development of stomatitis and gastro-enteritis, and, in continued dosage, of emaciation and progressive general enfeeblement. Gold has the common reputation of being a nerve tonic, especially in cases of nervous derangement in the genital apparatus, particularly the ovaries. Therapeutically, it has been used in ovarian inflammation and irritation, in amenorrhœa, in loss of virility, and in various conditions of impaired nerve power, and also as a substitute for, or adjuvant of, mercury in the treatment of constitutional syphilis.

In none of these applications can gold be considered a medicine of first-rate, nor possibly even of second-rate power. The sole compound of gold official in the United States Pharmacopœia is that entitled *Auri et Sodii Chloridum*, Gold and Sodium Chloride. This is "a mixture of equal parts, by weight, of dry gold chloride and sodium chloride" (U. S. P.). The compound is easily obtained by mixing in proper proportion solutions of the two salts and evaporating to dryness. It crystallizes in elongated prisms, but is commonly found as "an orange-yellow powder, odorless, having a saline and metallic taste, and slightly deliquescent in damp air" (U. S. P.). The compound is freely soluble in water, and the solution has a slightly acid reaction. This preparation is locally irritant even to causticity, and constitutionally exerts the virtues of gold as already set forth. The dose is about 0.005 gm. (about gr. $\frac{1}{12}$) three times a day, in lozenge or pill.

Edward Curtis.

GOLDTHREAD.—Coptis. The rhizome of *Coptis trifolia* (L.) Salisb. (fam. *Ranunculaceæ*). This plant is a pretty little evergreen bog-plant, with long, bright-yellow, thread-like rhizomes; bright-green and shining ternate leaves, and white, solitary, star-shaped flowers. It grows rather abundantly in the cold bogs of America, Europe, and Asia. The whole plant is generally collected, although the rhizome is undoubtedly the most efficient part. The description of the plant given above is sufficient for the drug, which has an intensely bitter taste, but no odor. The color, taste, and medicinal value of goldthread are due to a salt of the alkaloid *berberine*, which it contains in considerable quantity. A second alkaloid, *coptine*, is described by Gross as also present, but does not affect the medical properties of the former.

Goldthread is a simple bitter. It is frequently used in the country as a mouth wash for aphthous and herpetic ulcerations, etc. The ordinary dose is 1 to 4 gm. (gr. xv.–lx.).

The root of *Coptis Teeta* Wallich, of Asia, is a classic remedy for sore eyes, and still used in the Orient. Its properties are similar to those of goldthread.

W. P. Bolles.

GONORRHŒA.—Gonorrhœa, blennorrhœa, or clap is a contagious, inflammatory disease of the urethral mucous membrane, of venereal origin, and having as its cause a well-identified micro-organism, the gonococcus of Neisser.

This micro-organism was first isolated by Albert Neisser, in 1879, and has since been indubitably demonstrated to be the pathological principle of gonorrhœa.

It is a somewhat oval micrococcus, usually taking the diplococcic form, the individual coccus not being spherical but flattened on the side toward its neighbor, appearing more like a discoid formation than a true sphere; the individual cocci having, according to Haab, a diameter of 0.4 to 0.6 μ. They form in clusters, never in chains, this being due to the method of division; as a separation in one diameter is followed by the next in a direction perpendicular to the first. In this manner are formed groups or clusters of four, eight, sixteen, etc., and not long chains increasing in length by fission in the same direction. They are usually attached to epithelial cells and pus corpuscles, and are found free in the fluid only when present in great numbers. The gonococcus may be cultivated, probably the best medium for this purpose being hydrocele or chest serum in neutral agar in the proportion of one to three. The medium should always be alkaline in reaction, and kept at a temperature of about 36° C.

The period of incubation of a gonorrhœa, *i.e.*, from the time of inoculation to the appearance of the first symptoms, varies from three to seven days; and though occasionally a somewhat longer period elapses, an incubation extending over more than fourteen days is extremely rare, if it ever occurs.

The attention of the patient is usually first attracted by a slight pricking or itching of the meatus, and on examination he finds the orifice somewhat reddened, the lips may be stuck together, and a drop of viscid or semipurulent fluid squeezed out. The discharge rapidly increases and becomes purulent, and the act of urination gives rise to a certain amount of smarting. At the end of the first or beginning of the second week this discharge appears as a thick, green pus, which flows copiously from the meatus night and day, and so freely as to soil the clothing and genitals of the patient, the color of the discharge changing to a bright yellow on drying. Other symptoms of the inflammatory condition also appear. The meatus and surrounding parts are swollen, and the entire urethra in the pendulous portion is tender on pressure, and may be felt from the outside to be thickened and indurated. Sharp pains occur spontaneously, and are especially severe during erections. These latter are more frequent during the early morning hours in bed, and are extremely distressing to the patient, the penis being curved downward, owing to the diminished elasticity of the urethra (chordee). The urethral mucous membrane is swollen and the stream of urine small and split up. The passage of urine is extremely painful, causing an intense burning along the urethra.

This aggravation of the symptoms usually continues into the third week, the inflammatory process having by this time extended to the bulb of the urethra. In addition to the other symptoms a feeling of weight, heat, and fulness is felt in the perineum. During this inflammatory period the patient also experiences a feeling of general malaise with slight feverishness, which, together with the mental distress, causes him to be greatly depressed.

About the end of the third week, in typical cases of acute anterior gonorrhœa, a rapid improvement occurs. The inflammatory and subjective symptoms diminish; the secretion, though still profuse, becomes thinner, later diminishes in amount, and finally is present only as a small drop in the morning on rising, disappearing entirely about the sixth or seventh week after infection.

While this description may be considered fairly typical, by far the greater number of cases do not end so happily. The inflammatory process overcoming the resistance of the compressor urethræ muscle invades the deeper urethra, and a new set of symptoms develop, while the difficulty of effecting a cure is increased. Owing to the close anatomical relation with the prostate, seminal vesicles, and epididymides, the disease is apt to involve any of these organs and disagreeable complications ensue. At times the invasion of the posterior urethra is acute, and is announced by the desire to urinate frequently and with extreme urgency, which may become exceedingly distressing to the patient. The tenesmus may be almost constant and is not relieved by urination; while a few drops of blood may appear at the end of urination, which always alarms the patient but is of no serious importance. In subacute cases this tenesmus is less constant, being present only when there is a certain amount of urine in the bladder; the patient will experience a sudden desire to urinate and is often unable to avoid wetting his clothing At this time smarting or burning sensations, or lancinating pains, are experienced in the deep urethra, and they are increased by the acts of defecation and micturition. Nocturnal emissions are apt to be frequent, and are accompanied by pain in the deep urethra. These are due to the inflammatory condition of the caput gallinaginis, and are almost positive evidence that the deep urethra has become involved.

The secretion is similar to that of anterior urethritis (muco-purulent). The patient is usually much depressed, complexion sallow, a slight amount of fever is present, and there is loss of appetite with obstinate constipation.

In some cases, however, all these symptoms may be greatly intensified. Not only may the prepuce become œdematous but also the entire body of the penis may undergo enlargement through lymphangitis. At the same time there is likely to be an extremely abundant secretion, sometimes mixed with blood and containing large numbers of gonococci, which are also found in the free fluid. Extreme sexual irritation and chordee are present, and there is fever due to implication of the general system.

On the other hand, the infection may be subacute from the start. The period of incubation and the stage of prodromes last longer, the inflammation is less intense, and general symptoms may be entirely absent. While the secretion always contains pus, it is more gelatinous and does not become more than muco-purulent in these cases. Gonococci are present usually in the flat epithelial cells. This condition is extremely insidious and is almost certain to involve the posterior urethra, causing chronic posterior urethritis and prostatitis.

Diagnosis.—The history of a definite exposure, a period of incubation, together with the subjective symptoms, render the diagnosis of a gonorrhœal urethritis comparatively easy. At the same time there exist several forms of urethral inflammation which closely resemble it, particularly at the outset; so that it becomes exceedingly important, as regards both the prognosis and the treatment, to determine definitely the true character of the disease as early as possible. The true nature of the disease can be determined by the presence or absence of the gonococcus in the secretions, by means of the microscope.

An examination of a fresh specimen of gonorrhœal pus, under a high-power oil-immersion lens, will demonstrate the presence of gonococci in some of the pus and epithelial cells in the form of small clusters of minute refractive bodies having movements of oscillation and rotation; but in order to examine these satisfactorily the use of some staining agent becomes necessary. Fortunately, the gonococcus has a well-marked affinity for all of the basic aniline dyes, and is very easily stained with simple solutions of fuchsin, methyl violet, gentian violet, or methyl blue.

A good working method is to place a small drop of the suspected pus on a clean microscopic slide, and with another slide spread this out into a thin film as evenly as possible. This is allowed to dry thoroughly, and is then covered with a strong solution of any basic aniline color which is allowed to remain for about one minute, when it is washed off with cold water and a thin cover-glass placed over the stained specimen, which can be immediately examined under the microscope, or may be mounted in Canada balsam as a permanent specimen.

The microscope should be provided with a high-power lens (one-twelfth oil immersion) and the Abbe condenser.

A method of double staining is recommended by Weiss; this is sometimes useful, as it colors the microbes in a different manner from the neighboring tissues. A saturated solution of fuchsin and thionin and a two-per-cent. solution of carbolic acid in water are mixed in the proportion of one to four. The specimen is stained with this for half a minute and then rinsed with water. The gonococci appear blue, the protoplasm of the pus cells red, the nuclei bluish-red, the epithelia deep red, and their nuclei reddish-blue.

As the gonococcus is closely simulated by several other micro-organisms, it is sometimes necessary to differentiate it from these. Perhaps the easiest way of accomplishing this is by means of the staining method of Gram, which depends on the fact that gonococci do not stain with iodine. Heiman gives the following method of making the Gram test: "To 10 c.c. of water add 2 c.c. of aniline oil, shake well, and filter through moist filter paper. To the clear aniline water obtained add 1 c.c. of ninety-seven-per-cent. alcohol and 1 c.c. of a concentrated alcoholic gentian-violet solution. This is about the quantity required for ordinary staining. After passing the cover-glass quickly through the flame, it is then placed in this solution for from two to three minutes. Gram next states that the cover-glass may be washed in alcohol or not, as preferred. I prefer to drain off the excess on filter paper without washing in alcohol. The cover-glass is then placed for five minutes in Gram's solution of iodine, which consists of iodine, 1 part; iodide of potassium, 2 parts; water, 300 parts; immediately afterward it is to be placed in alcohol (97 per cent.) in order to wash out all the coloring matter. It is sometimes advisable to renew the alcohol.

"Now wash the cover-glass well with water and place it in a Bismarck brown solution 1 part, water 5 parts, for one or two minutes, then wash in water and mount in balsam."

The difficulty in regard to this method of differentiation is that it furnishes only proof of a negative character; as by its use the gonococci disappear from the field, while other forms of bacteria resembling them are stained by the iodine and remain.

Prognosis.—The idea so prevalent among the laity, and also unfortunately among a large number of the medical profession, that gonorrhœa is a comparatively unimportant disease and unworthy of very serious consideration, is erroneous in the extreme and cannot be too vigorously combated. For although it rarely results fatally in itself, its complications not infrequently end in sterility, the loss of an important joint, permanent damage to the kidney, or even death itself.

The fact also that the germ may linger for years in the urethra of the unsuspecting victim, eventually to contaminate an innocent wife, bringing in its train those terrible ovarian difficulties which it is so capable of producing, is alone sufficient to class it among the most serious maladies of the human race.

In regard to the duration of the discharge, it is impossible to give a definite prognosis; though it may be said that an individual who recovers in from four to six weeks may be considered exceedingly fortunate.

Treatment.—The discovery of the gonococcus as the etiological factor in gonorrhœa has naturally revolutionized the treatment of the disease, although many of the old remedies which had formerly been used purely empirically possess a bactericidal action and are useful in the modern methods of treatment.

To begin with, the diagnosis of a true gonorrhœa having been made, the patient should be instructed to avoid all factors which affect the disease unfavorably; and he should also be advised in regard to his manner of living during the attack. Most important is it that he should be informed of the contagious properties of the discharge, and of the danger of infecting either his own eyes or the eyes of those with whom he may be brought into familiar contact. This is a very real danger, particularly as patients are apt to grow careless as the disease progresses; indeed, not infrequently both eyes become involved, and sometimes the final result is a total loss of sight. The discharge, usually profuse, should be received on a pledget of absorbent cotton, which may be tucked into the prepuce, or placed in a small bag, which is tied over the penis behind the corona glandis. Many drug stores sell a contrivance known as the gonorrhœal apron, which consists of a small bag about six inches long by four wide, which is fastened about the waist by tapes, and the penis is introduced into it through a hole on the side next to the body. This is filled with absorbent cotton, which is removed and destroyed from time to time as it becomes soiled. A buttoned flap on the front side of the bag allows the penis to be freed for purposes of urination. The soiled cotton should be burned and the hands thoroughly washed with soap and water after touching the penis or soiled cotton.

The most favorable condition for a patient during the acute period is that afforded by rest in bed; but unfortunately this will rarely be submitted to. A patient who could readily be induced to remain in bed with a simple sore throat will stubbornly resist such a course in case of a gonorrhœa which causes him far more inconvenience; he feels that by remaining about he avoids the suspicion of his friends. At all events, all forms of violent exercise should be avoided, as also should sexual excitement, which exerts a most pernicious effect. The swelling and inflammatory condition of the penis may be somewhat obviated by soaking the penis in water as hot as the patient can bear, a procedure which will also relieve the dysuria, the urine being passed while the penis is still immersed. This dysuria, which at times is very distressing, is caused by the dilatation of the inflamed urethra by the stream of urine, and also by the acid character of the urine itself, which acidity should be overcome by drinking copiously of water, or still lithia waters, or of strong lemonade. The addition of citrate of potassium to the water is also beneficial. ℞ Potassii citratis, ℥ i.; aquæ destil., ℥ iv. M. et Sig.: A teaspoonful in a full glass of water four times a day.

If the dysuria be very severe, a drachm of a two-per-cent. solution of cocaine may be injected into the urethra, rubbing it backward to the deeper urethra with the finger underneath the penis, a few minutes before urinating.

In regard to the diet of the patient, it should be simple and easily digested; he should avoid hearty and rich foods, and especially asparagus, tomatoes, and rhubarb. Alcohol should be entirely interdicted in any form, and this prohibition should likewise extend to carbonated waters, ginger ale, and the like.

Smoking in moderation is not injurious.

It is especially important that the bowels should be kept open, and a laxative dose of some of the saline aperients every morning before breakfast is usually beneficial.

In weak and run-down individuals a tonic may be of service; and in such cases the diet should not be reduced.

Internal Remedies.—The employment of internal remedies in the treatment of gonorrhœal urethritis with any idea of affecting the course of the disease is worse than useless; they are frequently productive of digestive disorders which are as serious as is the disease for which they are administered. Among such remedies may be mentioned cubebs, copaiba, sandal-wood oil, oil of turpentine, etc., drugs which have been handed down by an effete empiricism, and the administration of which may be followed by a complete anorexia, vomiting, diarrhœa, cutaneous erythemata, and chronic gastritis. As gonorrhœa is a local process we cannot expect, except in a very roundabout way, to influence its cure by the use of internal remedies. At the same time, certain urinary antiseptics are beneficial in preventing the decomposition of the urine, and also, by rendering the urine antiseptic, they may prevent the extension of the disease backward into the posterior urethra, and they certainly tend to prevent the occurrence of an ascending pyelo-nephritis. Among these drugs may be classed the salicylates, salol, salicylate of soda, etc., likewise methyl blue; and, above all, urotropin, by far the most valuable urinary antiseptic which we at present possess. The dose of this latter drug is from five to ten grains four times a day. This acts by liberating formaldehyde in the urine, and is of great value in all suppurative diseases of the genito-urinary tract.

Local Treatment.—As gonorrhœa is caused by a microorganism which exerts its influence upon a localized portion of the body and cannot in any sense be considered a general disease, local treatment would appear to be the most rational method of dealing with it, and as a matter of fact it has given by far the best clinical results.

One of the oldest and best-known forms of applying this local treatment is by means of urethral injections, and it is the plan which is most frequently chosen, being especially advantageous, as it can be used by the patient himself. The method of using injections is by means of a piston urethral syringe, which should be made of either hard rubber or glass, with a well-fitting piston, a conical point, and a capacity of from two to three drachms.

In administering these injections upon his own person the patient should first fill the syringe by immersing the point in the fluid and drawing up the piston, all the air being excluded by holding the syringe with the point upward and gently pressing upon the piston until the fluid oozes out. The penis should be held in the left hand with the glans between the forefinger and the thumb, which support it from beneath so that when they are brought together the meatus is compressed and the injected fluid is held in the urethra as long as is desired, after the removal of the syringe. The syringe should be held between the thumb and middle finger of the right hand, while the forefinger manipulates the piston. The conical point is inserted into the meatus and wedged sufficiently firmly to prevent the escape of fluid alongside the syringe, the piston being pressed steadily home until the urethra is fully distended. The thumb and finger of the left hand then compress the meatus, retaining the fluid in the urethra.

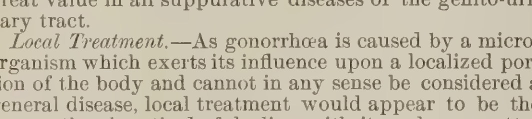

FIG. 2342.—Piston Urethral Syringe.

The patient should always urinate just before injecting, to prevent the discharge being washed backward by the injection as well as to present a clean surface for the medicated fluid to act upon.

The necessary essentials of a remedial solution suitable for use in such injections are that it should contain some antiseptic capable of destroying the gonococcus, but not of sufficient strength to injure the mucous membrane. It should be composed of ingredients which are completely soluble and should not be a mixture containing powders which may clog up the ducts of the urethral glands and so cause the formation of small follicular abscesses. It is desirable that the fluid injected should also have an astringent action and should not be of sufficient strength to cause the patient undue suffering.

In acute inflammations only very mild antiseptic injections should be used, but they should be administered more frequently than is necessary after the discharge has become chronic.

As every known substance has been used at one time or another as the basis of an infallible urethral injection, it is possible here to indicate only a few of the medicaments which have proved serviceable in my hands:

Potassium permanganate in aqueous solution varying in strength from 1 to 4,000 to 1 to 1,000; nitrate of silver of the same strength; the bichloride of mercury, 1 to 30,000, and, finally, the dioxide of hydrogen, 1 to 4.

Comparatively recently a new set of silver salts have been produced which have proved exceedingly valuable, possessing a marked bactericidal action and good penetrating power, and at the same time causing less pain than the silver nitrate. These are: protargol in watery solution of 0.5 to 2 per cent.; albargin, .05 to 0.2 per cent; argentamin, argonin, icthargol, and others which have given exceedingly good results.

In the latter stages of the disease when the discharge has become watery and the gonococci have disappeared, injections of a purely astringent character may prove of service. The sulphates or acetates of lead, zinc, or aluminum, or the vegetable astringents, hydrastis, krameria, rose-water, etc., may be used alone or in combination. The injection Brou, which has acquired a wide reputation among the laity, will serve as a type of this class of injection; it has the following composition:

℞ Zinci sulphat........................ gr. xv.
Plumbi acetat........................ gr. xxx.
Ext. krameriæ fluidæ,
Tinct. opii.................... āā ʒ iij.
Aquæ.................... q.s. ad ℥ vi.
M.

Abortive Injections. In attempts to abort a gonorrhœa at the very outset of the disease, exceedingly strong injections are sometimes used, as silver nitrate gr. xx.–xl. to the ounce. As a rule, if not always, these prove inefficacious; they are exceedingly painful, and are not to be recommended.

When the patient can come to the surgeon at least once a day, the continuous irrigation of the urethra with large quantities of fluid has proved a very successful method of treatment. An irrigator containing from two to four quarts of medicated solution is hung at an elevation; from this leads a rubber tubing, at the end of which is a glass or hard-rubber urethral nozzle. The patient stands up close to the edge of a sink or sits on the edge of a chair with a basin in front of him. The nozzle is pressed into the meatus, and the fluid turned on gradually until the urethra is filled, when a portion of the fluid is allowed to escape by the side of the nozzle, and circulation through the urethra is kept up in this way until the irrigator is emptied. A good form of nozzle for this purpose is known as Kiefer's, and consists of two hard-rubber tubes which come together in a conical point so that when the nozzle is held firmly in the meatus and the urethra is filled, fluid running through one of the tubes will flow out of the other. It must be remembered that the fluid will take the shortest way out, so that after the urethra has been distended with fluid, although the fluid continues to run from the outlet tube, the instrument fails to wash out the urethra unless it is so manipulated that the outlet is occasionally stopped with the finger which allows the urethra to balloon up; then the finger is removed and the fluid again permitted to run from the outlet tube.

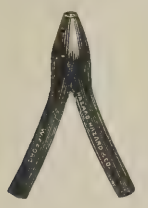

Fig. 2343.—The Kiefer Nozzle.

This tube can also be used to advantage in irrigations in which the bladder is filled without the use of the catheter. The finger being held steadily on the outlet tube, and the patient being requested to relax the sphincter muscles, the fluid will in most instances readily flow back into the bladder. This procedure should not be insisted upon too strongly. If the sphincter resists very forcibly, too much pressure should not be used, but frequently after one or two trials the surgeon will experience no difficulty in filling the bladder with ease in this manner in patients in whom at first it was found impossible to wash out the bladder in this way. The solutions used in this procedure are similar to those used in urethral injections, viz., the permanganate of potassium (from 1 to 6,000 to 1 to 1,000), nitrate of silver, bichloride of mercury, protargol, etc.

Posterior Urethritis.—While this has been considered one of the complications of gonorrhœa, it occurs so frequently that it may be said practically to constitute a constant symptom of the disease. At about the end of the third week the patient experiences a sense of heat and heaviness in the perineal region with an increase in the frequency of urination; it may be necessary to urinate every few minutes, and the act is often associated with considerable pain and occasionally with the passage of a few drops of blood. There is usually considerable urgency, the patient having to urinate instantly when the desire seizes him, without previous warning. Erections and painful nocturnal emissions are apt to occur; they are caused by the irritation of the inflammatory process.

On the other hand, the invasion of the posterior urethra may be exceedingly insidious and give almost no symptoms of its occurrence. In some cases a rectal examination will show a tenderness over the posterior urethra without prostatic enlargement.

To ascertain definitely whether the posterior urethra has become involved, perhaps the best method is one devised by Sir Henry Thompson, and known as the "two-glass test." In this test the first portion of the urine is passed into a clean glass, and the second into another. The compressor urethræ muscle being stronger than the internal sphincter of the bladder, the pus resulting from a suppurative inflammation in the posterior urethra, which lies between the two, is unable to overcome the firm resistance of the compressor, and therefore flows backward into the bladder and contaminates the urine within it, so that if anterior urethritis alone exists, the first portion of the urine will be cloudy, owing to the fact that it contains the washings of the anterior urethra, whereas the second portion will be clear, the first portion having washed the urethra clean. In posterior urethritis, however, both portions of the urine will be cloudy, because the pus formed in the posterior urethra has flowed back into the bladder and clouded the urine contained in it. Unless suppuration of the bladder or kidneys exists, this test is entirely satisfactory.

When posterior urethritis develops the irrigations should be allowed to go back into the bladder. The intense pain and frequency of urination may be controlled by suppositories of opium, and by an occasional local application of the nitrate of silver. A few drops of a solution of from five to ten grains to the ounce being introduced by means of Ultzmann's syringe, will be found exceedingly useful in stopping the tenesmus, or a two-per-cent. solution of protargol may be introduced in the same manner. To control the temporary increase in the tenesmus an injection of ten minims of a four-per cent. cocaine solution will often be found very effective.

Complications.—As the urethra is in close proximity to various organs, complications occur with a greater or less degree of frequency, and are often much more important and serious in their results than the original inflammation. Lack of space, however, prevents more than a casual mention of these.

Balanitis is an inflammatory condition of the mucous membrane of the glans penis which is apt to occur when the discharge is profuse. The patient should wash the penis three or four times daily with warm water and castile soap, drawing back the prepuce, and he should also allow the organ to soak for some time in an antiseptic solution.

Phimosis, a condition in which the preputial orifice is too small to allow the retraction of the foreskin over the glans, also sometimes occurs, promoting balanitis, which should be treated as before, a syringe with a long point being used to introduce the washes under the prepuce.

Epididymitis.—About fifteen per cent. of all cases of gonorrhœa are complicated by the extension of the inflammatory process to the epididymis; it occurs only after the gonorrhœal process has attacked the posterior urethra. The extension of the disease may be marked by a chill and rise of temperature followed by pain in the testicle and cord, often very severe, and a rapid swelling of the epididymis. This usually remains stationary for several days, and then finally subsides, often leaving, in the head of the epididymis, a nodule which remains permanently. This condition is serious, inasmuch as it frequently blocks the vas deferens, and when it occurs on both sides it may render the victim sterile. During the acute attack the patient should rest in bed, and to this he readily assents. The application of poultices, painting the tumor with a ten-per-cent. solution of silver nitrate, or lightly brushing it with the white-hot cautery, care being taken not to burn the skin, are all useful in quieting the inflammation. The addition of a handful of fine-cut tobacco to the poultices is considered of value by many practitioners.

Folliculitis.—The minute glands of the urethra frequently become inflamed, forming small round tumors which open spontaneously through the skin or occasionally into the urethra. They should be treated by hot applications or by the inunction of mercurial ointment; or, if suppuration occurs, they should be opened and the cavity washed out with an antiseptic and packed with gauze.

Cowperitis.—The glands of Cowper may be infected in the same way, and the treatment is the same as for folliculitis.

Prostatitis.—The prostate gland may also become involved during the course of an acute posterior urethritis. The inflammatory process may be either follicular or diffuse. In follicular prostatitis the diagnosis is exceedingly difficult as the symptoms are identical with those of posterior urethritis. Examination by the rectum usually indicates small points of induration and tenderness on pressure. When the inflammation is diffuse, however, the symptoms are much more characteristic. In addition to the frequency of urination, perineal pain, and tenesmus, there is a feeling of fulness in the rectum, with pain on defecation, and occasionally ribbon-shaped fæces are passed. The finger in the rectum detects a throbbing, hot, tender tumor, the prostate, which may attain the size of an orange. Fever is usually present.

As a rule, resolution takes place under treatment, but suppuration may occur. In the latter event the patient will have a chill and there will be a marked rise of temperature; occasionally, also fluctuation can be felt in the tumor through the rectum. If not treated surgically the abscess may burst into the urethra or the rectum, or through the perineum. At times it will open into both urethra and rectum, leaving the patient with the horrible condition of recto-vesical fistula; or the pus may burrow between the layers of the pelvic fascia, and so cause septicæmia and death. The treatment of this condition is by hot rectal enemata, the application of leeches to the perineum, and hot sitz baths three or four times daily, the vesical tenesmus being relieved and controlled by the use of opium. When suppuration takes place the pus should be evacuated through a perineal incision and drainage established.

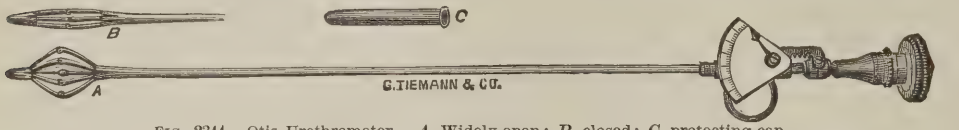

FIG. 2344.—Otis Urethrometer. *A*, Widely open; *B*, closed; *C*, protecting cap.

Vesiculitis.—Inflammation of the seminal vesicles occurs with greater frequency than has until recently been supposed. The symptoms are a feeling of weight and throbbing pain at the neck of the bladder, sexual hyperæsthesia, priapism, and seminal emissions. Exploration by way of the rectum reveals the fact that the vesicles are tender and swollen. Treatment is the same as for prostatitis.

Cystitis.—The gonorrhœal process rarely attacks the bladder proper, the inflammatory process being usually limited to the neck alone. When such an extension does take place, however, the results may be of a serious character. The cystitis, for example, may become chronic, or the inflammation may invade the connective tissue and muscular layers (parenchymatous cystitis), rendering the patient permanently disabled. After the acute symptoms have passed off, the bladder may be washed with only the mildest solutions, as boric acid in saturated solution, nitrate of silver, or potassium permanganate 1 to 6,000. At the same time urotropin should be administered internally.

Pyelitis.—This is a rare complication of gonorrhœa, but occasionally it does occur and may result in the loss of the kidney, though as a rule recovery finally takes place. The diagnosis can be made only with the microscope. Treatment: rest in bed, dry cups, hot fomentations and poultices over the region of the kidney, and the administration of diuretics and urinary antiseptics.

Gonorrhœal Rheumatism.—During the course of a gonorrhœa one or more joints may be affected and should be treated by the usual methods employed in synovitis. In rare instances the peritoneum, pericardium, or other distant organs may be invaded. For a detailed account of this complication consult the article on *Gonorrhœal Arthritis.*

CHRONIC GONORRHŒA.—When the discharge has lasted for a period longer than two months its continuance is due to the presence of some pathological condition in the urethra. As a rule, this will be found in the presence of stricture, a contraction of the meatus, or in localized infiltrated granular patches which fail to heal. The rôle which the gonococcus plays in the production of these infiltrations has been disputed, but in all probability it penetrates the deeper tissues and is the direct cause of the inflammatory deposit which subsequently becomes organized cicatricial tissue. Strictures which encroach so little upon the calibre of the canal as not to interfere in the slightest degree with its physiological functions are at the same time perfectly capable of indefinitely continuing a discharge once established, and are exceedingly apt to be overlooked by the surgeon. In a minority of cases of chronic gonorrhœa no stricture will be found to be present, the discharge being prolonged by the involvement of the sinuses and glands of the urethra, which are much more numerous and of greater depth than is generally recognized; by the presence of small neoplasms; by the involvement of the seminal vesicles; by the general condition of the patient; or, finally, even by a mixed infection of the tubercle bacillus. The discharge may be exceedingly profuse, or it may be so slight as to remain unnoticed by the patient, appearing only in the form of a single drop in the morning, or it may appear only in the form of threads and strings in the urine.

These threads, the so-called "Tripper Faden" of the Germans, consist of separate masses of purulent secretion exuding from the granular patches. Upon being washed out by the stream of urine, these masses are rolled up in the form of threads and appear as such floating in the urine. They consist of transparent cylindrical masses in which corpuscles and a few epithelial cells are embedded. The more compact these fibres appear the more pus they contain, but if they are transparent they consist for the most part of urethral epithelium with but little pus. The more epithelium there is in these threads the nearer the process is to a cure. The threads, which are principally composed of mucus and epithelium, have a tendency to float, while those composed chiefly of pus sink rapidly to the bottom of the glass.

Some authors hold that the location of the lesion can be diagnosed by the form of the threads. If they are short and thread-like, they are supposed to be formed in a gland duct; if long and thick, to arise from the urethra itself; and if short and lumpy, to come from the prostatic urethra. As they are in reality formed by the stream of urine washing out and rolling up into threads the secretion which originally had a flat, plate-like form, it is evident that we can form no satisfactory opinion, simply from their external appearance, as to what portion of the urethra they come from. When the microscope shows the presence of spermatozoa embedded in the substance of the thread, the probability is that it originated in the posterior urethra.

It is very important to locate the position and determine the character of the lesion upon which the continuance of the discharge depends. As has been said before, the most frequent cause is a urethral stricture, the presence of which may be determined by the use of the urethrometer or by means of graduated bulbous bougies.

The presence of areas in which a granulating or ulcerative process is going on, or of a neoplasm, can be definitely determined only by the use of the urethroscope, so that this instrument is exceedingly valuable in the diagnosis as well as the treatment of chronic urethral discharges.

Treatment.—No matter in what portion of the canal the disease may be located, the first indication for successful treatment is to remove all mechanical obstacles which stand in the way of a cure. All pathological narrowings should be divided by means of dilatation and urethrotomy combined, although in recent cases dilatation alone will often prove sufficient.

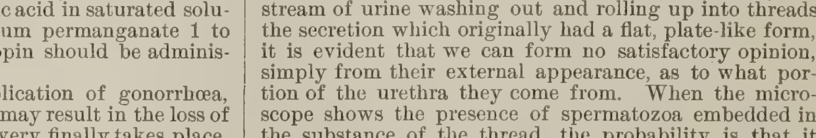

FIG. 2345.—Ultzmann's Syringe.

In the subsequent treatment injections similar to those employed in acute urethritis may be used, but they may be of greater strength and need not be used with so great frequency.

As in most cases of chronic gonorrhœa the posterior urethra is also involved, it will be found necessary to treat the entire urethra. This is best done by means of irrigations, in which the bladder is filled with fluid through a catheter, which is then removed and the patient allowed to eject the fluid in the same manner as if he were urinating; or the bladder may be filled without a catheter by the use of an irrigator and urethral nozzle as described in the treatment of acute posterior urethritis. The solutions best adapted are protargol, one per cent.; nitrate of silver or permanganate of potassium, 1 to 1,000.

When the posterior urethra is alone involved instillations of solutions of the nitrate of silver, of from five to ten per cent. strength, are very useful, from five to fifteen minims being introduced by means of the Ultzmann drop syringe.

A favorite method of treatment by Professor Ultzmann is the daily passage of a sound large enough to fill completely the urethra, the instrument being allowed to remain *in situ* for several minutes. These sounds should not be lubricated with vaseline or other oily substance, but with lubrichondrin, glycerin, or other substance which is soluble in water, as this mode of employing sounds is to be immediately followed by irrigation. In carrying out the latter procedure the patient should first be placed in the recumbent position, and then a short catheter—one that will reach only a short distance into the posterior urethra—should be introduced its full length. The syringe (capacity, 5 or 6 ounces) having previously been filled with the remedial solution, should next be connected with the catheter by means of a bit of soft india-rubber tubing. Then the fluid should be injected slowly into the urethra and on into the bladder. If the latter easily contains a large amount of fluid the syringe may be filled a second and even a third time. It will be known that the catheter is in the correct position if the fluid flows easily into the bladder and does not run out of the catheter when the syringe is removed; for if the instrument extended no farther than to a point in front of the compressor the fluid would flow back along the sides of the catheter and come out at the meatus. When the method described above is carried out successfully, the posterior urethra receives a double washing: first, by the introduction of the fluid through the catheter, which is provided with several slit-like openings instead of a single eye; and secondly, when the patient expels the large amount of fluid which has been introduced into the bladder.

The solutions used by Ultzmann and which are very efficacious are based on an ascending scale. He employs them in the following manner:—

First day, a solution of zinc sulphate, alum, and carbolic acid, each one part, to one thousand parts of water; second day, the same, 1 to 500; third day, permanganate of potassium, 1 to 2,000; fourth day, permanganate of potassium, 1 to 1,500; fifth day, permanganate of potassium, 1 to 1,000; sixth day, nitrate of silver, 1 to 2,000. The silver is strengthened in the same ratio as the permanganate of potassium, not being used in greater strength than 1 to 1,000.

I give this graduated method of Professor Ultzmann which has been standardized by him, and which has proved most serviceable in my hands, although I am inclined at present to substitute some of the later silver preparations for some of the solutions used by him. One of the great advantages of this method is the definite rule of progression, which allows the patient to become used by degrees to the increasing strength of the remedies employed. This rule should not be too closely adhered to, however, and if the patient complains greatly at any time, the progression should be made more gradually.

After one has reached the higher solutions of the silver nitrate, in carrying out the plan just described, it is well to resort to the instillations into the deep urethra as before described. They may be repeated advantageously on every second or third day.

The Urethroscope.—One of the most satisfactory methods of treating the lesions of chronic urethritis is by making direct applications to the diseased urethral mucous membrane by means of the electro-urethroscope. Within the last few years this instrument has been so simplified and improved that it can no longer be regarded as being for the use of the specialist alone, but should form a part of the armamentarium of all those who undertake the treatment of diseases of the urethra.

At the same time a certain amount of practical experience is necessary in order to recognize the various pathological conditions encountered, and this can be acquired only by the actual use of the instrument, as no amount of description can more than indicate the exact appearances of the urethral field.

The tube used should be the largest which will pass the meatus, and occasionally it will be found necessary to divide the latter in order to pass an instrument which will give a satisfactory view. This should be done, if possible, a week or so before the urethroscope is used, so that time is allowed for healing to take place. When this cannot be done it is often feasible rapidly to dilate the meatus with solid sounds sufficiently to allow the passage of the urethroscopic tube without bleeding.

If the anterior urethra alone is to be examined, one of the shorter tubes should be chosen, lubricated for its entire length with lubrichondrin or glycerin, and gently passed on as far as to the bulbo-membranous junction. The tube should be held between the index and middle finger of the right hand below the disc, the thumb pressing firmly on the handle of the obturator to prevent its being displaced. The left hand grasps the glans penis between the index finger and thumb.

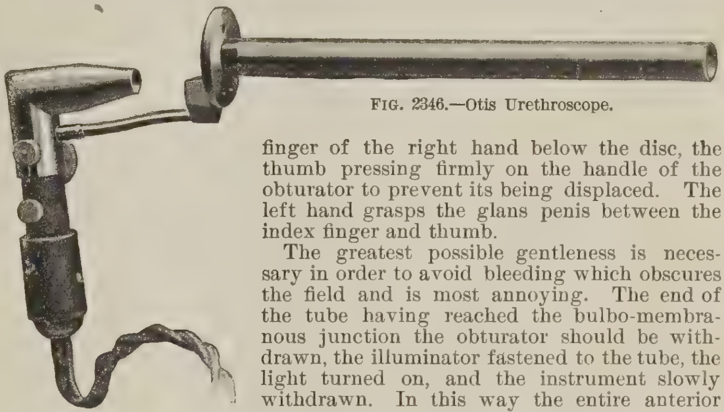

FIG. 2346.—Otis Urethroscope.

The greatest possible gentleness is necessary in order to avoid bleeding which obscures the field and is most annoying. The end of the tube having reached the bulbo-membranous junction the obturator should be withdrawn, the illuminator fastened to the tube, the light turned on, and the instrument slowly withdrawn. In this way the entire anterior urethra may be carefully observed bit by bit. Blood or discharge at any point should be removed with the swab, and applications can be made to any diseased areas which may appear in the field.

The examination of the deep urethra is an exactly similar procedure, except that it is necessary to pass the triangular ligament with a straight instrument, and therefore somewhat greater skill will be needed on the part of the operator.

In conclusion I may state that the urethral mucous membrane is exceedingly delicate and resents any but the most gentle advances, and that it is especially necessary to remember this when contemplating any instrumental procedure. For this reason, moreover, it is not infrequently the case that we see obstinate chronic discharges which owe their continuance to over-treatment, and which would get well if left entirely alone. It is also well to remember that the urethra may become tired of any one form of treatment if too long continued and that a change is frequently necessary if a cure is to be effected. *William K. Otis.*

GONORRHŒAL ARTHRITIS.—(Synonyms: Gonorrhœal Rheumatism; Gonorrhœal Synovitis; Blennorrhagic Rheumatism.) The term "rheumatism," as applied to this disease, is objectionable, implying a relation to ordinary rheumatism which does not exist.

DEFINITION.—Gonorrhœal arthritis is inflammation of a joint or of joints, due to the gonococcus of Neisser.

PATHOLOGY.—Gonorrhœal arthritis is to be regarded as one of the commonest manifestations of a general infection of the circulating medium with the gonococcus or its toxins. Other manifestations are endocarditis, myositis, disease of the tendons and fasciæ, and of the eye. According to Taylor, it is probable that septic absorption in urethritis does not take place until the infection has reached the posterior urethra. The gonococcus has been cultivated from the blood, first, I think, by Hewes in 1894, and later by Welch. Gonorrhœal arthritis, then, always implies infection of the circulating medium.

The joints show varying degrees of inflammatory change. There is first a simple synovitis with more or less fluid—serous or sero-fibrinous. Later the fluid may become purulent. The process tends strongly to extend to the fibrous and ligamentous structures about the joint, resulting in a periarthritis. Adjacent bursæ and tendon sheaths are very commonly involved.

Bacteriological studies, by the microscope and by cultures, give varying results. The gonococcus may be found alone or pus organisms may be found alone—the latter in cases with purulent exudation. The fluid may contain both gonococci and pyogenic microbes, or it may be sterile. It is probable that the gonococcus is always present at first and that there may be a simultaneous or, more often, subsequent infection with pus organisms. In the cases in which no organisms are found, it is probable that the gonococci have early disappeared. In some such cases the arthritis may not be due to gonorrhœa at all. Some cases may be due to the toxins of the disease, without any bacteria, like the joint affection following the use of diphtheria antitoxin. But probably in most cases the gonococcus is at some time present in or about the joint.

As a result of severe and protracted cases fibrous adhesions are prone to result. There may be almost complete fibrous ankylosis. This is especially apt to occur as a result of repeated attacks of arthritis from repeated reinfections of the urethra, or when the joint has been long immobilized. Changes resembling those of chronic rheumatoid arthritis may result. Nearly every joint in the body may be permanently damaged.

Etiology.—Enough has already been said in speaking of pathology to indicate the etiological relationship of the disease to the gonococcus. It is always a sequel of local infection with this organism—usually urethritis. It has also resulted from vulvo-vaginitis in children and from gonorrhœal infection in which no urethritis existed, as in ophthalmia neonatorum.

No age or sex is exempt, but it occurs most commonly in adult males—in other words it is commonest where gonorrhœa is commonest. Exposure to cold and trauma act only, if at all, by increasing susceptibility. Individual susceptibility varies greatly. Some men have it with every new gonorrhœa. Others, the majority, never have it at all. Persons subject to ordinary rheumatism or having the rheumatic diathesis do not show any special susceptibility.

Distribution.—Arthritis occurs in about ten per cent. of all cases of gonorrhœa (Taylor). The commonest site is the knee, and next the ankle, wrist, fingers and toes. While it is commonest in the larger joints any joint may be involved—even the jaw, chondrocostal, intervertebral, sacro-iliac, sterno-clavicular, and crico-arytenoid. In about forty per cent. of the cases but one joint is involved. But it may be polyarticular, and in fact a single attack may involve nearly every joint in the body.

Symptoms.—The disease may begin in almost any stage of gonorrhœa, most commonly about the fourth week. According to Taylor it seldom begins in acute gonorrhœa earlier than the second or third week, when the posterior urethra is involved. It may be delayed for months, till the urethritis has run on into a chronic gleet.

The onset is rapid—beginning with slight pain and stiffness. Premonitory fever and malaise are rarely present. As a rule general symptoms are mild throughout. Fever is slight in most cases. Rarely there is delirium or profound sepsis. Sweating is not a prominent feature. As the case goes on anæmia and debility are marked, especially when there have been unusual pain and confinement.

When the inflammation is at its height the appearance of the joint is quite characteristic. There is much swelling, due to fluid in the joint cavity and to œdema of the surrounding soft parts. Owing to the tendency of adjacent bursæ and tendon sheaths to share in the inflammation the swelling oftens extends up and down the limb for a considerable distance. There is not often great redness and the tenderness is usually less than in ordinary acute rheumatism. So, where the distribution is such that locomotion is not prevented, many cases are treated as hospital out-patients. Pain varies greatly: it may be almost lacking, so that the patient complains mainly of stiffness, or so severe as to prevent sleep and require morphine.

The course of the disease is slow and tedious. Once involved, the joint usually remains so till the case is over—there is no marked tendency to jump about from joint to joint. A large joint seldom recovers in less than from four to six weeks. The acute process may subside and leave a hydro-arthrosis lasting for months in spite of all treatment. In some cases complete resolution may never occur, the joint remaining more or less ankylosed.

In the so-called arthralgic form of gonorrhœal arthritis there occur, in the course of a gonorrhœa, fugitive pains in the joints and muscles, without any active inflammatory process. The symptoms may be very persistent.

When the joint becomes infected with virulent pus bacteria the case becomes like any purulent arthritis. Fortunately this is not common. If prompt surgical relief is not afforded, and there is a general infection, such a case shows the symptoms of pyæmia—chills, irregular fever, progressive asthenia, and death.

Relapses do not occur unless there is a new urethral infection. One attack does not confer immunity. Indeed, some individuals seem to have it nearly every time they get the clap.

Complications.—Bursitis and teno-synovitis are not uncommon. Involvement of the muscles, and of the fasciæ, especially of the palm and sole, sometimes occurs. The eye may be involved by means of organisms or toxins brought by the blood, a condition to be distinguished from the gonorrhœal conjunctivitis due to infection from without. Endocarditis and general infection with the gonococcus or with pus organisms is a very serious complication.

Diagnosis.—Gonorrhœa is common, and so are other forms of arthritis. Therefore even when joint inflammation occurs in the course of a urethritis it does not follow that the disease is gonorrhœal arthritis. The diagnosis can be made with absolute certainty only when the gonococcus is recognized in the fluid from the joint cavity. The distinguishing clinical features of the affection are the tendency to involve one or a small number of joints; its persistent character, long duration, and failure to jump from joint to joint; the usually slight general disturbance, the fusiform character of the swelling from the tendency to invasion of tendon sheaths, and the association with other manifestations of gonorrhœal infection.

Ordinary acute articular rheumatism usually involves many joints, shifting about from one to the other, the first ones recovering as others become involved. There are more elevation of temperature and greater redness, pain, and tenderness than in the gonorrhœal disease, and the bursæ and tendon sheaths are not apt to be invaded. These characters, together with the effects of treatment, explain why it is rarely mistaken long for gonorrhœal arthritis, even when coincident with gonorrhœa.

Long-continued cases may give rise to a suspicion of tuberculosis, especially when the joint in question is the hip. Gout and simple or traumatic synovitis should also be mentioned. In purulent cases it is of little moment whether the disease is the result of gonorrhœa or not, as the course and treatment are identical.

Prognosis.—Complete recovery is the rule. But the disease is an obstinate one and the treatment is not satisfactory. There is often danger of ankylosis, especially when the condition is recurrent. The patient should be warned that a new gonorrhœa is likely to mean a new arthritis, and that each new arthritis is likely to leave the joint in a less perfect condition than before. When the inflammation is purulent and associated with endocarditis from mixed infection with the streptococcus the prognosis is of course unfavorable.

Treatment.—It is of the first importance to remedy, by measures adapted to the individual case, the primary gonorrhœal focus. According to Taylor especial attention should be given to the posterior urethra.

Salicylates and alkalies are of no value in gonorrhœal arthritis. Yet on the chances of an error in diagnosis the writer is of the opinion that in many cases a vigorous trial should be given them—on the principles laid down for ordinary acute rheumatism. Potassium iodide has been much used, but is probably devoid of any specific action. The same may be said of quinine and methylene blue. Probably iron, arsenic and other tonics, together with fresh air and plenty of good food, are the best general measures.

During the acute stage the patient should be kept in bed and the part at rest. If pain is severe it may be relieved by an ice-bag. Immobilization by splints or plaster usually gives great relief. But immobilization should be as brief as possible, owing to the danger of ankylosis. Later on, "baking" the joint in hot, dry air or counter-irritation by means of tincture of iodine, vigorous blistering, or the cautery may hasten resolution. If ankylosis threatens massage and passive motion are indicated after the acute process has subsided.

If the effusion persists the joint may be aspirated with or without the subsequent injection of corrosive sublimate solution 1 to 2,500, carbolic acid 1 to 50, or iodoform emulsion. This should of course be done under the most rigid antiseptic precautions. It may be repeated if necessary. It has given excellent results in competent hands. For suppurative cases prompt and vigorous surgical measures are demanded. *Ralph C. Larrabee.*

GORDON SPRINGS.—Lake County, California. These springs lie in Cobb's valley, about half-way between Calistoga and Lakeport. They are romantically situated in the heart of a mountain and forest region. The climate is very fine. The location is about 3,000 feet above the sea-level. The principal spring flows about 300 gallons of water hourly, having a temperature of 100° F. The waters are sparkling, alkaline, and have antacid and aperient properties. Following is Winslow Anderson's analysis:

One United States Gallon Contains:

Solids.	Grains.
Sodium chloride	20.75
Sodium carbonate	3.19
Sodium sulphate	8.62
Potassium carbonate	.73
Magnesium carbonate	6.14
Magnesium sulphate	10.93
Calcium carbonate	11.16
Calcium sulphate	23.46
Alumina	3.55
Silica	2.27
Organic matter	Trace.
Total solids	90.80

Carbonic acid gas, large excess.

The waters have considerable reputation in chronic albuminuria and in cystitis; they are also valuable in acid dyspepsia. A pleasant resort has been established, and it is worthy of remark that persons suffering from chronic bronchitis, catarrh, asthma, and the early stages of consumption do well at this eyrie among the pines. *James K. Crook.*

GOUT.—The exact nature of gout is still unknown. One might with honesty begin a description of it as Sydenham did more than two hundred years ago: "Either man will think that the nature of gout is wholly mysterious and incomprehensible or that a man like myself who has suffered from it thirty-four years must be of a slow and sluggish disposition not to have discovered something respecting the nature and treatment of a disease so peculiarly his own. Be this as it may, I will give a *bona fide* account of what I know. The difficulties and refinements relating to the disease itself and the methods of its cure, I will leave for time, the guide to truth, to clear up." Numerous hypotheses are described for the consideration of students of the subject, and our knowledge of the malady has greatly increased since Sydenham wrote, but its mystery has not yet been fathomed.

Gout has been recognized as a malady from the earliest times. It was well described by Hippocrates (350 B.C.). Five hundred years later Galen ascribed its origin to noxious substances as "black bile," "blood," or "phlegm" about the joints. He believed the tophi were produced by their consolidation.

In the middle ages, according to the prevailing theory, the disease was believed to originate from "tartar," which was supposed to come from wine that had been drunk and which formed incrustations about the joints, like those found in wine casks. This theory was disproved when Schule (1776) showed that tophi were composed of urates.

Gout has been thought contagious. This was the belief of Boerhaave. Cullen advocated a nervous origin for the malady. In 1848 Garrod's thesis on "The Blood and Urine in Gout, Rheumatism and Bright's Disease" established the existence of an excess of urate of sodium in the blood and ascribed to it a causative relationship to the malady. From that time to near the present a majority of pathologists and clinicians have regarded gout as due to an excess of uric acid in the blood, and they have described those prone to it in its typical or irregular forms as of the uric-acid diathesis.

As our clinical knowledge of gout is comparatively perfect, it seems best, therefore, to describe its symptoms first and to consider its nature, causation, prophylaxis, and treatment later. Cases of gout are clinically placed in three groups: (1) Acute gout; (2) chronic gout; (3) irregular gout.

Acute Gout.—Premonitory symptoms are commonly observed. They are usually those of gastric indigestion, such as flatulence, sourness of the stomach, a feeling of fulness in the epigastrium and constipation, or irritability of temper, restlessness at night, dull headache, or melancholia. Twinges of pain in the small joints of the feet and toes are often felt for several days before the acute attack occurs.

Acute gout commonly makes its onset in the early morning hours, the patient awakening with intense pain in the metatarso-phalangeal joint of one big toe, oftenest the right. The pain is severe but becomes more intense during the next two or three nights. It is described as a sensation of squeezing. The feeling is as if the toe were in a vice. Throbbing, burning, and sometimes a lancinating pain, are also complained of. At first the veins about the affected part are unusually prominent. Soon, however, the joint swells uniformly and the skin becomes slightly red and glossy. It is exquisitely tender, so that even the weight of the bed-clothing is a source of increasing distress. The slightest motion of the joint also elicits a cry of anguish from the sufferer. Bodily temperature is increased, often only a little, sometimes to 102° or 103° F.

Often such attacks of podagra begin with a chill, or at least with chilly sensations and rise of temperature. After daybreak the pain subsides, fever lessens, and the patient may doze for a time. Although the intense pain is less, the swelling remains in the affected joint and it is kept immobile because of the pain which movements of it provoke. Toward night the symptoms again become more intense. So long as the attack lasts each night is made sleepless by an aggravation of the characteristic symptoms of the malady. Patients therefore become greatly wearied, even much debilitated by sleeplessness, suffering, and inability to maintain good nutrition, for appetite is lacking and digestion is impaired. An attack such as this lasts for from one to several weeks. Gradually the symptoms grow less intense, the swelling of the joint subsides, mobility returns, and often after an attack a patient will feel unusually well. Sometimes during convalescence the skin over the joint which has been affected peels off.

Attacks are frequently prolonged by one great toe after the other being involved or by other joints than those of the toes being attacked. Although the large toes are commonly first involved, the fingers, and later the large joints, may be as well.

The urine is frequently concentrated and deposits urates. Traces of albumin or sugar are also sometimes found in it.

Acute gout is apt to occur in the late winter and early spring. It recurs at variable intervals; it may be annually or at longer or shorter periods. Usually after several attacks it begins to recur more and more frequently and the individual's health becomes permanently impaired. It is extremely rare that only one attack occurs in a lifetime.

CHRONIC GOUT.—Chronic gout results from several acute attacks. The joints which have been affected become permanently swollen or deformed by uratic deposits in the fibrous tissue about them, and are commonly stiffened and sometimes permanently immobile. Tophi, as these deposits of urate of sodium are called, are also found upon cartilages, on synovial membranes, and the sheaths of tendons. The cartilages of the ear are affected with especial frequency. Nodules are also formed along the course of tendons on the back of the hands and feet. Uratic deposits within joints where they first take place are invisible and do not always cause noticeable enlargement of them, but rarely last long before the neighboring ligaments are involved. Intracapsular deposits can sometimes be detected by a grating noise produced when the rough surfaces are moved upon one another. When joints are impaired in usefulness the muscles which control them atrophy. In severe cases the skin over the tophi becomes necrotic, sloughs, and exposes the "chalk stones," permitting them to crumble or to be easily removed. This, however, rarely happens until the lesions are so extensive that in spite of the partial removal of a source of stiffness and deformity a renewed usefulness of the joint is impossible. Patients, typifying the severest cases, are helpless invalids and constant sufferers. In mild cases there is some stiffness at all times but there is not complete helplessness. Frequent acute exacerbations increase the pain which these patients suffer. They are accompanied by the usual symptoms of acute gout, and frequently are complicated by uræmia, pleurisy, pericarditis, or other visceral lesions.

The digestive disorders which so often precede and accompany acute attacks are present more or less constantly in chronic cases. Flatulence, acid indigestion, constipation, and gastric discomfort are the commonest symptoms of them. They are associated with headache, neuralgia, lassitude, mental depression, and irritability. Eczema and urticaria are common skin complications. In chronic gout the kidneys are usually involved and gradually become contracted, producing the symptoms which are peculiar to interstitial nephritis. The arteries are also liable to atheromatous changes and the heart to hypertrophy and ultimate enfeeblement.

The digestive and nervous symptoms are aggravated by an inability to take exercise, due to the joint deformities. Pain causes sleeplessness and exhaustion. Indigestion contributes to malnutrition, and it is usual for those who have chronic gout slowly to lose flesh and strength.

In spite of this chronic state of disease, surprising as it may seem, life is often prolonged into the period of old age. Indeed, it is usual for the malady to last for many years. Patients commonly show remarkable mental vigor.

Occasionally in the midst of acute articular gout or acute exacerbations of chronic gout, the acute arthritis suddenly disappears or greatly lessens, but is replaced by visceral complications. Such cases are often described as cases of retrocedent or suppressed gout. The visceral complications may be inflammations or other lesions of the bronchi, lungs, pleura, nasopharynx or larynx, of the stomach, intestines, heart, kidneys, brain, or peripheral nerves.

Epilepsy, delirium, and insanity are rarely a part of the disease. But neuralgias are common. Of these sciatica is the form most frequently observed. Gastralgia is also of frequent occurrence. It is associated with the usual indigestion of the affection. Of all the visceral complications of gout those of the circulatory system and kidneys are the most dangerous. Myocarditis is common. Endocarditis and pericarditis are of less frequent occurrence, but angina pectoris is often seen. Aortitis and aneurisms are other common circulatory affections. Functional irregularity of the heart and tachycardia are disturbances of frequent occurrence. Hypertrophy of the heart muscle is the rule in all chronic cases.

Interstitial nephritis develops sooner or later in those who suffer from chronic gout. It or uræmia growing out of it is a common cause of death. Indeed, fatalities rarely result from uncomplicated gout.

IRREGULAR GOUT.—Irregular gout is difficult to describe and often to recognize with certainty. Some of the viscera or the skin may develop lesions which the gouty are known to be prone to, and their sequence may make a diagnosis possible or their nature may be recognized by reasoning by exclusion. Irregular gout is very much commoner than classical gout. It frequently occurs in the women in families in which acute and chronic gout attacks the men.

In early life urticaria is common in those having a gouty diathesis, or the lithæmic state, and in late life chronic eczema is. Asthma, bronchitis, renal calculus, and diabetes mellitus are other maladies to which these same individuals are liable. Flatulent, acid indigestion and constipation associated with myalgias and neuralgias, with hemicrania or with mental depression or irritability are particularly significant of a tendency to the disease. Hot and itching feet at night and hot and itching eyeballs by day are common symptoms in women. Any of the various visceral lesions already mentioned may develop in those inclined to gout, although podagra or other articular evidence of the ailment may be wanting. Sooner or later the cardio-vascular and renal disorders incident to chronic gout develop in a majority of those who suffer long with irregular gout. Iritis, glaucoma, and hemorrhagic retinitis are common complications of the malady.

Urine.—Between attacks of acute gout the urine may be normal. During an acute attack it is concentrated and diminished in amount. On standing, a pink or "brick-dust" sediment is thrown down. Although concentrated a diminished amount of uric acid is usually voided. When convalescence is established a moderate excess of this ingredient may be eliminated. In chronic gout the urine is commonly copious, of low specific gravity, and contains a diminished quantity of uric acid. However, not infrequently gouty men are found who habitually void normal quantities of uric acid. When interstitial nephritis exists the urine, besides being copious and of low specific gravity, contains small amounts of albumin and hyaline and fine granular casts.

Blood.—During acute attacks and while the disease is chronic an excess of urates can be demonstrated in the blood. But in the early stages of the disease, during the intervals between attacks, the blood is quite normal. Uric acid can be demonstrated in the serum of those who have gout by adding ten or twelve drops of acetic acid to a few cubic centimetres of blood or of serum obtained from a blister produced upon the skin. A thread must be immersed in this mixture of serum and acid for twenty-four or forty-eight hours, when it will be found to be covered with crystals of uric acid.

DIAGNOSIS.—A diagnosis of acute gout can usually be made with ease, so distinct and characteristic are the symptoms. However, I have known a first attack to be mistaken for a trauma. But the development of symptoms characteristic of the course of the malady will correct such an error. It is rarely confused with acute articular rheumatism. In this last disease the large joints or numerous joints are involved from the beginning, the temperature is usually higher, and the skin is bathed with perspiration.

The presence of tophi makes it possible to distinguish chronic gout from chronic rheumatism and other forms of chronic arthritis. The history of numerous acute attacks is also a help to a diagnosis.

Irregular gout is more difficult to recognize, but attention to the symptoms described above and to their interchangeability in different attacks in the same person and connection, commonly with characteristic digestive disturbances, makes a diagnosis possible.

ANATOMICAL CHANGES.—The evidences of inflammation in the tissues involved are not different from those of other forms of inflammation, except that deposits of urates are observed with them. At first these deposits occur in the articular cartilages. They are seen as white dots or lines beneath the surface. Later they increase in size, coalesce, and produce destruction of the surface. The cartilages and capsules of joints, the fibrous tissue in bursæ, tendons, the periosteum, and the auricles are the structures in which tophi are oftenest found. The aorta is frequently thickened in spots by uratic deposits, as are sometimes the coronary arteries. An increase of fibrous tissue in the myocardium is also occasionally observable. The kidneys are commonly contracted and exhibit the conditions peculiar to interstitial nephritis. Lines of urates can be seen in many cases, both in the cortex and medullary portions of these organs. These deposits occur in parallel lines, partly in the uriniferous tubules, but mainly in the interstitial tissue between them. The liver is sometimes found in a condition of slight interstitial hyperplasia.

Theories as to Nature.—Although a clinical knowledge of gout has been possessed by physicians since the earliest times, its exact nature and cause are to-day unknown. A variety of hypothetical explanations have been offered, but none of them has as yet been established as correct. Garrod's theory has for many years been accepted by the majority of the profession. According to him, gout is due to an excess of urates in the blood and fluids of the body, from which they are deposited in certain tissues because of a diminished alkalinity of them. The excess of urates, it has been supposed, is due in part to excessive production because of disturbed metabolism, and in part to imperfect elimination. That the renal epithelium has a power of selecting certain substances for elimination is a demonstrated fact, and it has been supposed by some that in gout it refuses to excrete uric acid in the normal or necessary amounts. Ebstein modified the theory of Garrod by advocating that an excess of uric acid was produced in muscles and bones because of a peculiar local metabolic anomaly which is usually inherited. The deposit of urates in cartilage and fibrous tissue he accounted for because of the naturally slow circulation of blood through them, which, when it contains an excess of uric acid, causes a cellular necrosis in those tissues. The necrosis always produces a local acidity, and the alkaline urates of the blood are then precipitated as comparatively insoluble acid urates.

The uric-acid theory has also been modified by the hypothetical explanation that uric acid is an intermediate product in the transformation of waste nitrogenous matter into urea, a transformation made in the liver, and that an excess of uric acid in the blood results from such a derangement of hepatic functions as causes the formation of a lessened amount of urea and a proportionately larger amount of uric acid. The observed coincidence of gout and digestive disturbances has given color to this theory. Of late, however, physiologists have become convinced that uric acid is not an intermediate step in the formation of urea from proteid. Indeed very recent researches (Kossel, Horbaczewski) have led physiological chemists to believe that uric acid is derived from nucleins and not from other parts of cells.

Unfortunately for all these uric-acid theories gout cannot be produced experimentally by injecting uric acid into the blood or by preventing its elimination through the kidneys. Nor do the phenomena of the disease arise in other ailments, notably leukæmia, in which uric acid often exists in the blood in quite as large quantities as in gout. Experiment affords us no evidence that toxic properties are possessed by uric acid even when it is introduced into the blood in much larger amounts than have ever been found in gout itself.

Another theory which has not in the last fifty years had so many supporters as the uric-acid hypothesis or so many as at the end of the eighteenth century, but which nevertheless at all times has had influential advocates, is the theory of its nervous origin. According to it, gout is due to a disturbed metabolism, a fault of the system in which the chemical balance is deranged. The metabolic processes are presumed to be under the control of the nervous system, therefore such a perversion of them as occurs in gout primarily must be due to a disturbance of nerve centres. Just what change takes place in the central nervous system is not conjectured. Those who believe in a nervous origin of gout base their faith chiefly upon the following points: (1) Its frequent inheritance. (2) The effect of psychic disturbances, such as anger or mental depression, in provoking its attacks. (3) A tendency to neuralgia and myalgia in such patients. (4) Influence of barometric changes. (5) Joint involvement, which is common to many nervous diseases. (6) Many neurotic manifestations observed in other members of the family in which gout appears.

In 1884 Gaucher discovered that the injection of xanthin and hypoxanthin into healthy animals caused changes in the structure of the kidneys, similar to those of interstitial nephritis. More recently others have confirmed these observations and found that the xanthin bases will produce various nervous phenomena as well as high arterial tension and ultimately arteriosclerosis.

Horbaczewski, who in 1891 showed that uric acid is probably derived from nuclein, has also gathered evidence to show that xanthin and hypoxanthin or the alloxuric bases are to blame for the phenomena of irregular gout or lithæmia rather than the urates. It is true that uric acid in the form of biurate of sodium constitutes the tophi of gout and produces local deformities and sometimes inflammation, but in the form of a soluble, alkaline, quadriurate in which it exists in the blood it is not toxic.

Although gout has been supposed by some to be an infectious disease, there is no adequate evidence that such is the case.

Causative Conditions.—It is quite evident from this brief review of the leading hypotheses advanced to explain the causation of gout that we are to-day about as ignorant as our predecessors a century or two ago were. What knowledge we possess to-day is negative, that is, disproves theories that have been widely held. Nevertheless, much is known of the conditions under which gout is likely to arise. Heredity plays a large part in its production. According to Garrod seventy-five per cent. of all cases inherit the disease. Oftentimes the habits of families which their inherited environment produces also predispose them to it. But gout may be acquired as well as inherited. Acute and chronic gout are rarely seen in this country, but irregular gout is common and is increasing. Gout occurs oftenest in England, next in frequency in France and Holland, less in Germany and rarely elsewhere in Europe. Symptoms of it have been observed at all periods of life, but its onset occurs in much the largest proportion of cases between the thirtieth and fortieth years. Initial symptoms are extremely rare in infancy, childhood, and old age. Women are attacked less frequently than men, at least with the symptoms of prodagra and chronic gout. Insufficient exercise, and what amounts to the same thing, a deficient supply of oxygen, are important factors in creating a disposition to the ailment. A sedentary life causes the inhalation of relatively a small amount of oxygen. Shallow breathing, which is cultivated under the circumstances, lessens the vigor of the lymphatic and venous currents which carry off waste matters from the viscera, and causes a torpidity of liver and digestive organs. Lack of exercise also causes the same interference with vigorous metabolism in the voluntary muscles. When people live or work in overcrowded rooms they are sure to feel the need of oxygen. Virchow has laid stress upon the frequent production of tophi in the joints of the poor who live under these conditions. Since the earliest times it has been admitted that eating unduly large quantities of food will produce the ailment in many persons. Especially is this true of the use of large quantities of meats rich in extractives, or cooked with rich gravies and sauces. Although oftenest too much food, that which is too rich, and too little exercise together cause gout, rare cases have been observed in which an acute attack was provoked in those disposed to it by too little food and too much exercise. In these latter patients a lowering of vitality by underfeeding and overworking excited the ailment. The habitual use of fermented liquors is a most common and universally recognized cause of gout. It is difficult to explain the mode of action of these liquors. It is not merely the alcohol which they contain, for the users of distilled liquors are much less prone to the disease than are the users of fermented beverages. Nor is it an acid, nor sugar, nor, as far as we know, any one ingredient in beers and wines which makes the drinkers of them so liable to develop gout. Often a few glasses of wine will awaken symptoms of the malady in those who are susceptible to it. It may be that the disturbances of digestion which overeating and the use of fermented liquors cause are more to blame than individual articles of food or beverages. Mental depression such as grief and anxiety or prolonged mental exertion are also frequent predisposing causes. They may help to produce their ill effects by making digestion slow and disturbing the functional power of the organs which play a part in it. It is well known that lead workers are especially liable to symptoms of gout as well as to arteriosclerosis and interstitial nephritis.

Many of these conditions which predispose to the disease act together, that is, simultaneously upon individuals. Many of them are also the exciting causes of acute outbreaks of the ailment. Exposure to cold, great fatigue, anything which lowers the vitality for the moment may be an exciting cause for those who are susceptible.

PROPHYLAXIS.—A knowledge of the conditions which dispose the gouty to attacks affords us a key to its prophylactic treatment. Good hygienic surroundings, daily sufficient exercise (often large amounts are required), moderate eating, and freedom from undue anxiety, worry or mental labor, are the best prophylactic measures.

TREATMENT.—Little can be done to shorten acute attacks of gout, but the pain attending them may be lessened by suitable treatment, and a great deal can be done to prevent a recurrence of acute attacks by instituting a proper regimen.

It is impossible to remove the inherited fault of nutrition, but it is possible to retard the development of symptoms. Temperance must be taught as the cardinal rule of life, abstemiousness in eating, drinking, the enjoyments of the pleasures of life, or the inclination for mental work. Overeating, even the most moderate kind, must be avoided. A varied diet may be permitted, provided it includes foods which are simply prepared and easily digested, and provided they are eaten in moderate quantities.

When gout is fairly established, not only must temperance be insisted upon, but certain articles of diet must be forbidden. These are sweets, confections of all kinds, fats, articles cooked with much fat, game, and the richer meats, especially when dressed with rich sauces. Vegetables, rich in oxalates, ought also to be avoided by the gouty.

These patients should eat fairly varied foods and the diet should be well balanced, containing a normal proportion of albumin, carbohydrates, and fats; and the individual articles of food should be so prepared as to be most easily digested. Meat may be eaten moderately, but green vegetables, certain fats, and cereals, may be taken generously. The diet for those who are gouty must not be so restricted as to lessen their vitality. A milk diet has been urged as the best for the prevention of outbreaks of gout in those disposed to them; but milk, unless used in excessively large quantities, is not sufficiently nutritious; and while it may well be used as an important element of food it should not be the only article taken by the gouty.

Soups should be forbidden when the symptoms of goutiness are clearly manifested, but they may be taken in small amounts by those inclined to this ailment. Whenever they are used, they should be entirely free from fats, and preferably should not be made with a meat stock. Eggs, oysters, and clams may also be eaten, but lobsters, crabs, and shrimps are not to be recommended. Most fish can be eaten without harm, especially such as bluefish, whitefish, perch, shad, bass, and trout; but fish richer in fats and those that are smoked and salted, such as salmon, mackerel, halibut, and cod, are not so wholesome. Rich sauces should always be avoided. Meat should be eaten not oftener than once daily, and generally roasted or broiled. Those which are most to be avoided are pork, veal, game, and salted or smoked meats. Fat should be used in very moderate amounts except butter which can be used with a reasonable degree of freedom, and cream in moderation. Such carbohydrate foods as bread, rice, sago, tapioca, oatmeal, and cracked wheat may be eaten generouly, but pastries, hot breads, pancakes, and other articles of a similar kind, which are liable to form doughy masses in the stomach during the period of gastric digestion, should be avoided.

Sugar is not wholesome for the gouty. Such vegetables as rhubarb, tomatoes, radishes, spinach, cabbage, and, if they cause flatulence, baked beans, should be avoided.

The following green vegetables may be used freely: peas, stringbeans, corn, potatoes, turnips, carrots, parsnips, celery and celery plant, cauliflower, artichokes, broccoli, salads, cucumbers, and egg plant. Of the fruits, the following are best adapted for the use of these patients: pears, apples, raspberries, blueberries, blackberries, and oranges; but grapes, bananas, prunes, strawberries, and melons are not so wholesome. Pickles and condiments are to be avoided at all times.

Eating between meals should not be permitted. Gouty patients should be taught to eat slowly and to masticate their food carefully.

Especially should those inclined to gout avoid eating a large variety of food at one meal. Simplicity in diet as well as temperance in eating must be taught them. The variety which we all crave should be furnished by changes in food from meal to meal and from day to day.

Although by clinicians generally red meats are forbidden those who have chronic gout, cases have been successfully treated upon an almost exclusive meat diet. Salisbury steak, a little lettuce or spinach, and stale bread, varied occasionally by chicken, squab, eggs and fish, have constituted the entire list of foods of these patients. The uniformity of the food and the ease of its digestion have prevented abnormal fermentations in the gastro-intestinal tract just as an exclusive milk diet will do. This is the secret of success in such cases.

In the midst of acute attacks it is best to administer little of any kind of food. Milk is the best staple article and may be the only one. Gruels and eggs may also be eaten, and oranges and lemons may usually be permitted.

Tea and coffee in small amounts and with no, or very little, sugar, may be used by those who are predisposed to gout, provided they have no acute symptoms of the disease or of indigestion; but if digestion is slow, or there are other symptoms of gout or goutiness, these beverages should be forbidden.

It is universally admitted that alcoholic beverages of all kinds are harmful. Even in very small amounts they will, not infrequently, provoke attacks of gout. The degree of tolerance of alcoholic beverages by those who are gouty is, of course, very variable. It is not necessary, in order to provoke gout, that these beverages should be taken to the point of intoxication. Indeed the habitual drunkard rarely develops symptoms of the disease, but it occurs most frequently in those who are habitual users of alcoholic beverages in moderate amounts. Ale, beer, and the sweet and the heavy wines are the beverages which are most apt to provoke the trouble. Of wines, the dry white wines and old Bordeaux have been found the least harmful. Although individuals vary in their susceptibility to the ill effects of alcoholic beverages, and although the different beverages vary in their potency to do harm, they should all be forbidden the gouty.

Patients who are gouty should drink water copiously in order that the kidneys may be made to act freely and that the waste matter may thus be washed out of the system. From five to eight glasses of good pure water should be drunk daily.

Many spring waters have been recommended as preventives of gout. It is probable that large quantities of water do more good by the physical presence of fluid in the blood-vessels and tissues than the various mineral ingredients which spring water may from time to time contain. There are three varieties of spring waters especially recommended for gout: First, those which are particularly pure and contain a minimum amount of mineral matter. Without doubt, their effect is a physical one. Second, the alkaline waters of which Vichy is a type. Alkalies well diluted, introduced into the blood, do seem to stimulate normal nutritive changes in the tissues of the body. The alkaline waters also have a beneficial effect upon the contents of the stomach, which are usually acid because of abnormal fermentation. Third, spring waters which contain iron, arsenic, and lithium. They are useful, especially the arsenical waters, for those gouty persons who have affections of the skin and bronchial mucous membranes. Many of the cases of gouty dyspepsia are helped by these waters. Royat, in France, may be regarded as a type of this group of mineral waters.

Spring waters rich in sodium salts are not beneficial for the gouty, as these salts in unusual quantities in the blood hasten the precipitation of insoluble urates in joints or other tissues.

Hot mineral springs are resorted to by many who have chronic gout, for the purpose of bathing. Acute attacks are not benefited, but partially immobile joints with muscular atrophy are benefited. If patients have high arterial tension or hypertrophied hearts hot baths must be avoided.

Exercise is essential in order to prevent gout and to avert repeated attacks in those who are prone to it. The amount of exercise required must be determined by each person. As a rule it must insure several hours of outdoor life each day and for at least a few minutes daily must be violent enough to provoke sweating. When repeated attacks have stiffened the joints and enfeebled patients, it must be more gentle. Walking, bicycling, horseback-riding are the best. These more gentle means of exercise can often be supplemented with benefit by daily or frequent massage. Of sports golf, which insures mild exercise for several hours out-of-doors, is the best. The more violent games are rarely adapted to the gouty who are in middle life or have passed it.

Sufficient exercise should be taken daily, for the results thus obtained cannot be stored up at one time for future use.

In acute attacks physicians still resort, as Cullen recommended them to do, "to patience and flannels." Abortive treatment cannot be recommended. It has been attempted by strapping tightly the affected joint, applying ice to it, administering large doses of colchicum and sometimes morphine. Attacks have undoubtedly been stopped short in this way, but very dangerous symptoms have also followed the treatment, such as fainting and disorders of the heart. Most frequently soothing applications are made to the diseased joint, such as chloroform liniment or menthol (8 gm.) in camphorated soap liniment (120 c.c.), or in an oil composed of Guaiacol 25 c.c., Ol. gaultheriæ, 25 c.c., and Ol. olivæ, 50 c.c. Pomades with cacao butter and olive oil as bases are often used. To them may be added morphine, cocaine, belladonna, menthol, guaiacol, and other local anæsthetics and analgesics.

After each local application has been made the affected foot or joint is wrapped thickly in flannel to protect it from cold and to promote local sweating. Rendu ("Traité de Therapeutique Appliqué," 1895, Paris) advises wet bandages which are gradually made colder until the diseased part is accustomed to ice-cold applications. The cold benumbs the sensibility, lessens pains and swelling, and shortens the duration of the malady. Like the so-called abortive treatment it must be used with care.

Blood-letting and blisters are no longer used in gout, but purgatives are. Calomel and jalap constitute a favorite prescription of English physicians. Certainly at the onset of an attack it is important to empty the gastro-intestinal tract. A full dose of calomel followed in a few hours by a saline (the liquid citrate of magnesia is particularly eligible) does much good. At the same time the patient should abstain from food for from twenty-four to forty-eight hours but should drink water freely. When food is administered, and this should not be until copious bowel movements have insured the emptiness of the intestines, milk should be given.

Of medicine colchicum is chiefly relied upon to relieve the acute symptoms. Twenty to twenty-five minims of the wine of colchicum root may be given three or four times daily. Instead of this preparation the tincture of the seeds of colchicum may be used. As soon as the sedative effects of the drug are obtained it should be given in smaller quantities and often can be discontinued. If used too long it will provoke nausea and excessive diarrhœa. Indeed, a peculiar susceptibility to these effects of the drug makes its employment impossible in certain cases. Colchicum probably produces its good results by its sedative action upon the nervous and cardio-vascular systems and by helping elimination by its purgative properties.

Next to colchicum the salicylates are found useful. The salicylate of sodium is most used, but by some physicians the salicylate of lithium is preferred. A combination of the salicylate of sodium and bromide of lithium has proved useful to my patients. The salicylates are less certain in their effect than colchicum, but especially useful after colchicum is discontinued and in prolonged subacute attacks.

Alkalies are also used commonly. The best are the potassium and lithium salts. They are usually combined with colchicum or the salicylates. Originally they were given to hasten the elimination of uric acid by making soluble salts of it. Numerous other drugs in recent years have been tried for the same purpose, such as piperazin, lycetol, and lysidin. The doubt which prevails to-day in the minds of pathologists in regard to the pathogenic properties of uric acid makes their employment theoretically less urgent. Lithium has been shown to be useless so far as increasing the solubility of urates in the blood is concerned, for when administered by the mouth it forms insoluble compounds in the stomach and does not unite with the uric acid. However, I am convinced that lithium salts are beneficial in the indigestion of the gouty, probably because they unite with constituents of the contents of the stomach, lessen their acidity and toxicity.

Guaiac is another remedy which is often employed in gout with benefit. Its mode of action cannot be satisfactorily explained. It proves most useful in subacute or mild acute cases.

Chronic gout must be treated hygienically for the most part and acute exacerbations must be treated as acute gout is. The salicylates and alkalies are especially useful in these cases. Piperazin and similar drugs have been much used of late years to dissolve tophi. The clinical results of their employment as they are described in periodical literature are conflicting. It and lysidin are also credited with the relief of pain. Massage can be employed in chronic gout, and often after acute attacks, with benefit. It must, however, be applied with gentleness. It helps to reduce swelling, to make the joints more supple, and to strengthen the unused muscles. When joints are permanently deformed it is necessary by massage, electricity, and hydrotherapy to keep the atrophying muscles strong, in order that as much usefulness as possible may be preserved to the diseased part.

Little can be done to remove uratic deposits. Most attempts by local treatment are found to be more harmful than useful. Surgical interference is not to be recommended unless suppuration occurs near them (and it is a rare complication, not a part of the disease) or sloughing of the skin over them takes place; then the pus should be evacuated and any exposed urates scraped out and the wound treated as any other sluggish and infected wound would be.

A residence in a mild genial climate where an outdoor life can be had continuously is of great advantage in checking the progress of this ailment.

Often diet must be still further modified because of arteriosclerosis or contracted kidney and albuminuria. It must then be made even simpler. Red meats should not be used or, if at all, rarely. Indigestion and constipation must be carefully corrected or guarded against. Great pains must be taken to prevent fermentation in the gastro-intestinal tract.

The iodides are frequently needed to lessen arterial tension. They may have to be given for weeks at a time. Potassium iodide is chiefly used, but Bouchard and Dyce Duckworth recommend the iodide of lithium. Nitroglycerin is sometimes needed for its temporary but more pronounced effects upon the arteries.

In irregular gout chief reliance must be placed upon hygienic treatment. Various symptoms of the malady may for a time need medical treatment addressed to meet them. For instance, in the eczema of the gouty local applications are of benefit; but an abstemious, carefully regulated diet, the copious drinking of water, the maintenance of good elimination by the bowels, kidneys, and skin, and suitable exercise, are essential to success.

For the headaches and neuralgias much can be done with the compounds of salicylic acid, phenacetin, antifebrin, and similar drugs, but the relief is imperfect or transitory unless a suitable regimen is prescribed and maintained. Hemicrania can frequently be averted, when the temporal arteries begin to be tense and twinges of pain give warning of an attack, by a full dose of citrate of magnesia.

Often such patients must change their business in order to obtain permanent relief, thereby avoiding the anxiety and confinement which a commercial or professional life necessitates. *N. S. Davis, Jr.*

GOWERS' TOXIC PARAPLEGIA. See *Spinal Cord Diseases: Combined Scleroses.*

GRAMINEÆ.—(The Grass Family.) This is doubtless, all things considered, the most important family of plants. The bamboos contribute most important building and structural material in the tropics, as well as considerable fibre material, which latter is also contributed by many other grasses. The uses of straw in this connection are too well known to require description. The grasses contribute by far the most important stock fodders, while the cereals constitute the most important part of human food and the principal source of alcoholic beverages and of alcohol itself. The sugar-cane, as well as sorghum, is a grass. An important fixed oil is obtained from Indian corn, which is also the chief source of glucose, and the importance of the starch yielded by it, as well as of those obtained from wheat, rye, rice, and barley, is apparent. Several important volatile oils are yielded by species of *Andropogon.* With one or two unimportant exceptions, poisonous properties are unknown in the family. Very few of the species are of distinct medicinal use, though Triticum is official, and ergot proceeds indirectly from rye. *Henry H. Rusby.*

GRANATUM. See *Pomegranate.*

GRAND HAVEN MINERAL SPRING.—Ottawa County, Michigan.

Post-Office.—Grand Haven. This is the terminal station, on Lake Michigan, of the Detroit, Grand Haven and Milwaukee Railroad. It can also be reached from Chicago by lake steamer. The location is a cool and pleasant place in summer, and excellent opportunities are afforded for surf bathing in the lake. According to an analysis by C. G. Wheeler, the water is composed as follows:

One United States Gallon Contains:

Solids.	Grains.
Sodium carbonate	2.09
Potassium carbonate	2.74
Calcium carbonate	2.01
Magnesium carbonate	1.52
Iron carbonate	.08
Sodium sulphate	71.29
Sodium chloride	306.03
Potassium chloride	1.93
Calcium chloride	148.05
Magnesium chloride	71.53
Magnesium iodide	.05
Magnesium bromide	.17
Calcium fluoride	.05
Alumina	.30
Silica	1.05
Total	608.89

This water contains sufficient sulphate of sodium to give it great efficacy in cases of engorgement of the liver, abdominal plethora, and dyspepsia associated with these conditions. *James K. Crook.*

GRANULATION TISSUE.—Definition.—In crushing injuries, wounds involving the loss of considerable tissue, neglected wounds or those infected with pathogenic bacteria, or in wounds in which close coaptation by sutures is impossible, the healing process takes place by secondary intention, or, it is said, healing occurs by granulation. The origin of the latter expression is traceable to the appearance in such injured parts of minute pink or rosy elevations, the granulations; such surfaces are said to be granulating and the tissue forming the tiny nodules, as well as that below and about them, is granulation tissue. Granulations are peculiarly limited to exposed situations; similar processes of healing upon other surfaces, such as the intestinal canal and serous membranes, are very rarely if ever marked by elevations comparable to the granulations of healing wounds. This term consequently had its birth in the outward objective features of healing injuries of various sorts as well as locations. Granulations are described, in the older works of surgery and pathology, as arising from the sectioned ends of bones, in abscesses undergoing "self-purification," chronic ulcers, fistulous openings, etc. The essential requisite seems to have been that they should occur either where they would be plainly visible or easily demonstrable or in such hidden locations where previous experience had proven their development. Necessarily this conception of granulation tissue was from the clinical viewpoint almost exclusively.

With the fuller knowledge of the process of inflammation, and especially of the regenerative changes connected with resolution, the designation granulation tissue has invaded topics of a more general character than those connected simply with surgical pathology. This tendency is, without doubt, due to the selection, by writers, of wound healing by secondary intention, as the type of regeneration or resolution in the inflammatory process; and because the cellular changes in resolution have more or less in common, no matter what the location is. The term granulation tissue has, therefore, by degrees acquired the significance of embryonal tissue. From this pathological conception, the chronic processes of inflammation, tuberculosis, syphilis, actinomycosis, leprosy, etc., in which proliferative changes predominate, acquired the group-name granulomata. There may be no granulations in the surgical sense in a gumma or actinomycotic growth, yet they are commonly described as made up of granulation tissue. The analogy between the granulation tissue of a healing wound and a deeply seated chronic inflammation such as a gumma of the liver or testicle, is a histologic one; the former possesses perceptible granulations, the latter a structure similar to such delicate and sometimes barely visible excrescences. Granulations do not, as a rule, develop in the granulomata, but they are obvious characteristics of all sorts of wounds.

That consideration of granulation tissue which maintains its parity to embryonal tissue and its inflammatory origin belongs to the general subject of inflammation (see *Inflammation*), whereas the following description deals solely with granulation tissue as it is met with clinically, with the structures that gained the name primarily.

Healthy Granulations. — The surface of open wounds after a few hours becomes covered over with a delicate pellucid, gray or whitish layer which slowly becomes thicker and finally resembles the buffy coat. Its formation takes place after the cessation of hemorrhage, although some clear or slightly blood-tinged fluid may ooze from spots on its surface or from the edges for some time. Exposure to the drying influences of the air causes this exudate to change into a compact, rather brittle crust that effectually protects the underlying tissue; it is often some shade of brown from the admixture of blood. The protection of wounds by dressings may lessen the formation of a crust and the fibrinous coating may remain thin and translucent. For a number of days there may be no change in the appearance of such defensive vestures. After a variable length of time, depending upon the anatomical location, the variety of tissue, the individual's age, and other factors, granulations arise. It is usually a number of days, from four to ten, before they attain macroscopic proportions.

When it was regarded as good surgical treatment to approximate the edges of the flaps with strips of adhesive, after amputation of an extremity, it was observed that granulations appeared earliest on the vascular soft parts and sooner on the sectioned cancellous than compact bone. If, after a certain period of repose, the dried blood clot of the exposed wound or the dressing of the more carefully protected wound be removed, minute pink points will be visible upon the paler tissue around. They mark the site of future granulations, whose development is easily followed by examination at intervals. The pink spots deepen in hue and others appear; they enlarge to blotches that have a bright ruddy aspect, and become elevated as small globular tuberosities. In *sensu strictu*, this is granulation tissue.

These small eminences vary in size and give the surface a decided granular appearance; they level the smaller irregularities of rough and lacerated injuries. The tissue that forms them is common to all chronic inflammations; it is embryonal tissue in process of cicatrix production. The elevations containing loops of newly proliferated blood-vessels have been explained by Hamilton upon the basis of lessened pressure; in this manner he would account for their absence in deeply seated morbid conditions. It is doubtful if altered conditions of pressure are the only agencies influencing their development.

Perfectly healthy granulations may vary in height and form, they may possess flat or rounded tops and a uniformity or irregularity in size may be observed. Double or compound granulations are described. Their consistence varies within narrow limits; possessed of broad bases these warty growths give the impression of firmly interwoven tissue with soft but not fluid contents. On removal of the covering exudate by gentle washing, a clean, moist or glazed surface, translucent and devoid of visible vessels is exposed. Although there is no distinctive color to healthy granulations, the more livid hues bespeak poor circulatory conditions. A faint pellicle with bluish zones that merge into the white of the adjacent skin marks the healing margins from which epithelization has already begun. Healthy granulations are extremely sensitive if they arise in tissues well supplied with nerves; others from such structures as compact bone and tendons have no sensibility. When situated on a flat surface they seldom rise much above the level of the adjacent skin. The cells composing granulation tissue are those peculiar to chronic inflammation; however, in the average granulating wound there are probably a greater variety than in the usual deeply seated chronic inflammation. Our knowledge of the histology and histogenesis of the healing process is in the main derived from experimental work upon animals, nevertheless it is generally accepted that healthy human granulations may contain all varieties of leucocytes and all forms of fibre-producing cells; also red blood corpuscles, phagocytes, giant cells, budding blood-vessels, fibrin, bacteria, and an intercellular substance of altered fluid from the blood and lymph vessels.

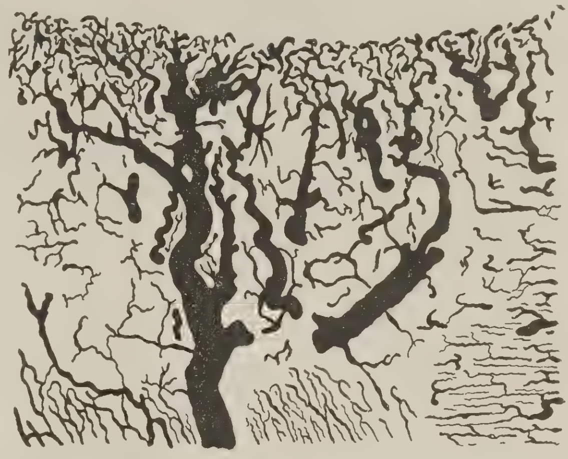

Fig. 2347.—Injected Blood-Vessels in the Granulation Tissue from an Experimental Injury of the Tongue of a Dog. The arteries have a greater tortuosity. Six days after injury. (Modified from Thoma.)

Pathological Granulations.—The extent to which, in a specific example, the exudative and retrogressive or degenerative changes exceed those of proliferation, depends upon many factors; chief among these are the stage of healing and the initial cause. It has long been recognized by surgeons that variations may occur in the general mode of healing, deviations from the normal that permit the use of such a pleonastic expression as pathological granulations. The luxuriant or exuberant granulations have been known by the laity immemorially as "proud flesh" and as altogether undesirable in a healing wound. The torpid or languid granulations and the spongy or fungous forms may so delay healing that there is an easy transition from granulation tissue to ulcers. Ulcers consist of granulation tissue when the macroscopic evidences of proliferation attain the degree of distinct granulations; other ulcers, the seat of extensive necrosis and exudation, may not possess any proliferating tissue; such ulcers are not granulating. Over forty years ago Paget made the statement that "all the varieties in the aspect of granulating wounds and sores, which the practised eye can recognize as signs of deflection from the right way to healing, are so many instances of different diseases of the granulation substance, diseases not enough investigated, though of much interest in the study of both the healing process and the organization of new products in inflammation."

This complaint finds an echo in the claim made by Reinbach, who, in an article recently published, states that he was unable to find in the literature at his command a single instance of researches of this character, and he adds that Ziegler also knew of none. Reinbach prefers to abandon the older nomenclature comprising such terms as fungous, spongy, erethistic, croupous, etc., for the general term pathological granulations.

Of these he recognizes two forms with several subordinate types: (1) The *luxuriant superficial granulation*, that is usually "self-purifying" and characteristic of acute processes, and (2) the *superficial chronic granulation*. The strictly torpid granulations he classifies with ulcers on account of the absence of formative tissue. As for the first form they are marked by the histologic features that belong to the process of suppuration (see *Inflammation*). Quantities of bacteria occur—generally cocci that show no special arrangement—and at different levels the changes indicative of miliary or microscopic abscesses. Leucocytes swarm within such granulations, and among them eosinophiles and mononuclear leucocytes are numerous. The capillary loops of the outer zones suffer some necrosis. In spite of the exudative and destructive changes karyokinetic figures are numerous in the deeper portions in fibroblasts and endothelial cells, and the fibroblasts produce fibres and become connected in the usual way.

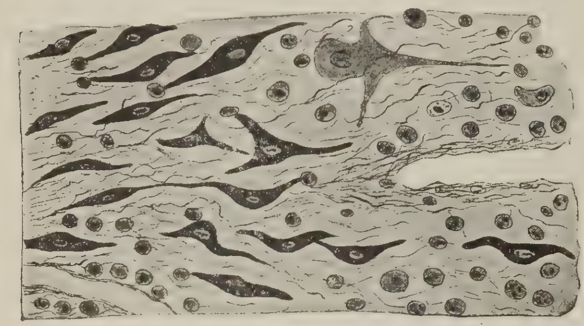

FIG. 2348.—Organizing Granulation Tissue. The left edge represents the deeper part. The round cells are both mono- and polymorphonuclear leucocytes. There are many spindle-shaped fibroblasts. (Modified from Ribbert.)

As examples of superficial chronic granulations, Reinbach mentions both the torpid granulations, which, however, show some signs of growth, and those covered with mottled and white patches caused by necrosis of the outermost parts. The first of these subdivisions, although very slow to heal, nevertheless contain vertical bands of fibre-forming cells. They often follow burns and constitute virtually lesions intermediate between granulation tissue and real ulcers. The second variety, covered by a fibrinous exudate in spots and by necrotic tissue, was described by Billroth as "croup of the granulations." Surgeons on meeting with these hindrances to the normal course of healing are inclined to suspect wound diphtheria, *i.e.*, a true infection with the bacillus of diphtheria. However, such areas of necrosis superficially located upon otherwise healthy granulations may be caused by other non-pyogenic bacteria, for example, the Bacillus coli.

The fibrin upon these diseased granulations, commonly limited to the periphery, may extend to considerable depths; when the spots clinically are dark yellow and brown, the necrosis may be accompanied by practically no inflammatory changes.

A careful review of the work of Reinbach demonstrates quite clearly that the interferences with the process of cicatrization in granulation tissue are due to the precipitation of fibrin either as a covering or among the cells, to simple necrosis, or to that form of necrosis which with serous exudation or liquefaction is generally known as suppuration. His work is based upon the careful histologic examination of tissue removed from many conditions that were associated with granulating surfaces. There is urgent need of equally thorough bacteriologic examination of such diseased human granulation tissue, especially researches that would include the use of animals.

There is yet another fact that prevents normal cicatrization, and that is obstruction to the blood supply of the growing tissue. The obstruction is only partial, and without doubt in many instances is attributable to an arterial supply that is inadequate in the number of vessels or their total calibre. In other cases the action of morbid conditions more centrally located or dependency of the part leads to inefficient supply of blood. That an œdema of granulation tissue may occur is well known; doubtless a deficiency in quality or quantity of nourishment is responsible for the occasional total failure of resolution. Briefly, granulation tissue may be the seat of extensive necrosis, œdema, and suppurative or fibrinous inflammations as well as combinations of these processes. Other pathological conditions, such as hemorrhage and the various cellular degenerations, may arise, but generally only as minor and incidental changes. The causes of pathological granulations often are to be sought in the character of the primary lesion, rather than in secondary infection or the injury of healthy granulations. Infection at the time of injury is frequently responsible for subsequent difficulties in healing.

THE PROTECTIVE QUALITIES OF GRANULATION TISSUE.—It is well known that granulations bleed readily; slight trauma of any sort disturbs the unorganized tissue and lacerates the embryonal and sprouting capillaries. As for infection, many experiments have proven that in this respect granulation tissue constitutes a serviceable barrier. One of these was the now classical experiment of Billroth. He ascertained that no ill effects followed daily dressing of healthy and experimentally produced granulations of a dog's back with lint saturated with pus, whereas inoculating such animals with the same material caused death. This simple test was many years later followed by the extensive experimental study of Afanassieff, who in a more scientific manner and by exact bacteriologic technique verified the results of Billroth.

Granulations were produced upon many animals of different species, and upon them virulent cultures of such bacteria as the bacillus of anthrax and the vibrio Metschnikovi were carefully smeared with a thick platinum needle. The serum exuding from granulations so treated was examined from time to time, stained preparations and media inoculations being made also; the virulence of the resulting growths was examined; histologic examination of the granulation tissue for bacteria and the inflammatory changes was carried out, and animals were killed in order to ascertain if general infection had occurred. Ample control experiments were employed.

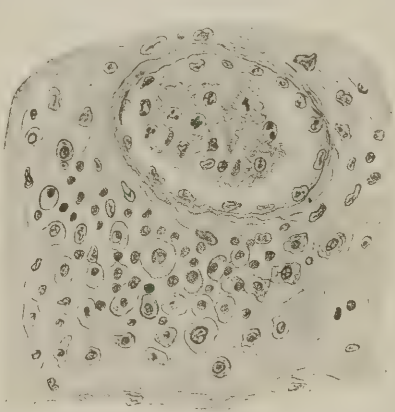

FIG. 2349.—Perivascular Collection of Round Cells or So-called Lymphoid Tissue. They contain various forms of leucocytes, and as the inflammation becomes chronic, plasma cells occur in such cell accumulations. (Modified from Ribbert.)

He found that bacteria placed upon healthy granulations of animals did not penetrate, nor did general infection result. Inoculations made with recovered growths of the bacteria denoted an attenuation in virulence by the sojourn upon granulation tissue. Afanassieff was strongly inclined to look upon the protection afforded by the granulation tissue in the light of a vaccination. Such an explanation, however, is controverted by two facts. One of these is that local reactions in the granulation tissue were not observed with sufficient regularity in all animals to be in accord with the production of a bacterial immunity. Another fact is that Noetzel has repeated many of the experiments of Afanassieff and found that after bacteria were kept in contact with granulating wounds for many days the animals did not acquire any immunity.

It must be remembered that in granulation tissue mechanical obstacles exist to infection, such as the outward current of fluid from the vessels and the exceedingly slow circulation. Phagocytosis undoubtedly plays some part, although it may be that the ingested bacteria are no longer viable at the time of their incorporation. The extracellular destruction of the bacteria by the fluids present in granulation tissue (Afanassieff) or by enzymes, belongs to fundamental problems of immunity (see *Immunity*).

One cannot overlook the fact that when granulation tissue has formed, a defensive mechanism has been produced and its production is in response to external injury. But granulation tissue usually contains bacteria; especially frequent are the ordinary pyogenic forms.

Although resistant to bacterial infection, granulating wounds allow of the ready absorption of many soluble substances. Roux, Bonnet, Demarquay, Gorny, Maas, and Hack, and many others, have made experiments regarding this. Not all substances are absorbed with equal facility. The concentration of the solution, its chemical composition, the size of the granulating surface, and the character of the injury producing it, as well as the time contact is allowed, all influence the absorption. Granulating surfaces following burns and caustics are not so permeable as some others; absorption is more rapid from some healing wounds than from freshly cut surfaces. Apomorphine and curare are not readily absorbed, but carbolic acid diffuses with great facility. Various alkaloids such as strychnine, morphine, pilocarpine, cocaine, etc., have been used, and carmine, sodium sulpho-indigotate, iodoform, potassium iodide, sodium salicylate, as well as many other substances. Hack recovered ferrocyanide of potassium from the urine ten minutes after its application to a granulating surface, and Maas was able by spraying abscess cavities with a camphor solution, in a patient with vertebral caries and pyæmia, to sustain the heart action sufficiently to allow operation. These and many other interesting and curious facts have been discovered about this phase of granulation tissue.

Cicatrization.—With healing of wounds by granulation a scar is formed that becomes paler as contraction takes place. Resolution in this form of inflammation is not marked by any peculiarities that distinguish it from cicatrization elsewhere. It is, however, customary to refer in this connection to the very deforming contractions that sometimes follow burns, but it is the location of the cicatrix rather than any special properties it possesses that marks it as singular. The loose subcutaneous adipose and areolar tissues allow scars to produce disfigurements that excite special interest on account of their exteriority. Similar malformations may occur in less exposed locations that are fully as interesting and as remarkable—for instance, the acquired dextrocardia and lesser dislocations of the heart that follow indurative processes of the neighboring viscera. They constitute excellent examples of the partial failure of inflammation as an adaptive process. The development of keloids in scars might be cited as another instance in which abnormal resolution builds a growth, which, to the surgeon at least, must ever serve as a striking illustration of the failure of inflammation as an adaptive process. In contrast to these irregularities in resolution and fully as interesting is the failure of granulation tissue to organize about certain fistulous passages and their openings that lead to foreign bodies, necrotic tissue, etc. These are the so-called "sequestrum granulations." The failure of cicatrization in these cases seems to indicate a better adaptation of the process of inflammation, as it occurs in granulation tissue, to meet the requirements.

GRAPE.—(Including *Raisin*, or *Uva Passa.*) The genus *Vitis* Tourn. (fam. *Vitaceæ*) comprises about thirty species of Vine, a number of which, either in their improved forms, or as hybrids, contribute our grapes. The young leaves, tendrils, and green fruit of the vine are sour and astringent, containing *tartaric, malic,* and other fruit *acids* or their salts; *tannic acid, quercetin, quercitrin,* etc., sugar, gum, and several earthy and alkaline bases. They are more or less employed in Europe in the form of "teas" or syrups as domestic remedies. The juice of one particularly sour variety expressed from the green fruit, and known as *verjus,* is used to make a flavoring and refreshing syrup. The sap of the stems has also been employed. Ripe grapes, and especially raisins, are much sweeter, containing from ten to forty per cent. of *sugars* (*dextrose, levulose, inosite*) besides the acids, salts, etc., above mentioned. Still these are more or less employed for the same purposes as the herbage. Their medicinal virtues are very unimportant.

From the ripe fruit of the European Vine, *Vitis vinifera* L., raisins, and from one of its varieties the Greek, Zante or English "currants" are made merely by careful drying. Raisins are slightly laxative, like figs and other dried sweet fruits, and they have a peculiar power in imparting flavor. *Henry H. Rusby.*

GRASSE, FRANCE, a town of 15,000 inhabitants, is eleven miles north of Cannes, from which it is reached by railway in forty minutes, and also by direct railway from Nice. This resort of the Riviera was brought especially to public notice by the visit of the Queen of England in the spring of 1891. It is very picturesquely situated, high above the hillsides, and is well sheltered from the cold winds on the north. It has an elevation of 1,070 feet, and possesses a very mild and salubrious climate, essentially the same as that of Cannes, with the exception that it is less stimulating than a resort directly upon the seashore.

The temperature is a little lower in winter than that at Cannes, on account of the elevation; the mean temperature of the year being 60.2° and for the winter 46.4°, while that at Cannes is 60° and 47.75° F. respectively. "Grasse," say Weber and Foster (Albutt's "System of Medicine," 1896), "forms a useful intermediate station during April and May for patients who find the heat in those months already too oppressive at Cannes."

For the climatic detail one is referred to the articles upon Cannes and Nice. In brief, Grasse affords a favorable winter resort for invalids unable to remain near the sea. Grasse possesses a luxuriant vegetation and is celebrated for the cultivation of flowers and the manufacture of perfume, which is the most extensive in France, if not in the world. The air is heavy with the scent of flowers, which with some invalids is said to produce an exaggerated form of hay fever. Great fields of orange blossoms, heliotrope, hyacinthe, roses, violets, jonquils, geranium, and other flowers are cultivated about Cannes and Grasse; 60,000 acres being devoted to this industry, yielding annually 2,200,000 pounds of roses and 4,000,000 pounds of orange flowers.

At the foot of the village are great plains of olive trees. The views are very beautiful and extensive, and the excursions round about are many and attractive. The town itself is not particularly attractive, but this is compensated for by its picturesque situation and beautiful views.

The water supply is good, but the sanitary condition was said by Linn ("Health Resorts of Europe"), in 1893, to be far from perfect. The accommodations are good but apparently limited.

The climate is said to be beneficial to sufferers from asthma, gout, nervous affections, insomnia, neuralgia, and rheumatism. *Edward O. Otis.*

GRAVEL. See *Kidney Diseases.*

GRAVES' DISEASE. See the APPENDIX.

GREAT BEAR SPRING.—Oswego County, New York. This spring is located near Fulton. It has been known for many years, having been used by the aborigines. Within the last few years the spring has been improved and the water has an extensive sale in Syracuse. More recently it has been introduced into New York and other large cities. The water is but feebly mineralized, but it is remarkably pure, and its freedom from organic matter gives it excellent qualities for the table. Its very small cost is an additional advantage. The following analysis was made in 1890 by Dr. William Manlius Smith, of Syracuse:

ONE UNITED STATES GALLON CONTAINS:

Solids.	Grains.
Calcium sulphate	0.72
Calcium carbonate	3.50
Magnesium carbonate	1.25
Magnesium chloride	.47
Sodium and potassium carbonates	Traces.
Total	5.94

James K. Crook.

GREEN LAWN SPRING. Jefferson County, Illinois.

POST-OFFICE.—Mt. Vernon. Hotels and boarding-houses. These springs are located in the city of Mt. Vernon, 76 miles east of St. Louis. This point is reached by the Louisville, Evansville and St. Louis, by the Jacksonville and Southeastern, and by the Louisville and Nashville railroads. The springs are six in number, and are surrounded by a park of about eight acres in extent in the centre of the city. Their waters are discharged from a vertical stratum of slate about eight inches in width and bisecting a horizontal stratum of slate of between two and three feet in thickness. They belong to the class known as saline-chalybeate waters, each spring differing somewhat in properties from its fellow. The one most used, known as the "Washington" Spring, contains the carbonates of lime, iron, and magnesia, bicarbonate of sodium and potassium, and chloride of sodium, with traces of iodine and bromide. Free sulphurous acid is present in considerable quantities, and the water is quite heavily charged with carbonic acid gas. The temperature of all the springs, with one exception, is about 56° F. In this single exceptional case, in which the temperature ranges about 10° higher, the waters are used for bathing purposes in rheumatism, with good results. A peculiarity of the Washington or main spring is its eccentric behavior, which seldom fails about the time of the autumnal equinox. It is said that the waters always become turbid at these periods and the same disturbances have been observed after great storms or earthquakes, even though these events occur in regions remote from the springs. The waters are said to remain red with an excess of iron for a short time after these disturbances and then to become harsh and acrid from an excess of alkaline ingredients. The country surrounding Mount Vernon is about equally divided between prairie and timber, a considerable portion of the latter being found on elevated ridges. On the north a belt of timber, about ten miles in depth, affords protection against the winds of winter and causes a considerable modification of temperature. The waters of the main springs are very efficacious in the treatment of dyspepsia, torpid liver, biliousness, and other disorders of the chylopoietic organs. *James K. Crook.*

GREENBRIER WHITE SULPHUR SPRINGS.—Greenbrier County, West Virginia.

POST-OFFICE.—White Sulphur Springs. Hotel and cottages.

ACCESS.—Viâ main line of the Chesapeake and Ohio Railroad direct to Springs. This celebrated summer watering-place is located on the western slope of the Appalachian Mountains, at an elevation above tide-water of more than 2,000 feet. The situation is well within the famous spring region. Within a radius of thirty miles are the Rockbridge Alum, the Hot, the Warm, the Healing, the Sweet, and other well-known springs, while the Natural Bridge, Millboro, the Alleghany, and other resorts are near by. For many years past the Greenbrier White Sulphur Springs have been regarded as a representative summer resort of the South, and it has lost none of its ancient and well-deserved prestige by the development of other springs. As in ante-bellum days, here will still be found the best elements of the social life of the South, with a generous intermingling of Northern beauty and gallantry drawn thither by the numerous attractions of the place. The surrounding scenery typifies the picturesque beauty and grandeur of the Alleghanies. The visitor from the heated and dusty city is at once attracted by the vast lawn of green, velvety turf, shaded by noble forest oaks, luxuriant sugar maples, and venerable pines. Under these monarchs of the forest wild flowers are seen in profusion and in great variety. Among the surrounding mountains are "Kate's" and "Greener," each a mile distant and reaching an altitude of 3,500 feet, and the mountains known as "White Rock," three miles distant, the summits of which form a figure of gigantic size, known as the old "Titan," which, in solitary grandeur, keeps guard like a giant over the White Sulphur. What has been said of other Alleghany resorts applies in full measure to this. The mean annual temperature from April 15th to November 15th is about 63° F., or about the same as the mean annual temperature of Naples, Nice, and the Madeira. The atmosphere is salubrious and invigorating, and at no time excessively warm. The Grand Hotel, with its one hundred cottages, gives accommodation to an immense number of visitors. There are two important springs here, viz., the famous old "White Sulphur," and the "Chalybeate." The Sulphur Spring yields 1,800 gallons of water per hour, and this amount does not vary even during the longest spells of wet or dry weather. It has a uniform temperature of 60° F. An analysis by Prof. A. A. Hayes, of Boston, shows the following mineral contents:

ONE UNITED STATES GALLON CONTAINS:

Solids.	Grains.
Calcium carbonate	7.07
Magnesium sulphate	35.42
Calcium sulphate	78.35
Silicates	3.46
Magnesium chloride	1.00
Organic matter	4.36
Total	129.66

Gases.	Cubic Inches.
Carbonic acid	11.28
Sulphureted hydrogen	.24
Oxygen	.48
Nitrogen	4.64
Total	16.64

This analysis was made many years ago (1842), and a newer and further analysis is desirable. The water acts on the kidneys, bowels, liver, and skin. As a diuretic its effects are very soon apparent; but some days are usually required before it produces a decided action on the bowels. Its operation on the liver, too, may not be manifest for some time, and when there is much sluggishness of this organ some auxiliary medication is required. Its effect upon the skin is very apparent, though not immediate. The analysis does not fully explain another important action of the water, an effect which has been attested to by several generations of qualified medical men. This is its alterative power, or that peculiar influence by which it effects a salutary alteration in the blood, in the various secretions, and upon the numerous tissues of the body. No general directions can be given for the internal use of the water. The hours, the quantity, and the period for which the water should be drunk depend upon the individual requirements of the case, and should be ascertained by consulting a physician experienced in the use of such waters. Combined with the influence of the favorable surroundings, the use of the water often proves curative in obstinate cases of chronic bronchitis, in hay fever, in bronchial asthma, and in nasal catarrh. Conjoined with the use of the hot sulphur baths it is of decided value in rheumatism and gout, and is an efficacious adjuvant in the treatment of tertiary syphilis, chronic metallic poisoning, and dartrous skin diseases. According to Dr. Moorman, for many years the resident physician, the water is contraindicated in organic heart disease, carcinoma of the stomach, and phthisis pulmonalis. The water never proves beneficial when it persistently excites the frequency of the pulse. The water used for bathing flows from the sulphur spring. The bathing establishment has recently been greatly enlarged and remodelled, and it is now believed that it will prove in all respects satisfactory to those wishing to avail themselves of its use.

The Chalybeate Spring. About forty rods from the White Sulphur Spring is a chalybeate spring in which iron exists in the form of carbonates. For the last twenty years this water has been considerably used by a number of visitors who require a ferruginous tonic, and its effects have realized the early hopes that its discovery created. It has not been fully analyzed. *James K. Crook.*

GRINDELIA.—California Gum-weed. *Rosin-weed.* "The dried leaves and flowering tops of *Grindelia robusta* Nutt. and of *G. squarrosa* Nutt. (fam. *Compositæ*)" (U. S. P.). These are large and coarse, perennial, resinous herbs, of the far western and southwestern United States. The former was first introduced, then the latter, as possessing different properties. It being quickly determined that the properties were similar, they were united under one title. Nevertheless, many physicians prefer the *G. robusta.* It is much scarcer and more difficult to obtain, and the other is very commonly supplied, broken up or otherwise treated to make a distinction, when robusta is specifically called for. A good mark of distinction is given below. The following is the official description:

Leaves about 5 cm. (2 inches) or less long, varying from broadly spatulate or obovate to lanceolate, sessile or clasping, obtuse, more or less coarsely and sharply serrate, often spinosely toothed or even laciniate-pinnatifid, pale yellowish-green or yellow, very smooth, finely dotted, resinous, thick and brittle; heads many-flowered, the involucres of many series of imbricated scales with acute, spreading or recurved tips. The heads of *G. squarrosa* are mostly longer than broad, contracted-campanulate or conical-urceolate; those of *G. robusta* are broader than long, depressed-urceolate. Ray-florets deep-yellow, ligulate, pistillate; disc-florets yellow, tubular, perfect; pappus of two or three mostly unequal awns, about as long as the disc-florets; odor balsamic, slightly narcotic; taste resinous and gummy, pungently aromatic, somewhat bitter. The quality is roughly indicated by the amount of resinous matter exuded upon the surface.

Resin is the principal constituent. There are also a little volatile oil, wax, gum and tannin, together with a bitter glucoside, in small amount. Its uses are external and systemic. The fluid extract, if painted upon a surface poisoned by rhus and similar agents, is one of our best remedies. It forms a dry coating which excludes the irritating atmosphere and prevents the spread of the poisonous fat, probably also absorbing it into the resinous film. It is of some similar use for treating burns and as an injection for urethritis and vesical catarrh. Its internal action, as a sedative expectorant, is not so readily explained. It is largely used, by way of the stomach, in chronic and subacute bronchitis, in asthma, and in whooping-cough. It is mostly given in the form of the official fluid extract, in doses of 1 to 4 c.c. (fl. ʒ ¼ to i.).

Hysterionica or *Baylahuen*, the herb of *H. Baylahuen* (Gay) Baill. (*Haplopappus B.* Gay) is a Chilian drug, very closely related, botanically, chemically, and physiologically, to grindelia. It contains a large amount of a brown, odorous, somewhat acrid resin and an essential oil. It is considerably used at home as an anti-diarrhœal and anti-dysenteric, and was introduced to Europe and the United States about the year 1890. Repeated trials showed it to possess some value in ameliorating the diarrhœa of phthisis. At the same time, it was found to act as a sedative diuretic and not to produce gastric irritation. The fluid extract was given in ♏ x. doses every six hours, and the administration prolonged. The drug has not come into general use. *Henry H. Rusby.*

GRIPPE, THE.—See *Influenza.*

GROWTH.—This article is divided for convenience into four sections: I. Definition of growth. II. Growth as a function of cells and tissues. III. Human growth statistically considered. IV. The laws of mammalian growth.

I. Definition of Growth.—Definitions of growth are almost as numerous and various as the writers on the subject. Among these we may distinguish two principal points of view. According to one of these, growth is defined as increase of size or volume. From this point of view any increase of volume is growth no matter to what cause it may be due, and differentiation is regarded as an entirely distinct phenomenon which may or may not accompany growth.

From the other point of view the term growth implies in a general way an increase in the number or size, or in both, of the histological elements; and also, but more vaguely, implies that the elements advance, or at least remain stationary in the scale of organization. In other words, if the increase in volume be due to developmental processes, or if it be accompanied by progressive differentiation, it is growth. But if, on the other hand, increase of volume be due to the deposition of products of degeneration, as, for example, fat, it cannot properly be regarded as growth. This definition is not so definite as the first, which, therefore, should be preferred.

II. Growth as a Function of Cells and Tissues.—It is evident that the growth of an organism is the sum of the growths of its tissues, and the growth of the tissues depends on that of the cells; hence growth ultimately rests upon, first, the increase in size of single cells, and, second, the multiplication of cells. Owing to their peculiar mode of growth, the plants afford the best material for the study of the process in its simplest form. At the tip of each stem or rootlet there is a mass of cells in an embryonic condition, and during rapid growth these cells undergo frequent cell division. There is at the extreme tip a cell or a group of cells that always divide by a transverse partition into a distal and a proximal daughter cell or cells. The daughter cell at the tip, the distal one, remains in an embryonic condition and divides again in the same manner. In this way the proximal daughter cell becomes separated from the tip by the successive divisions of the apical cell or group of cells. If we follow one of the proximal cells through its life history, we shall see that it at first divides repeatedly, forming a group of small cells with dense protoplasm and thin cell walls. This is the period of most rapid multiplication. A little later the process of cell division becomes less frequent in this group, and the cells become larger and exhibit large vacuoles containing a clear watery fluid. This is the period of greatest growth. Finally, the cells cease both to multiply and to increase in size; and the cell walls become thickened and assume the character of the tissue to which these cells belong. This is the period of histological differentiation.

In the development of the plant cell, then, may be recognized three stages: (1) Multiplication, (2) growth, and (3) histological differentiation. These three stages are represented by three zones in root or stem. The zone of multiplication surrounds the tip and extends but a short distance from it. Here growth takes place but slowly, so that between one act of division and the next a cell may double in size. But the most rapid growth is in the next zone, where a cell may increase to several times its original size without undergoing division. Sachs studied the daily rate of growth of the root of a bean (Phaseolus). A disc 1 mm. long was carefully marked off just behind the tip and was then measured daily. The rate of growth was found to increase from a little over 1 mm. on the first day to a maximum of about 14 mm. on the seventh day. After that the rate decreased rapidly to about 2 mm. on the tenth day. Ciesielski observed the rate of growth of different areas in the roots of several leguminous plants. The rootlets were marked off in half millimetres and the amount of growth in each space was measured after twenty hours. It was found that there was practically no growth in the first millimetre. Beyond that the rate increased gradually to the third or fourth millimetre, reaching there in the different species a rate of 1.8 to 2.6 mm. in twenty hours, and then the rate decreased again until at a distance varying from 5 to 6.5 mm. from the tip growth in length was found to have ceased.

From an analysis made by Kraus upon hothouse plants of *Heterocentron roseum* it was found that the percentage of water in the tissues increases from 73 per cent. at the tip of the stem to 88 per cent. at the first internode, and reaches a maximum of 93 per cent. in the second internode. Farther along the stem there is a slight decrease, the amount being 92.7 per cent. in the fifth internode. In plants, then, it appears that the period of most rapid growth is also the period of most rapid absorption of water by the cells.

In animals we do not find this division into zones of growth, and there is, as a rule, no area of embryonic cells to furnish material for growth for an indefinite period. On the contrary, the extent of growth for each species is more or less strictly limited by conditions of which we know very little. In the period of cleavage of the egg and anatomical differentiation (see article *Differentiation*) the whole embryo is in the condition found at the tip of the stem of a plant. The cells are all small, rich in protoplasm, and undergo division frequently, while there is little or no growth of the embryo as a whole. Then comes the period of most rapid enlargement accompanied by an increase in the amount of water, and this is followed by the period of histological differentiation. The rate of growth per unit of body weight decreases gradually until the animal reaches the limit of its species.

This was brought out by Davenport (1875) in his researches upon the embryos of frogs, the results of which are given in the following table:

GROWTH OF FROG EMBRYOS.

Days after hatching.	Average weight in milligrams.	Weight of dry substance in milligrams.	Weight of water in milligrams.	Per cent. of water.	Average increase daily in per cent. of body weight.
1	1.83	0.80	1.03	56	
2	2.00	.83	1.17	59	9.7
5	3.43	.80	2.63	77	23.9
7	5.05	.54	4.51	89	23.8
9	10.40	.72	9.68	93	54.0
14	23.52	1.16	22.36	96	25.2
41	101.0	9.9	91.1	90	1.2
84	1,989.9	247.9	1,742.0	88	

The frog embryo takes no food for several days after hatching, so that there is a loss of dry substance until about the eighth day; and yet it is between the seventh and ninth day that there is the greatest daily increment per unit of body weight. As the percentage of dry substance increases the rate of growth becomes less. The time of most rapid growth is the time when the cells absorb water most rapidly.

Similar results were obtained by Fehling (1877) from the measurement and analysis of twenty-one fresh human embryos, as shown in the following table:

GROWTH OF HUMAN EMBRYOS.

Number.	Length centimetres.	Sex.	Age.	Weight.		Per cent. of water.
				Fresh grams.	Dry grams.	
1	2.5	F.	6th week	0.975	0.24	97.54
2	15.0	M.	4th month	36.5	3.0	91.79
3	13.5	M.	4th month	56.5	5.1	90.97
4	18.5	M.	5th month, 1st half.	95.5	8.9	90.7
5	18.5	M.	5th month, 1st half.	104.7	8.2	93.2
6	19.0	F.	5th month, 2d half.	156.8	14.6	90.7
7	21.5	M.	5th month, 2d half.	244.0	22.0	90.96
8	22.5	M.	5th month, 2d half.	235.0	24.0	89.81
9	23.0	F.	5th month, 2d half.	264.0	29.5	88.9
10	24.0	F.	5th month, 2d half.	299.0	32.8	89.3
11	26.0	M.	6th month	361.8	39.1	89.2
12	30.0	F.	6th month	575.0	79.5	86.4
13	33.5	M.	6th month	771.0	125.2	83.77
14	34.5	F.	7th month	910.0	159.0	82.6
15	34.0	M.	7th month	832.9	138.2	83.5
16	36.0	F.	7th month	836.0	136.5	83.9
17	35.0	M.	7th month	1,117.0	170.71	84.8
18	38.0	M.	8th month	928.0	159.5	82.9
19	53.5	M.	Term	3,284.0	855.52	74.1*
20	44.0	M.	9th month	1,760.6	456.1	74.7†
21	45.0	M.	9th month	1,495.7	391.2	73.9‡

* Still-birth. † Died in uterus.
‡ Premature birth; atrophic; died thirteen days later.

It will be noticed that the youngest embryo, in the sixth week, contains the largest proportion of water, 97.54 per cent. From that the proportion decreases to about 74 per cent. at the time of birth. These figures should be compared with the next table in which Fehling summarizes his results as to the increase of weights.

INCREASE OF WEIGHT OF HUMAN FŒTUS.

	Weight at beginning of period. Grams. *a.*	Absolute monthly growth. Grams. *b*	Relative monthly growth. $\frac{b}{a}$
Second month	1	3	3.0
Third month	4	16	4.0
Fourth month	20	100	5.0
Fifth month	120	165	1.29
Sixth month	285	350	1.22
Seventh month	635	585	.92
Eighth month	1,220	480	.39
Ninth month	1,700	540	.31
Tenth month	2,240	1,010	.45
Term	3,250		

The relative monthly growth is high in the second month and increases to a maximum in the fourth. After that there is a decrease, sudden at first, and then more gradual.

For comparison with the growth of the human embryo Fehling studied the growth of embryo rabbits. For this purpose he reckoned the age of the fœtus in periods of three days, each period being supposed to correspond to a month of human gestation. Two embryos, the largest and the smallest, were chosen from each litter for analysis. Some of his results are given in the following table:

WEIGHT OF RABBIT EMBRYOS.

Number.	Weight of mother.	Period.	WEIGHT OF FŒTUS IN GRAMS.		Per cent. of water.
			Fresh.	Dry.	
1	1,850	5	0.619	0.052	91.5
2	1,850	5	.663	.057	91.4
3	1,500–1,600	7	10.631	1.5	85.9
4	1,500–1,600	7	12.83	1.7	86.7
5	....	8	23.6	3.5	86.3
6	....	8	24.6	4.0	83.8
7	....	8	15.95	2.25	85.9
8	....	8	12.3	2.0	82.2
9	1,806	8	18.61	2.94	84.2
10	1,806	8	18.68	2.32	87.6
11	3,240	9	62.35	11.35	81.8
12	3,240	9	45.78	7.6	85.6
13	2,854	9	41.98	8.0	81.0
14	2,854	9	50.33	9.33	81.5
15	1,800	9	29.25	4.9	83.2
16	1,800	9	28.56	5.83	79.6
17	About 1,800	10	34.29	7.22	79.0
18	About 1,800	10	33.05	6.7	79.7
19	....	New-born	38.4	8.4	78.4
20	....	New-born	38.3	8.8	77.1
21	....	14 days.	179.5	43.8	75.6
22	....	14 days.	224.0	75.4	65.1

The weight of the mother has great influence on the weight of the fœtus, and is given for that reason in this table. This factor is of less importance in human statistics, where the range of variation is comparatively much restricted.

The table shows a gradual decrease in the percentage of water in the tissues of the fœtus, and this is associated, as in man, with a gradual decrease in the relative rate of growth as shown in the following table:

GROWTH OF RABBIT EMBRYOS.

Period	Weight at beginning of period. Grams. a	Absolute growth during period. Grams. b	Relative growth per period. $\frac{b}{a}$
5	0.619	5.557	8.97
6	6.176	5.558	.89
7	11.734	6.916	.59
8	18.65	10.258	.55
9	28.908	4.762	.16
10	33.67	4.68	.13
Term	38.35		

The figures for the sixth period in this table are somewhat doubtful, for there is nothing to show that they were obtained by actual observation.

Per period the relative growth of the rabbit embryo appears to be less than that of the human embryo, but the period in the former case is only one-tenth as long as in the latter. The relative daily growth of the two, as calculated by Fehling for each period, is as follows:

RELATIVE DAILY GROWTH OF FŒTUS.

Period.	Man.	Rabbit.	Period.	Man.	Rabbit.
2	0.1		7	0.032	0.197
3	.142		8	.014	.183
4	.178		9	.011	.054
5	.049	2.99	10	.015	.046
6	.044	.305			

The more rapid rate of relative daily growth observed in the rabbit is associated, according to Fehling, with a greater percentage of water in the tissues.

All these results tend to show that in both animals and plants the most rapid increase in weight in proportion to the weight of the body takes place at the time when the tissues are at their least density. As the solid constituents of cells increase the relative rate of growth decreases.

Little is known of the effects of external conditions upon the rate of growth of animals, but upon the growth of plants external conditions have been shown to have a very marked effect. For a full discussion of this subject the reader should consult Davenport's very excellent summary ("Experimental Morphology," vol. ii., 1899).

III. GROWTH OF MAN.—We know very little concerning the earlier period of the growth of man, since the growth of the fœtus and of the infant has been but little studied. We have numerous observations on the weight of the child at birth, and on the growth from the fifth to the twentieth year (during the school age); some on the growth up to twenty-five years, referring chiefly to the upper classes (college and university students), and valuable statistics of men in armies have been compiled. As regards the growth and size of man, American investigations easily lead, for the anthropometric work of Gould and Baxter, and the researches of Bowditch, on Boston school children, and of Porter on the school children of St. Louis, have never been approached in value. Peckham's work in Milwaukee is also excellent. Quetelet, the pioneer in this field, pursued an erroneous method, which led him to false conclusions, which are, nevertheless, still currently cited, especially in Europe.

We divide the subject as follows: 1 Growth of the fœtus; 2, weight of the new-born child; 3, growth of infants, 0 to 5 years; 5, growth of children; 6, size of adults.

1. *Growth of the Fœtus.*—The difficulty of determining the age of the human fœtus, and of obtaining specimens certainly fresh and normal, has prevented our having any very definite information on this subject. Preyer has compiled the following table of the length of the human embryo in centimetres:

Lunar month.	Toldt (200 obs.).	Hennig (100 obs.).	Hecker.
First	1.5 (1.3)	0.75	......
Second	3.5	4.0	......
Third	7.0	8.4	4 to 9
Fourth	12.0	16.2	10 to 17
Fifth	20.0	27.5	18 to 27
Sixth	30.0	35.25	28 to 34
Seventh	35.0	40.25	25 to 28
Eighth	40.0	44.3	39 to 41
Ninth	45.0	47.2	42 to 44
Tenth	50.0	(49.0)	45 to 47

If the absolute length at the end of each month is divided by the increase during that month we obtain what Preyer calls the relative growth. Hennig's figures give the following relative growth for each month: First, 1,000; second, 0.812; third, 0.523; fourth, 0.419; fifth, 0.410; sixth, 0.219; seventh, 0.124; eighth, 0.093; ninth, 0.069; tenth, 0.037. All the above data are obviously inexact. Toldt's are evidently cooked up, and not derived from observation; nor do the lengths mean the same thing, for of the early stages the head and trunk only were measured; of the later stages the head, trunk, and legs. A falser and more misleading device for studying growth has never been put in practice. The fœtus, too, being spirally coiled in early stages, cannot have its length determined accurately. Far better would it be always to determine the weight. The growth of the fœtus in weight has been most inadequately studied, although the weight is the *only* available measure of the growth of the fœtus as a whole. Hecker's data are perhaps the best. The weights are in grams:

Month.	Maximum.	Minimum.	Average.
Third	20	5	11
Fourth	120	10	57
Fifth	500	75	284
Sixth	1,280	375	634
Seventh	2,250	780	1,218
Eighth	2,438	1,093	1,569
Ninth	2,906	1,500	1,971
Tenth	....	1,562	....

The range of the maxima and the minima suggests that errors in the determination of the ages may have occurred—such errors of a month are not rare with obstetricians. These figures may be compared with Fehling's, given in the preceding section.

Appended here are Hecker's data as to the weight of the placenta in grams, and the length of the umbilical cord in centimetres:

Month.	No. of obs.	Placenta.	Cord.
Third	3	36	7
Fourth	17	80	19
Fifth	24	178	31
Sixth	14	273	37
Seventh	19	374	42
Eighth	32	451	46
Ninth	45	461	47
Tenth	62	481	51

2. *Weight of the New-born Child.*—It is subject to very considerable variations. For middle Europe the average may be held to be about 3,340 gm. for boys, 3,190 gm. for girls, the latter being somewhat lighter. The variations are very great, ranging from 1,000 to 5,000 gm. For instance, the following table is given by Pfannkuch, who unfortunately jumbles the two sexes together:

Kilograms.	Obs.	Kilograms.	Obs.
1.50 to 2.0	23	3.00 to 3.25	150
2.00 to 2.25	36	3.25 to 3.50	115
2.25 to 2.50	52	3.50 to 3.75	79
2.50 to 2.75	90	3.75 to 4.00	46
2.75 to 3.00	110	4.00 to 4.50	13

It will be noticed that the maximum number of cases (150) falls between 3.00 and 3.25 kgm., and that the further the weight is removed on either side, above or below, from this mean, the fewer are the cases. The tables by other authors show the same general results, with usually slight differences in the quantitative values. For the most part these tables cannot be combined with one another, for they nearly all fail to fulfil some obvious requirement of good statistics; indeed, amateur statistics are generally provoking to the expert. It is, therefore, not desirable to attempt an analysis of the recorded data. As an example of statistics at once valuable and grossly defective, the following table is given after Siebold. The author gives the weights in pounds, but has neglected to say, as is necessary in Germany, what kind of pounds; hence the metric equivalents cannot be calculated. Moreover, the number of cases weighing even pounds and half-pounds is far in excess of those weighing pounds, and one-fourth or three-fourths, which shows inaccurate weighing, of course. To correct this the quarter-pound groups of the original table are condensed into half-pound groups:

Weight in lbs.	Boys.	Girls.	Weight in lbs.	Boys.	Girls.
4.0 to 4.5	4	10	7.5 to 8.0	286	200
4.5 to 5.0	19	24	8.0 to 8.5	101	44
5.0 to 5.5	44	53	8.5 to 9.0	79	42
5.5 to 6.0	172	195	9.0 to 9.5	15	14
6.0 to 6.5	220	235	9.5 to 10.0	7	2
6.5 to 7	353	353	10.0 to 10.5	..	1
7.0 to 7.5	286	240	10.5 to 11.0	..	1

The extremes recorded in medical literature are very far apart, and statements of excessively large size are by no means rare, but can be received with incredulity only, as, for instance, the case reported of a still-born child weighing 8,250 gm.! (*Berliner klin. Wochenschr.*, 1878, No. 14.) Vierordt gives as the accredited extremes 717 gm. (Ritter), and 6,123 gm. (Wright).

The factors which determine the weight at birth are very obscure. It is, of course, safe to say, vaguely, that it depends on the nutrition of the fœtus; it is probable that individual differences in the rate of growth exist before as well as after birth, and it is probable that the length of gestation is the most influential single factor, to judge from my own experiments on the growth of mammals.

It has been demonstrated that the variations in the weight of the child depend upon various maternal circumstances.

First. It is correlated with the age of the mother, as is shown in the following table, giving the weight of the children in grams according to three observers:

Age of the mother.	Ingerslev.	Fassbender.	Petersson.
15 to 19 years	3,241	3,271	3,451
20 to 24 years	3,299	3,240	3,485
25 to 29 years	3,342	3,333	3,591
30 to 34 years	3,375	3,367	4,062
35 to 39 years	3,428	3,292	3,591
40 to 44 years	3,326		3,676

From such tables we learn that very young mothers have the smallest children, and those of about thirty-five years the heaviest. It is much to be regretted that the tables do not show the correlation by single years, and also the number of observations.

Second. The weight of the child increases with the weight (Gassner) and length (Frankenhäuser) of the mother. Gassner states that the weight of the child is to that of the mother as 1 to 19.13, or 5.23 per cent. of the maternal weight. Frankenhäuser states that if the height of the mother is less than 4 feet 6 inches, the child weighs 6 lbs. 15 oz.; if it is 4 feet 6 inches to 4 feet 11 inches, the child weighs 6 lbs. 25 oz.; if it is more than 4 feet 11 inches, the child weighs 7 lbs. 3 oz.

Third. The weight of the child increases according to the number of previous pregnancies, as indicated by the following table:

Number of pregnancies.	(Hecker.) Gm.	(Ingerslev.) Gm.
One	3,201	3,254
Two	3,330	3,391
Three	3,353	3,400
Four	3,360	3,424
Five	3,412	3,500
Six	3,353	

Here again we encounter faulty statistics, for it is not shown that we have any other effect than that of age, for the conclusion claimed cannot be established until it is proved that primiparæ have smaller children than multiparæ *of the same age.*

Fourth. Negri has maintained (*Annali di obstetricia*, 1885) that the compilation of three hundred and thirty-three observations shows that the children of women whose menstruation is early are larger than the children of those whose first menstruation is late.

Fifth and sixth, the influence of race and climate, which have not yet been subjected to any proper exact study.

In conclusion, I may add that it seems to me probable that all these influences produce their effect principally by prolonging or abbreviating the period of gestation. In other words, the variations in the weight of children at birth are to be referred immediately to two principal causes: (1) Differences in the age at birth; (2) individual differences of the rate of growth in utero.

3. *Growth of Infants.*—(*a*) *Alteration in weight during the first week.* There is an interruption of the normal rate of growth during a few days after birth, both in man and other mammals (Section IV.). It lasts for a variable period, and is variable in degree. In most cases, with the human species, it is so great as to cause an actual loss of weight, but frequently it shows itself only as retarded growth. A great many authors have written upon this subject, but there is not a single one who appears to have correctly understood the statistical relations. In fact, the discussion thus far has turned upon the question whether a loss or a gain of weight is normal and physiological. That question is of little importance, since it is now settled that the retardation of growth is constant. It depends on the degree of retardation whether there is merely a small gain or an actual loss. During the first month the average daily increase is about 35 gm. (Fleischmann), but during the first two or three days, or sometimes more, the rate of increase is very much less, often even negative. Gregory, for instance, gives the following data:

Day	1	2	3	4	5	6
Number observed	33	33	33	33	33	33
Weight change, grams	−139	−64	+33	+50	+50	+36

The retardation of the growth is prolonged by defective nutrition, of which the cause may lie in either the mother or the child, and by illness of the child. A healthy baby ought to get back to its initial weight by the sixth or seventh day, and failure to reach the initial weight by the ninth day may be taken as an indication of illness.

The cause of the post-natal retardation is not fully elucidated. That it is not due to the mother's condition is

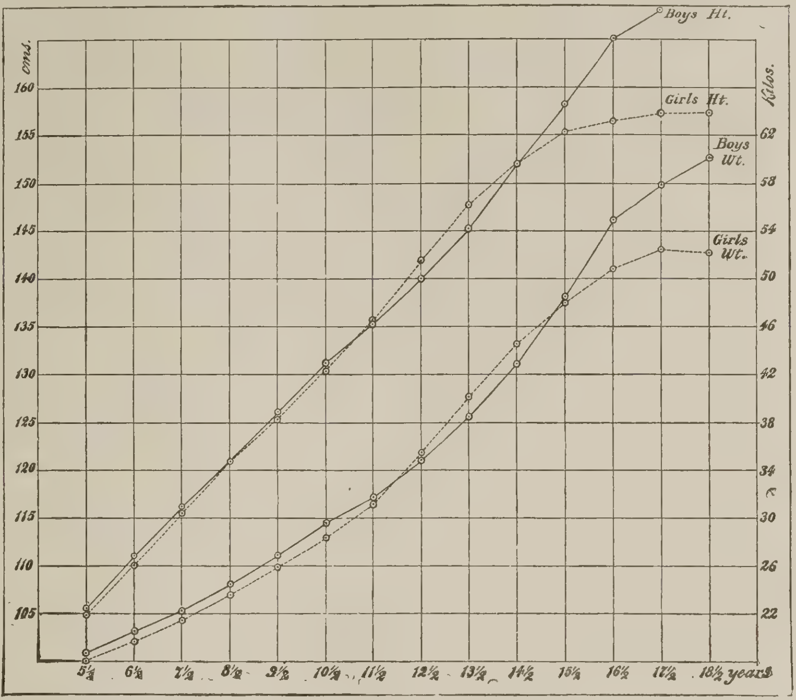

FIG. 2350.—Graphic Representation of the Growth of Boston School Children, based on the whole number of Bowditch's observations, irrespective of nationality of parents.

shown by two considerations: (1) The retardation occurs also in chicks at hatching, although they are not dependent on the parent for nutrition; (2) Ingerslev put sixteen children, just born, to wet-nurses, who had borne four to five days previously and gave abundant milk, nevertheless the children all lost weight. It seems probable that the loss is due to the establishment of respiration, and to the increased expenditure (metabolism) of the body to maintain the normal temperature. During gestation and incubation the parent supplies caloric to its young, but after birth (or hatching) the young is self-dependent, and rapidly wastes its tissues to keep up its body warmth.

(*b*) *For the growth from the first to the fifty-second week* we must depend chiefly on—(1) the careful compilation given by Meek and quoted by Vierordt, in which, however, the sex, nutrition, race, and social condition of the children are not considered, all factors which have a very great influence on the weight; (2) the observations of Albrecht (*Central-Zeitung f. Kinderheilkunde*, 1879, No. 7), who followed the growth of eighty children at Berne. From Meek the following data are excerpted:

Week.	No. of observations.	Weight, gm.	Week.	No. of observations.	Weight, gm.
First	22	3,228	Twenty-eighth	21	7,187
Second	25	3,367	Thirty-first	19	7,524
Third	31	3,412	Thirty-fourth	19	7,842
Fourth	31	3,532	Thirty-seventh	18	8,126
Seventh	33	4,103	Fortieth	17	8,344
Tenth	34	4,600	Forty-third	17	8,533
Thirteenth	36	5,022	Forty-sixth	17	8,760
Sixteenth	34	5,529	Forty-ninth	15	8,995
Nineteenth	32	5,864	Fiftieth	15	9,102
Twenty-second	26	6,497	Fifty-first	14	9,198
Twenty-fifth	23	6,925	Fifty-second	8	(10,172)?

Albrecht states that in his experiments, taking the weight of the child at 3,300 gm. at birth, the following is the average daily increase for each month in grams:

Month	1	2	3	4	5	6	7	8	9	10	11	12
Grams	30	29	29	24	20	18	14	11	11	9	8	7

The corresponding figures by Bouchaud are:

Month	1	2	3	4	5	6	7	8	9	10	11	12
Grams	25	23	22	20	18	17	15	13	12	10	8	8

By Fleischmann:

Month	1	2	3	4	5	6	7	8	9	10	11	12
Grams	35	32	28	22	18	14	12	10	10	9	8	6

The individual variations are very great, and the growth of any individual goes by fits and starts. A considerable delay in growth is not important, even if lasting for several, say three or four, weeks, as it is counterbalanced by a subsequent excessively rapid growth.

(*c*) *Concerning the Growth from the End of the First to the End of the Fifth Year.*—No statistics sufficiently extensive and accurate to be worth quoting are known to me. Quetelet's, which are often repeated; are misleading, because he weighed only children which in his judgment were well developed; hence, his figures do not give an average of anything except Quetelet's notion of what a child ought to be, which is now definitely known to be essentially different from what children are.

5. *Growth of Children.*—Concerning school children we possess a good many valuable data. The best statistics by far are those of Bowditch. The average weights obtained by him are given in the accompanying table in kilograms; the clothes make up about eight per cent. of the weights given. The average standing heights, without shoes, is given for both sexes in the same table. These data refer to nearly twenty-five thousand measurements on the school children of Boston, Mass.

GROWTH OF BOSTON SCHOOL CHILDREN.

Age.	Boys.			Girls.		
	Height in cm.	No. of observations.	Weight, kgm.	Height in cm.	No. of observations.	Weight, kgm.
5 to 6 years	105.6	848	18.64	104.9	605	17.99
6 to 7 years	111.1	1,258	20.49	110.1	987	19.63
7 to 8 years	116.2	1,419	22.26	115.6	1,199	21.53*
8 to 9 years	121.3	1,481	24.46	120.9	1,299	23.61*
9 to 10 years	126.2	1,437	26.87	125.4	1,149	25.91
10 to 11 years	131.3	1,363	29.62	130.4	1,089	28.29
11 to 12 years	135.4	1,293	31.84	135.7	936	31.23
12 to 13 years	140.0	1,253	34.89	141.9	935	35.53
13 to 14 years	145.3	1,160	38.49	147.7	830	40.21
14 to 15 years	152.1	908	42.95	152.3	675	44.65
15 to 16 years	158.2	636	48.56	155.2	459	48.12
16 to 17 years	165.1	359	54.90	156.4	353	50.81
17 to 18 years	168.0	192	57.84	157.2	233	52.41
18 to 19 years	169.3	84	60.13	157.3	155	52.24

* In Bowditch's tables, as printed, incorrect numbers are given.

The results are more easily followed in the graphic representation, Fig. 2350; the ordinates represent the heights or weights, the abscissæ, the ages. We can distinguish three periods: (1) The steady growth of childhood, up to ten and one-half or eleven years in girls, to twelve or twelve and one-half in boys; (2) the period of præpubertal acceleration, when the growth is much more rapid, lasting in girls from eleven to fourteen or fifteen, in boys from twelve and one-half to sixteen and one-half; (3) the postpubertal decline. In girls the præpubertal acceleration begins earlier and is more marked than in boys; hence, though during childhood girls are smaller than boys, yet from twelve to fifteen they outstrip them, and are both taller and heavier than boys of the same age. Puberty ensues later in boys than in girls. The postpubertal falling off in growth is more rapid in girls than in boys; accordingly, after the fifteenth year boys gain fast over the girls. That the acceleration is really præpubertal is shown by the fact that the age of the first catamenia averages in Boston about fourteen and one-half years, so far as determined by the present imperfect statistics. Pagliani has proved the same relation in Italy. Most conclusive is the record of the growth of individuals, which demonstrates that the first menstruation is preceded by rapid, and followed by slower, growth.

Dr. Bowditch has shown, also, by his statistics that the children of American-born parents are, in the community of Boston, taller and heavier than children of foreign-born parents, a superiority which depends probably chiefly on the greater average comfort in which such children live and grow up, and partly upon differences of race and stock. The children of the well-to-do classes are taller and heavier than those of poorer classes. American (Boston) boys are taller for their age than English boys, concerning whom we have statistics, and are also heavier in proportion to their height; the comparison holds between the laboring classes and the upper classes both, as well as between boys taken without distinction. Incidentally it may be said that the popular conception of a "Yankee," as tall and slim, has no foundation in life, the Yankee, on the contrary, being stouter than the Englishman.

In general it may be said that growth is favored by healthful conditions; it is impaired by illness, probably, of any kind, but, of course, by some diseases much more than by others. It is favored by country more than by city life; by outdoor more than by sedentary occupations; by summer more than by winter; by vacation more than by attendance on school. A considerable body of statistical material on these and similar points is available, but unfortunately it is much scattered and has never been collated.

The growth of the organs calls for much further investigation. At present we can compare only the adult with the new-born child, but even of these the data are few. From Vierordt's compilation the following table is taken:

	NEW-BORN CHILD.		ADULT.	
	Weight in grams.	In per cent. of the body weight.	Weight in grams.	In per cent. of the body weight.
Skeleton	445	16.7	11,560	15.35
Muscle	625	23.4	29,880	43.09
Tendon		....		
Skin	337	....	4,011	
Brain	....	14.34	......	2.37
Suprarenals	8.5	.31	8.0	.014
Thymus	9.4	.54	5.0	.0086
Thyroid	6.5	.24	29.1	.05
Lungs	....	2.16	......	2.01
Heart	....	.89	......	.52
Liver	....	4.39	......	2.77
Kidney	....	.88	......	.48
Alimentary canal	....	2.53	......	2.34

The weights in grams and the percentages are from different authors. There are certain observations on the growth of organs, notably by Lorey, Frerichs, Bischoff, Bambeke, and Thoma, but the number of cases heretofore recorded is so small that no satisfactory statistics are possible.

It would be very interesting to know how the chemical composition of the body changes with age, and it is to be hoped that we shall soon have complete analyses of bodies at various ages.

6. *Size of Adults.*—No available statistics in regard to women are known to me, those referring to men, and taken from armies, are very extensive; the best worked out are the data in regard to the American army, as discussed by Gould and Baxter. The former had the material collected by the Sanitary Commission during the Rebellion; the records were hastily and inaccurately made by the single States, but the number of observations was so large that the errors may have corrected themselves to a considerable extent. Baxter, whose material was much more extensive and reliable, has not thought it worth while to tabulate the weights in proportion to age, but gives good tables of the stature.

GOULD'S TABLE OF THE MEAN WEIGHTS OF WHITE SOLDIERS.

Age.	No. of observations.	Weight, lbs.	Age.	No. of observations.	Weight, lbs.
16	216	121.03	36	184	149.29
17	456	128.02	37	167	148.81
18	1,100	133.93	38	153	147.22
19	1,150	137.05	39	123	146.38
20	1,357	141.38	40	98	150.01
21	1,446	143.06	41	61	146.30
22	1,351	143.60	42	102	146.97
23	1,108	144.31	43	73	145.62
24	1,059	146.31	44	83	152.79
25	745	146.84	45	67	147.06
26	599	147.05	46	37	146.97
27	551	146.93	47	19	145.05
28	512	147.21	48	35	146.82
29	386	145.51	49	10	145.19
30	395	147.62	50	21	138.06
31	242	147.65	51	12	144.25
32	298	146.00	52	10	139.49
33	225	148.53	53	11	151.15
34	225	148.29	54	8	159.60
35	339	145.57	Over 54	20	143.49

From this table the increase in weight is seen to continue up to about the thirty-fifth year, but the figures of the weights are irregular after the number of observations falls below 600. That the period of growth reaches to this age is more clearly shown by Baxter's table of the height at different ages.

TABLE OF AGES AND CORRESPONDING HEIGHTS (WITHOUT SHOES) OF 190,621 AMERICAN-BORN WHITE MEN FOUND FIT FOR MILITARY SERVICE.

Age.	Number of observations.	HEIGHT.	
		Inches.	Metre.
Under 17 years	468	64.11	1.6284
17 years	937	65.67	1.6675
18 years	30,456	66.39	1.6863
19 years	14,994	67.07	1.7036
20 years	11,526	67.51	1.7148
21 years	14,146	67.78	1.7216
22 years	10,479	67.92	1.7252
23 years	8,907	68.01	1.7275
24 years	7,335	68.02	1.7277
25 years	7,940	68.05	1.7285
26 years	6,986	68.09	1.7295
27 years	6,351	68.11	1.7300
28 years	6,033	68.13	1.7305
29 years	4,447	68.17	1.7315
30 years	6,256	68.18	1.7318
31 years	5,562	68.20	1.7323
32 years	4,635	68.20	1.7323
33 years	3,939	68.29	1.7346
34 years	2,782	68.35	1.7361
35 years	4,966	68.47	1.7391
36 years	4,138	68.28	1.7343
37 years	4,172	68.26	1.7338
38 years	4,014	68.24	1.7333
39 years	3,402	68.23	1.7330
40 to 45 years	15,750	68.23	1.7330

These tables show that it is necessary to be extremely cautious in fixing upon any year to mark the adult age, for the cessation of growth is so gradual that its ending cannot be determined. In practice, it is convenient and sufficiently accurate to call twenty-five the adult year; for women it ought probably to be somewhat less. That the tables are far from what we could wish is true, chiefly owing to the inherent defects of the original observations; we must also regret that Baxter did so much less than his material would have permitted. But, on the other hand, both Baxter and Gould are far in advance of their predecessors. Anthropometry has been much written upon. Baxter gives an excellent review of the subject, with sketches of the many mystical laws announced by older authors upon human proportions, but we still lack a good general treatise upon vital statistics.

IV. The Laws of Mammalian Growth.—Growth is a subject as yet but little investigated, and this section is based on Minot's experiments, made chiefly on guinea-pigs, but including also rabbits and chickens. The preceding table summarizes the most important general results of these experiments; the table refers only to male guinea-pigs, it not being necessary to include the females or other animals.

Growth of Male Guinea-Pigs.

Age.	Number of observations. Grams.	Average weight. Grams.	Increase over last measurement. Grams.	Average daily increase. Grams.	Daily per cent. increase. Grams.

160 to 170 days..	75	590.5	27.6	1.8	.3
175 to 185 days..	76	604.7	14.2	.9	.2
190 to 200 days..	70	627.0	22.3	1.5	.2
205 to 215 days..	61	663.3	36.3	2.4	.4
8 months.......	56	672.0	8.7	.3	.05
9 months.......	53	737.7	65.7	2.2	.3
10 months.......	56	761.6	23.9	.8	.1
11 months.......	68	770.3	8.7	.3	.04
12 months.......	68	793.9	23.6	.8	.1
13 months.......	66	754.9	− 39.0	− 1.3	− .2

The last column but one shows that the daily increase during the first three days is zero. This is due to the postnatal retardation, which is very marked in guinea-pigs, as it is also in man. The exact data are:

	Weight. Grams.	Increase.
At birth....................................	70.8	....
One day....................................	68.9	−1.9
Two days....................................	70.0	1.1
Three days....................................	73.4	3.4
Four days....................................	77.3	3.9

The daily gain slowly increases till about the fourteenth day, and then slowly but steadily falls off. The observations are so few in number that there are many irregularities, which need not be heeded in this article. Usually the absolute increment is taken as the measure of the *rate* of growth, which is not justifiable. To show the rate of growth—as well as the observations permit—is intended by the last column, which gives the daily increase for each period, calculated at a *percentage of the weight at the beginning of that period.* We thus secure values for legitimate comparisons, because the absolute increment during any period is the product of the amount of growing material multiplied by the rate of growth; hence, if the rate is to be found, the growing amount and the absolute increment being known, the amount must be divided by the increment; this was done, and the fractions so obtained converted, for readier comparison, into percentages. As regards the guinea-pig, it shows at once that as soon as the animal has recovered from the postnatal retardation its rate of power of growth declines steadily. The observations of Fehling upon the embryos of man and rabbits show that this retardation in the relative rate of growth begins long before birth, and observations on plants make it probable that it has its beginning with the commencement of histological differentiation. This fact leads, of course, to the assumption that the vital powers undergo a steady decline, and that instead of there being a period of development, followed at maturity by a period of decline, there is a continuous decline, of which the final term is the natural death of the organism. We must, in fact, fundamentally change our conceptions of the phases of life. A man builds a wall, which keeps growing, but as the man becomes tired it increases more slowly, and stops when he is worn out. So the vital forces build the body, which develops, but all the while the forces are losing their power. The comparison is somewhat faulty, but may help to a clearer conception of decline during development.

The constant loss in the rate, which appears to be the fundamental law of growth, at least in mammals and probably in all metazoa, may be shown in another manner very strikingly. If we calculate at what age after birth the animal will have added ten per cent. to its original weight, and then the age at which it will have again added ten per cent. to its weight at the end of the first period, and so on, we obtain the following table:

Growth of Male Guinea-Pigs.

Weights increasing at the rate of ten per cent. Grams.	Age at which they fall. Days.	Differences. Days.	Weights increasing at the rate of ten per cent. Grams.	Age at which they fall. Days.	Differences. Days.
70.80	0.0	....	244.34	38.8	5.2
77.88	4.1	4.1	268.77	43.7	4.9
85.66	5.6	1.5	295.64	50.2	6.5
94.22	7.7	2.1	325.20	59.2	9.0
103.64	9.6	1.9	357.72	68.6	9.4
114.00	11.8	2.2	393.49	77.3	8.7
125.40	14.0	2.2	432.83	88.6	11.3
137.94	16.2	2.2	476.11	100.7	12.1
151.73	18.7	2.5	523.72	120.0	19.3
166.90	21.7	3.0	576.09	160.6	40.6
183.59	25.3	3.6	633.69	201.3	40.7
201.94	28.7	3.4	647.05	258.2	56.9
222.13	33.6	4.9	766.75	298.3	40.1

To make the first addition of ten per cent. requires long, 4.1 days, owing to the postnatal retardation; the second addition takes only 1.5 days; the succeeding additions occupy increasing periods, overlooking slight irregularities. In other words, the older the animal the longer it requires to add ten per cent. to its weight. In this table, also, we see the decline progressing during the so-called period of development.

The same law of decline holds true for rabbits and chickens, and also for man. In man there is a very noteworthy modification, produced by the very marked præpubertal acceleration of growth, during which the decline is interrupted, as shown by my calculations from Bowditch's tables; but compared with the whole course of decline the interruption is but slight, and is counterbalanced by an over-rapid postpubertal decline. No essential importance is to be assigned to this phenomenon, since it is well known to embryologists that during development there are often displacements in time and in the growth of individuals. Minot observes that an accidental quickening or slowing of growth is followed by a reverse period, in the first case of slowing, in the second of quickening. There appears, therefore, no objection to the conclusion that in man also the period of apparent development is a period of real decline.

This leads us to the corollary that the stoppage of growth is not due to the reaching of maturity, but is merely the final term of a series of losses. It has been asserted by Herbert Spencer, Carpenter, and others, that there is an inherent opposition between growth and reproduction, because the assimilative processes cannot perform enough to supply material for the growth of mother and offspring both. These authors and their followers see in the commencement of reproduction the beginning of a tax upon the organism which stops its growth; but as Minot has pointed out, the cause is mistaken for the effect, and probably the loss of vital force is the stimulus causing reproduction. Certainly the decline, which goes on from birth, cannot be caused by a phenomenon which begins only when the decline is nearly completed. Direct observations show that Spencer's view is erroneous, for growing guinea-pigs will bear one-third of their own weight of young while growing, and still reach as full an adult size as those producing no young (Hensen). My own experiments suggest that they become even larger. We thus learn that the fundamental conception on which Spencer's theory rests is imaginary—that conception being, that the assimilative power is approximately equal only to the needs of the growing animal. In reality there is a large excess of assimilation possible within normal limits.

The next point to be noticed is that animals tend, as they grow, to approximate to the special size of the species. This shows itself by the fact that the range of variation is less for adults than for the young. The following table shows this: The first column gives the age; the second column gives the average variation above the mean weight for that age, the variation being expressed as a percentage; the third column gives the variation below the mean—averages being based on 4,200 observations in all

Male Guinea-Pigs.

Age.	Variation above. Per cent.	Variation below. Per cent.
0 to 0 day	19.51	19.49
1 to 15 days	18.95	18.99
16 to 30 days	17.13	16.87
31 to 65 days	15.68	16.31
70 to 140 days	12.12	13.31
145 to 215 days	7.52	7.48
8 to 12 months	10.66	9.72
13 to 17 months	10.38	11.41
18 to 24 months	12.10	10.82

The variation of adults is barely over half that at birth in range. Remarkable is the low variation from 145 to 215 days, and from 8 to 12 months. The higher values for older periods is perhaps due to variations in obesity, which we know from common observation increases in the human species with age. The growth of an individual also indicates the existence of this tendency to attain the typical adult size; if the growth of the animal is retarded by illness, after recovery the growth is accelerated to make up. This has practical importance, for, unless the illness of a child is very prolonged, no permanent effect upon its size is to be anticipated.

The size of an animal or the limit of its growth depends upon, first, the rate, and second, the duration of its growth. This is well shown by comparing man with the rabbit and the guinea-pig, as to the average daily growth. A man acquires a weight of about 63,000 gm. in twenty-five years; a rabbit, of the larger breeds, about 2,500 gm. in one year, and a guinea-pig about 750 in the same period. For man add 280 days, for rabbits 30 days, for guinea-pigs 68 days, on account of the period of gestation.

Man.................. 63,000 gm. ÷ 9,139 + 280 = 6.69 gm. per diem.
Rabbit................. 2,500 gm. ÷ 365 + 30 = 6.30 " " "
Guinea-pig........... 750 gm. ÷ 365 + 68 = 1.73 " " "

Man grows about as fast as a rabbit, but becomes much bigger, because he grows longer; but the rabbit is bigger than the guinea-pig, because he grows much faster. This is matter of common observation; all that we gain from our calculation is a quantitative expression more suited for ready comparison.

Of course, the whole shaping of the organism depends upon variations in the growth rates of the single parts, but what causes such variations is unknown. Many writers have sought to account for the variations by purely mechanical factors, principally strain and pressure; but although such assumptions have been very frequently put forward by His, van Beneden, Kölliker, and a host more, they must all be condemned as more or less ill-considered speculations. A growing trout assumes a certain form; why? because it is its inherited tendency; of the physiological nature of that tendency we know hardly anything, except that it is *not* mechanical, but only an unexplained growth force.

Literature.—The only general works are the very important treatise of Vierordt in Gerhardt's "Handbuch der Kinderkrankheiten," Bd. 1, Abth. 1, pp, 219–290; Davenport's treatise in the second volume of his "Experimental Morphology" (1899); and the useful summaries given by Preyer in his "Physiologie des Embryos," by Hensen in the sixth volume of Hermann's "Physiology," and Daffner, in "Das Wachstum des Menschen" (1897). The number of special papers is very large; a few references are given below; for additional ones consult Vierordt. *Charles Sedgwick Minot.*

GUACAMPHOL, the camphoric acid ester of guaiacol, occurs in white, needle-like crystals or powder, and is tasteless and odorless, and insoluble in the ordinary solvents. It is said to pass unchanged through the stomach, and to split up in the intestines into guaiacol and camphoric acid; so it has been employed as an intestinal antiseptic, particularly in tuberculous diarrhœas. It is especially recommended, however, by Kaminer and Lasker, for combating the night sweats of pulmonary tuberculosis. The dose is 0.5–1 gm. (gr. viij.–xv.) in capsule at bedtime. *W. A. Bastedo.*

GUACO.—The drug at present known by this name is only one of a number of products known by it in tropical America. It is the leaves of *Willoughbœa* Neck, or *Mikania* Willd., probably of more than one species (fam. *Compositæ*). It is a native of South America, and grows also, either wild or introduced, in the West Indies. Guaco has a great reputation among the inhabitants of many South and Central American countries as an antidote to snake bites, and as a sort of corollary it has been supposed to be useful in hydrophobia, cancer, cholera, epilepsy, syphilis, etc. Fauré separated an amorphous bitter principle (which is probably not chemically pure) which he has called *guacin.* An odorous principle that appears to be present in the fresh, must be mostly dissipated in the dried, leaves. There is nothing in its chemical or evident physical properties that should lead one to regard guaco as other than a mild aromatic bitter, of the Eupatorium order.

In its native regions it is preferably given in the fresh state. Here the dried leaves may be prepared in any of the usual ways, and rather freely administered.

W. P. Bolles.

GUAIAC, including Guaiac Wood, Guaiaci Lignum, or *Lignum Vitæ.* "The heart-wood of *Guaiacum officinale* L. and of *G. sanctum* L. (fam. *Zygophyllaceæ*)" (U. S. P.), and Guaiac, Guaiac Resin, Guaiaci Resina, or "*Gum Guaiac.*" "The resin of the wood of *Guaiacum officinale* L." (U. S. P.). These are small evergreen trees of northern South America and the West Indies, having the habit of a small apple-tree, and forming a brilliant mass of bright blue, when in full bloom.

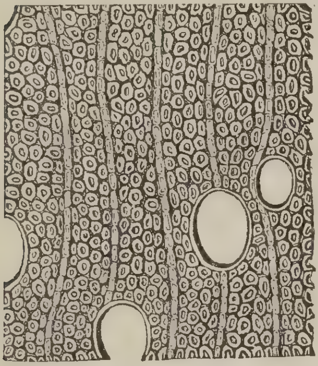

FIG. 2351.—Section of Guaiacum Wood. (Baillon.)

Guaiacum wood was carried to Europe soon after the discovery of the West Indies (early in the sixteenth century), and made a rapid reputation for itself as a remedy for syphilis and gout, a reputation that it unfortunately very soon lost again in great measure. Two products of the tree are imported—the wood, which if of fair size and soundness, goes to the turners to be made into pulley-sheaves, mallets, mortars, tool handles, etc., and the crude resin, rudely obtained from the living tree or fresh wood.

The wood comes in logs several feet in length, and from two to six or eight or more inches in diameter, often irregularly crooked and branching; they consist, excepting the smallest, of a bright yellow, hard *alburnum,* and a very dark greenish-brown, exceedingly hard and heavy heart, consisting of very much thickened wood cells, and an abundance of a peculiar composite resin. This wood is almost as hard and heavy as ivory, and turns the edges of tools not especially sharpened for it. That which reaches the drug market consists principally of the turnings and refuse of what is manufactured for the purposes above named. It should consist only of the brown or green heart-wood, which is heavier than water, to which it does not impart its color. Upon the addition of nitric acid, if it has not been deprived of its resin, it should give a dark, bottle-green color. The resin, of which there should be about 25 per cent., is the only active constituent, so that its properties are also those of the wood.

The resin, which is obtained partly by incising the trees, and partly as a spontaneous exudation, also sometimes forced out from the wood by heat, is a crude and impure substance. The officinal description is as follows: In irregular masses, or subglobular pieces, externally greenish-brown, internally of a glassy lustre, and, in recent guaiac, usually reddish-brown, transparent in thin splinters, fusible, feebly aromatic, the odor becoming stronger on heating; taste somewhat acrid; powder grayish, turning green on exposure to air.

Soluble in potassium or sodium hydrate T. S. and in alcohol; the alcoholic solution is colored blue on the addition of tincture of ferric chloride.

It is very brittle when cold, plastic with slight heat.

Composition.—It contains about seventy per cent. of *guaiaconic acid,* a yellow or brown, brittle, amorphous resin; ten of *guaiaretic acid,* which is crystalline; nine or ten of *guaiacic acid,* something like guaiaconic acid, and three or four of gum, besides a little volatile oil, ash, coloring matter, and various impurities.

Action and Use.—The reputation of guaiac depends upon clinical evidence entirely, and has had spells of waxing and waning. It is stimulating, or in large doses irritating to mucous membranes and markedly increases their secretions, thus acting as a laxative. The high estimate early placed upon it in syphilis has disappeared since the real efficiency of mercury and iodine has been established. In gout, although perhaps useful, it is certainly no specific; as an emmenagogue it is no better nor worse than many others. In chronic and mild subacute rheumatism, and in rheumatic arthritis, the evidence in its favor is strong. It is perhaps one of the best remedies for these intractable maladies. It is considerably used in inflammatory conditions of the throat and fauces, especially when there is deficient secretion.

Administration.—The dose of guaiac (resin) is from 0.5 to 2 gm. (gr. viij.–xxx.). It may be given in pill or powder, but the tinctures, of which there are two,—one simple (*Tinctura Guaiaci,* U. S. P., strength 20 per cent.), made with alcohol, and one associated with ammonia (*Tinctura Guaiaci Ammoniata,* U. S. P., strength 20 per cent.), made with aromatic spirit of ammonia,—are more generally used in doses of 2 to 4 c.c. (fl ʒ ss.–i.). Both become turbid upon mixing with water, and are oftenest given in milk. Guaiac wood is used as an adjuvant in the Compound Syrup of Sarsaparilla.

W. P. Bolles.

GUAIACETIN, pyrocatechin-mono-acetic acid ($C_6H_4.OCH_2.COOH.OH$), is a white, odorless, crystalline powder, readily soluble in water. Nièd and Meitner have used it with benefit in tuberculosis, claiming for it the special advantages that it promptly lowers temperature, lessens the mucous secretion, and diminishes the night sweats. It is an admirable stomachic (Meitner), and so may be continued even when chronic gastritis exists. The dose is 0.5 gm. (gr. viij.) three times a day in solution or capsule.

W. A. Bastedo.

GUAIACOL.—*Methyl-pyrocatechin.* $C_6H_4.OCH_3.OH$. Guaiacol constitutes from sixty to ninety per cent. of wood creosote, from which it is separated by fractional distillation, the boiling point of guaiacol being 206° to 207° C. Specific gravity, at 15° C., 1.33. It is a colorless liquid, with a strong aromatic odor, slightly soluble in water, 1 part to 85, readily soluble in alcohol, ether, glycerin, and oil. Guaiacol may also be prepared synthetically from catechin, and by the dry distillation of guaiacum resin. From these sources it is obtained in colorless, prismatic crystals. These are considered to be absolutely pure guaiacol, and are official in the Paris Codex. The guaiacol of commerce is very variable in strength and often very impure, the impurities being such as are common in creosote and are the result of careless distillation. The adulteration is evident by the lower specific gravity, the stronger odor, and by becoming darker upon exposure. The pure guaiacol, with concentrated sulphuric acid, gives a faint yellow coloration which is changed to a cherry-red by the addition of acetone; the impure article gives a more or less red color with the acid alone.

Guaiacol is absorbed from the stomach or intestines, from the unbroken skin, and by inhalation. It is rapidly excreted and may be detected in the urine, saliva, or perspiration within fifteen minutes. In twenty-four hours it is entirely excreted. Guaiacol may be detected by distilling the solution with dilute sulphuric acid, and adding to the distillate a small quantity of a dilute solution of liquor ferri sesquichlorati (two or three drops to a test tube of water). If guaiacol is present a reddish-brown color is developed, the intensity of which depends upon the amount of guaiacol.

The action of guaiacol is the same as that of creosote, the advantages claimed for it being its greater purity and more definite composition. Locally, it is antiseptic and analgesic, and when administered by the mouth it exercises the same effect upon the stomach and intestinal tract. Its action after absorption is as yet not well understood. Many consider that its beneficial effects are produced simply by its tonic and stomachic action; others, including Schueller who brought it to the notice of the profession, ascribe its virtues to a direct antiseptic action which destroys all bacterial growth that comes under its influence. Another and more recent view is that it combines with the toxins of the pathogenic bacilli, forming soluble compounds which are rapidly eliminated by the excretions.

The superiority of guaiacol over creosote, in the treatment of tuberculous conditions, was first advocated by Prof. Max Schueller, of Berlin, in 1880.[1] In his work, the author relates the experience which he derived from administering various drugs to animals affected with tuberculosis. Creosote, guaiacol, benzoate of soda, and many similar drugs had been experimented with and he had selected guaiacol as the most effective. In 1891[2] he published a second treatise in which he reviewed the work which he had carried on during the intervening years, and explained in detail his method of employing it. In all forms of tuberculosis he administers it continuously in small doses, as in his experience large doses were not of any special value. He particularly insists upon its continued use, which should be followed for some months after the bacilli have disappeared. He advocates, for children, a dose of two or three drops, and for adults one of from three to five drops, four times daily. He gives it in plain water, to which a little table salt has been added, and sometimes in milk, wine, or spirits. In surgical tuberculosis, in addition to its internal use, he also injects it directly into the diseased part, or, if the surface of the skin has already been destroyed, he curettes the tissues and applies the guaiacol directly to the denuded surface.

Although guaiacol has not replaced creosote in the treatment of tuberculosis, it is very extensively employed and is one of the drugs looked upon with favor in this disease. Experience has shown that it does not possess all the virtues which were originally attributed to it, but reports indicate that it is used with much success and by many it is thought to be of great value. Its use is not limited to tuberculous conditions. It has been employed with favorable results in all septic diseases, in puerperal and typhoid fevers, erysipelas, pleurisy, bronchial catarrh, whooping-cough, and many local inflammatory conditions.

The method of administering guaiacol varies. Many prefer to give it in continuous small doses, from three to five minims three times a day, as advised by Schueller, while others adopt the ideas of Sommerbrodt in the use of creosote, and give it in rapidly increasing doses for the purpose of saturating the system and acting directly upon the pathological processes. With this in view the quantity may be increased by one drop at each dose until fifteen drops, three times a day, are given, and this dose is to be maintained for an indefinite period. It has been demonstrated that as much as sixty minims three times a day may be given without ill effect.[3] When the remedy is given in large doses or when its use is continued for a prolonged period, the action of the kidneys should be watched, as any interference with this function would cause an unexpected retention of the drug in the system.

It should always be administered well diluted, in milk, wine, spirits, or water. The addition of a vegetable bitter, as tincture of orange, gentian, or cardamoms, serves to disguise its taste and to add to its stomachic properties. If capsules are selected they should always be followed with draughts of water or some diluent.

If for any reason the remedy cannot be given by the mouth, enemata may be adopted, and the following formula has proved satisfactory: guaiacol, gr. vij.; sweet almond oil, ʒ iss.; gum acacia, ʒ i.; water, ℥ viij.

With a view of increasing its therapeutic action its use subcutaneously has been advocated. At the International Congress of Medicine, Paris, 1890, Dr. Weill reported an experience extending over eleven years. He dwells upon the importance of using the crystals and saturating the system. The formula is as follows: Crystalline guaiacol, oil of sweet almonds sterilized, each 10 gm.; hydrochlorate of cocaine, 2 cgm.; to be dissolved in an equal quantity of water. This is kept in a dark bottle and 1 c.c. is injected into the gluteal region daily. Other methods of giving the guaiacol are adopted at the same time, and they furnish a good example of "intensive guaiacolization." Thus, for example, every night the same solution is applied to the skin over the chest, and enemata of milk, containing forty drops of the solution, are employed. The drug is also given internally. Weill advises that this treatment should be continued for several months, with intervals of eight or ten days every three weeks.

Iodoform, eucalyptol, and other similar drugs have been combined with guaiacol for use subcutaneously. Of these iodoform is the most favored.[4] The drugs are dissolved in sterilized oil and injections of iodoform, one-sixth grain, with guaiacol, one grain, are given daily.

The submucous injections have been advised in laryngeal tuberculosis; and inhalations from respirators, or from heated water, have proved of much service.

The local use of guaiacol has not been adopted to any extent, but favorable reports of its employment in this manner are met with. A five to ten per cent. solution in sterilized olive oil is used with rigid antiseptic precautions. From ten to fifteen minims are injected deeply into the diseased tissue, in two or three places, and the operation is repeated once or twice a week. In addition to its action upon the disease, guaiacol is thought to promote the formation of fibrous tissue by its astringent and congestive properties. It must, however, be used with care, as it may produce much local irritation.

The absorption of guaiacol through the unbroken skin is very rapid, and advantage is taken of this to obtain its physiological effects. Fifty to sixty minims are applied to the surface, and the part is covered with oil silk. Within fifteen minutes, the pulse relaxes, the skin becomes cool and moist, and the temperature begins to fall. The effect lasts for four or five hours. The application may be repeated night and morning according to the course of the fever. This method of employing the remedy calls for the exercise of care, as the reports of ill effects show that they generally occur when it is used in this way. On account of the rapid absorption of the drug, the fall of temperature may be rapid, descending below normal, with cold extremities, clammy skin, feeble pulse, and other indications of threatened collapse.

Guaiacol combines with the metals to form crystalline salts, but these are not of therapeutic value, owing to their being very unstable. With acid radicles it forms permanent salts and many of these have been prepared as agreeable substitutes for the crude drug. Most of them have been issued under registered trade names and freely advertised.

Guaiacol Benzoate, "Benzosol": $C_6H_4OCH_3OCOC_6H_5$. A crystalline salt in which one atom of hydrogen is replaced by a benzoyl radicle. It occurs in small colorless, tasteless, and odorless crystals, nearly insoluble in water. It contains fifty-four per cent. of guaiacol, and after administration it slowly breaks up into its constituent elements, guaiacol and benzoic acid.

It is given in doses of from five to ten grains, three times a day. It is used in all conditions in which guaiacol is indicated, and is thought to be particularly serviceable in intestinal tuberculosis and diarrhœa.

Guaiacol Carbonate, "Duotol": $(C_6H_4OCH_3O)_2CO$, a neutral, white, tasteless, odorless powder. Insoluble in water, containing ninety-one per cent. of guaiacol. In contact with the alkaline secretions of the intestines it breaks up into guaiacol and carbonic acid. The minimum dose is eight grains three times a day. Guaiacol carbonate is the most popular of the guaiacolates, probably from its being extensively advertised as duotol. It has been much used in tuberculosis and in typhoid fever, and as an antiseptic in various intestinal disorders. Reference may here be made to *cresotol* which closely resembles guaiacol carbonate, it being the carbonate of creosote, including guaiacol as well as the other constituents. It was introduced by von Leyden[5] and has been very much employed in the same conditions for which guaiacol has been used. It is a transparent liquid, odorless, but having a bitter taste. The dose at first should be five minims, and then it should be gradually increased. Doses as large as a teaspoonful have been given for a prolonged period without ill effects.[6] Professor von Leyden advised that five minims be given three times a day, and that the dose should be increased from day to day by three drops until twenty-five drops were reached; this to be continued for a few weeks and then gradually reduced to the original dose. Such a course should be repeated if necessary.

Guaiacol Cinnamate, "Styracol": $C_6H_4OCH_3OC_9H_7O$. A German proprietary medicine patented under the latter name. In the intestines it is decomposed into its two constituents, and the beneficial effects of cinnamic acid, as well as those of guaiacol, are manifested. It, however, has not been much employed.

Guaiacol piperidin, "Guaiaperol." A compound occurring in granular crystals, soluble in thirty parts of water, with a slight odor of creosote. It has been employed in the treatment of pulmonary tuberculosis and it is thought to possess the stimulating properties of piperidin in addition to the action of guaiacol. Dose: from five to thirty grains.

Guaiacol Valerianate, "Geosote." A liquid combination of guaiacol and valerianic acid, having the characteristic odor of valerian. Dose: five minims in capsules. This preparation has received much attention and is thought to have a particular value as an application in local forms of tuberculosis. It has been used in the Loomis Sanatorium for consumptives and reported upon favorably.[7]

Guaiacol salicylate; g. phosphate; g. phosphite; potassium guaiacol-sulphonate or "thiocol"; *quinine guaiacol-sulphonate,* or "guaiaquin"; *calcium guaiacol sulphonate,* or "guaiacyl"; and many similar derivatives of guaiacol have been introduced as substitutes for the pure drug. Each one is supposed to add some special therapeutic value, and although all have had some favorable mention, none has attracted much attention or proved of any special value. *Beaumont Small.*

GUAIACOL CACODYLATE is a combination of cacodylic acid with guaiacol employed by Barbary hypodermically in dose of 0.03–0.05 gm. (gr. $\frac{1}{2}$–$\frac{5}{6}$) in tuberculosis. The injection is painless, and serves as a means of introducing arsenic into the system. *W. A. Bastedo.*

GUAIACOL-ETHYL, guëthol, homocresol, ajacol, thanatol, pyrocatechin-mono-ethyl ether ($C_6H_4.OC_2H_5.OH$), is a homologue of guaiacol in which the methyl group is replaced by ethyl. It is an oily liquid, insoluble in water or glycerin, and soluble in alcohol, ether, or chloroform. It resembles guaiacol physically and physiologically, but has a greater analgesic and sedative action. It has been used topically for neuralgia, neuritis, painful joints, epididymitis, etc., in ten to fifty per cent. ointment, or hypodermically in ten-per-cent. glycerin mixture. A case of painful tuberculous cystitis, with tenesmus, was relieved by the intravesical injection of 5 c.c. (♏ lxxv.) of the ten-per-cent. glycerin preparation (Merck). Its internal dose in tuberculosis is 0.25–0.65 c.c. (♏ iv.–x.) three times a day in milk or in capsule. Von Mering believes that this preparation is better than guaiacol *W. A. Bastedo.*

GUAIAKINOL, the dibromguaiacolate of quinine, crystallizes in yellow, clinorhombic prisms. At 15° C. (59° F.) it dissolves in less than two parts of water, and on account of this solubility promises to be useful. Clinical data are wanting. *W. A. Bastedo.*

GUAIAMAR, the glycerol ester of guaiacol ($C_6H_4.OCH_3.OCH_2.CHOH.CH_2OH$), is formed by the action of anhydrous glycerin on guaiacol. It is a white, neutral, non-hygroscopic, crystalline powder, soluble in twelve parts of water, and in alcohol, chloroform, ether, and glycerin. It has a bitterish, aromatic taste, and is split in the alimentary tract into guaiacol and glycerin. George F. Butler has studied its action at the Cook's County Hospital, Chicago, and claims it to be antipyretic, diuretic, diaphoretic, and antiseptic. It stimulates the appetite and prevents gastric fermentation, deodorizes and loosens the bronchial excretions, and is a very efficient antiseptic to the alimentary or genito-urinary tract. It is less irritating than benzosol or guaiacol carbonate, though occasionally more so by idiosyncrasy. Butler recommends it in typhoid fever, tuberculosis, bronchitis, broncho-pneumonia, chronic cystitis, gonorrhœa, and the summer diarrhœas of children. Its dose is 0.2–1 gm. (gr. iij.–xv.). Locally, with belladonna and mercurial ointments, he applies it to rheumatic joints; and, with balsam of Peru and zinc ointment, to bedsores. *W. A. Bastedo.*

GUAIASANOL, di-ethyl-glycocoll-guaiacol hydrochloride, was introduced by E. Einhorn and Hütz as a soluble form of guaiacol. It crystallizes in white prisms, having a faint odor and a saline, bitter taste. It is neutral to litmus, and is freely soluble in water from which it is precipitated as a basic oil by the alkaline carbonates. Guaiasanol liberates guaiacol in the alimentary tract, and is used both externally and internally for the same purposes as guaiacol. Experiments show that it is without unpleasant effects in daily dosage of 3–12 gm. (gr. xlv.–clxxx.). It may be used hypodermically, and in two-per-cent. solution is unirritating to wounds.
W. A. Bastedo.

GUARANA.—(Pronounced *Gwaw-rah-nah'.*) "A dried paste, consisting chiefly of the crushed or pounded seeds of *Paullinia Cupana* Kunth (fam. *Sapindaceæ*)" (U. S. P.). This is a climbing shrub, native of the hottest parts of South America, but the seeds are obtained wholly from cultivated plants.

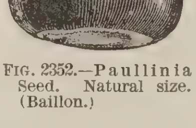

FIG. 2352.—Paullinia Seed. Natural size. (Baillon.)

The genus contains upward of one-hundred and twenty species, and its members are rich in saponin, also contained in guarana, on account of which parts of several of them are used as fish-poisons.

The guarana plant is very extensively cultivated, especially upon the banks of the Itenez River, a southern tributary of the Madeira. It is grown to stout stakes or poles and the plantation resembles an ordinary vineyard. The panicles of small white flowers are succeeded by fruit clusters looking not unlike large bunches of immense grapes. When ripe, the yellow fruit splits into three husks and the seeds are lost. They are gathered just previous to this time and the seeds are shelled and washed. The seed is large (1 cm. in diameter), globular or spheroidal, with a flattened base, and a slightly pointed apex. Its surface is dark-brown and very shiny, excepting the large chalaza at the base, which is light-colored, and, before it is disturbed, covered with a large aril. It is exalbuminous and entirely filled by the large fleshy embryo.

In general appearance and structure it may be described as a small horse-chestnut. After shelling, the seeds are lightly roasted, by which the testa is loosened. The latter is then broken off and winnowed out, and the kernels are coarsely broken up in a wooden mortar and with a wooden pestle. Just enough water is added to form an adhesive mass. This mass is then moulded by hand into cakes, balls, or, more commonly into sausage-shaped rolls, six to ten inches in length by one or two in diameter. The drying of these is the most delicate and critical part of the operation. It is conducted by artificial heat, in specially built houses, great care being taken to avoid a disagreeable flavor from the smoke or from the subsequent development of some variety of mould through imperfect or unequal drying. Adulteration occurs only occasionally. It consists in making various additions—usually tapioca starch—to the mass before it is subjected to the drying process.

As regards the home consumption of guarana, it is the exact equivalent of tea or coffee, except that it is grated off and taken suspended in cold water. It is the staple beverage of millions of people. Its excessive habitual use brings on nervous disorders similar to those from other caffeine-containing beverages, and ending in a kind of palsy.

Description.—In subglobular or elliptical cakes or cylindrical rolls, hard and heavy; outer surface somewhat shortly nodular, smooth, slightly lustrous, deep chocolate-brown; rather brittle, the fracture uneven, often fissured in the centre, of a deep flesh color or pale reddish-brown, showing numerous coarse, angular, lustrous fragments of seeds partly invested with blackish-brown integuments; odor slight, peculiar, a little resembling that of chocolate; taste very astringent, somewhat bitter, afterward sweet, especially when chewing is followed by the taking of a swallow of water.

Composition.—Guarana stands at the head of caffeine-yielders, containing four or five per cent. A quarter of its weight is tannin, and there are starch, saponin, resin, and small amounts of fixed and volatile oil. It should not yield more than two and one-half per cent. of ash. It should be remembered that the domestic value of guarana depends largely upon its flavor. Many lots defective in this particular are exported for medicinal use and are not necessarily inferior for this purpose. At the same time, adulterated lots are undoubtedly manufactured especially for such export, but only rarely.

Action and Medicinal Use.—Because of its tannin, guarana is to be compared rather with tea than with coffee. Caffeine is elsewhere so fully treated that its action cannot be here discussed.

As the contained dose of tannin is a small one, it is, in fact, a mode of giving caffeine, and little or nothing more. Its principal clinical reputation lies in its value in nervous and sick headaches, of which there is considerable evidence. It has been the foundation of several widely known secret remedies for these afflictions.

The powdered drug can be given in gram doses or more, repeated once an hour, until the headache is relieved, or until several doses have been given. The fluid extract (*Extractum Guaranæ Fluidum*, U. S. P.) is rather neater, and of the same theoretical strength. Milk is a good vehicle for either. *Henry H. Rusby.*

GUARANINE.—A name applied to *caffeine*, when derived from *guarana*. *Henry H. Rusby.*

GUERNSEY AND THE CHANNEL ISLANDS.—The Channel Islands, comprising Jersey, Guernsey, Alderney, Sark, and several smaller rocky islets, are situated in the bay of St. Michael, off the coast of Normandy, and lie between the latitude of 49° 10′ and 49° 42′ North and 2° 2′ and 2° 40′ West longitude. Guernsey and Jersey are the only two islands which require consideration as health resorts, and their claim as such is based upon the mild sunshiny nature of their climate, especially in the late autumn and winter. "Recent statistics show that Jersey receives more sunshine than any other part of the United Kingdom." In these islands "camelias and rhodendrons flower in the open in February, frost is rare, and lasting snow unknown."

St. Helier's in Jersey and St. Peter's Port in Guernsey are the chief towns. The following table gives the climatic characteristics of Guernsey, which are practically the same as those for Jersey.

Climate of Guernsey and Jersey. Means for Ten Years. Height Above Mean Sea-Level, 180 Feet.

	January to March.	April to June.	July to September.	October to December.	Year.
Temperature—					
Mean average.........	43.7° F.	53.0° F.	60.5° F.	48.8° F.	51.5° F.
" daily range.....	7.6	10.8	10.9	7.6	9.2
" of warmest.....	47.5	58.4	66.0	52.6	56.1

Prevailing direction..	....	....	....	....	W. and S. W.
Weather—					
Amount of sunshine...	304 hrs.	665 hrs.	648 hrs.	247 hrs.	1864 hrs.
Mean cloud...........	7.1%	6.0%	6.6%	7.2%	6.6%
Rainy days............	47	34	39	59	179

From this table we see that the general climate of these two islands (Jersey and Guernsey) is a mild, moist, marine one. The diurnal range of temperature is small, and there is an average of five hours of daily sunshine. Of the total rainfall one-fourth occurs in the months of October and January. March and April are considered the most trying time of the year on account of the north-easterly winds.

Of course the islands are exposed to the winds from all directions, which, coming from the ocean, are moist and salt-laden. The prevailing winds are westerly and south-westerly, especially the latter.

The following table of yearly averages of wind is given for Guernsey, for the period from 1845 to 1862, inclusive:

Northeast wind prevailed on 100 days.
Southwest wind prevailed on 104 days.
Northwest wind prevailed on 110 days.
Southeast wind prevailed on 51 days.

The drinking-water is obtained, for the most part, from wells. The drainage at St. Helier's and St. Peter's Port is by sewers into the sea.

The therapeutic effects of this climate arise from its mild sunshiny nature and its marine atmosphere. Elderly persons with low vitality and those with bronchial affections derive benefit from it. It is also of especial value for delicate scrofulous children and those of rachitic tendencies. It is unfavorable, on account of its moisture, for rheumatism, neuralgia, and renal diseases. Those with a tendency to respiratory troubles should not remain after the end of February. The Channel Islands are reached by boat from Southampton, Weymouth, or Plymouth in from six to ten hours, or from St. Malo or Granville, France, in two or three hours.

From a personal visit to Jersey the writer can testify to the delightful scenery of the island, both land and water, and the charm of the lovely drives through the winding roads, bordered by luxuriant vegetation. The air is fresh and invigorating and the sunshine most brilliant.

The writer desires to express his indebtedness in the preparation of this account of Guernsey and Jersey to "The Climates and Baths of Great Britain," by the Royal Medical and Chirurgical Society of London, 1895.

Edward O. Otis.

GUINEA WORM. See *Nematodes.*

GUINORAL (Chinoral) is an oleaginous, very bitter liquid, containing quinine and chloral. It is used as a hypnotic in doses of 0.5–1 gm. (gr. viij.–xv.), and also as an antiseptic. *W. A. Bastedo.*

GUM ARABIC.—Acacia. *Gum Acacia. Gum Senegal.* "A gummy exudation from Acacia Senegal Willd. (fam. *Leguminosæ*)" (U. S. P.). In roundish tears, often an inch or more in diameter, transparent, except for the whitish fissures, of a glassy fracture, ranging from nearly colorless to a deep reddish-yellow, nearly tasteless and odorless, wholly soluble in two parts of water, to form a thick mucilage of a faintly acid reaction. The presence of starch in powdered acacia is detected by a blue color on the addition of iodine, that of dextrin by a red color. A pure solution will not be affected by neutral lead acetate.

This gum was formerly yielded by other species of acacia, notably *A. vera* Willd., and the very finest gum of commerce, now scarce and high, still proceeds from this species. It is chiefly in smaller tears, which are more brittle and broken, and less translucent and glassy, owing to the much more numerous fissures. Both species are small thorny trees of northern Africa, *A. vera* more abundant in the eastern, *A. Senegal* in the western districts. The gum is a decomposition product from cellulose and is more abundantly produced by unhealthy trees. It exudes from natural fissures and artificial incisions. Gums practically equivalent to acacia are produced by species in related genera. An excellent article is produced by species of Prosopis, growing in the southwestern United States, and known as Mesquit Gum, but the supply is too irregular to be utilized. The varieties of acacia are now little known by the locality-names formerly applied to them, the grading being done almost wholly by number, the quality depending upon whiteness and solubility. The pure gum consists wholly of compounds of arabic acid with potassium, calcium, and magnesium. Acacia has no physiological action, except that of a mechanical demulcent. Its pharmaceutical uses, as an excipient, for emulsionizing, and for suspending insoluble substances or those the acridity of which it is desired to mitigate, are very numerous and important.

GUNSHOT WOUNDS.—No chapter in surgery has undergone such radical changes as that pertaining to gunshot wounds in war. The changes have been coincident with the introduction of antisepsis and the new armament in hand weapons which employ armored projectiles. The changes with reference to the latter concern the military surgeon mostly. His *confrères* in civil life will continue to observe gunshot injuries, as far as their mechanical effects are concerned, as formerly. The wounds of this class that come under his care are mostly from pistol shot, the missiles of which are made of soft lead, are propelled at comparatively low rates of speed, and show a marked tendency to lodge and to deform upon impact with resistant structures.

In order to obtain a correct understanding of gunshot wounds a consideration of the implements which are concerned in their production is necessarily of much importance.

Portable Firearms.—Arms of this class are often referred to as portable hand weapons. They include the firearms that are carried by hand in contradistinction to the larger guns of the artillery class. They are the pistol, shotgun, the smooth-bore muzzle-loading musket, and the rifle. A knowledge of the development of portable firearms as a whole, and of ballistics in particular, is indispensable to a correct appreciation of the subject of gunshot injuries. For all practical purposes a study of the evolution of the military rifle as it presents itself to the military surgeon will be quite sufficient to a general understanding of the subject.

Military Rifle.—A study of the guns concerned in the evolution of the small arms which culminated in the present military rifle deals with: (1) smoothbores like the flintlock and musket; (2) the percussion-cap, muzzle-loading rifle; (3) the breech-loading rifles; and (4) the breech-loading magazine rifle with small calibre.

1. The smoothbores of the first class are represented by the old-time flint lock and later by the Spanish musket, whose calibre varied from .63 to .75. They fired a bullet made of soft lead weighing from 465 to 555 grains; the explosive was loose black powder in charges varying from 270 to 345 grains. The projectile was spherical in shape, with an initial velocity of from 540 to 690 foot seconds, while the maximum effective range was never more than 350 yards.

Our first three wars—the Revolutionary War, the War of 1812–14, and the Mexican War—were fought with weapons represented by this class. As implements of war they were considered very effective in their day, and yet at no time could the best type of them be loaded at greater speed than thrice per minute.

2. The percussion-cap, muzzle-loading rifles were first used in the Italian War of 1859; they were subsequently used in our Civil War, and in all European wars up to 1866. Instead of igniting the powder charge by means of a taper as in the old match-lock, or by the spark of a flint as with the flintlock, it made use of a small cap containing a detonating substance. The cap was placed over a hollow piece, the cavity of which led to the powder charge. The latter was ignited by causing the hammer to strike the cap.

In the earlier patterns of these guns there was so much escape of the powder gases through the inequalities between the ball and sides of the weapon, with consequent loss of energy, that the practice of slightly reducing the calibre of the gun as compared to that of the diameter of the ball, and grooving the interior of the former, was resorted to. This was done to insure greater accuracy in the fit of the ball. In order to allow more of the surface of the ball to come in contact with the barrel, it was elongated. The fit of the ball was so tight that it was necessary to drive it down with a ramrod and hammer, both of which formed part of the equipment of the soldier at that time. This gave greater exactness of fit between the ball and barrel and both added to the energy and extended the range by retaining the projectile a trifle longer in the barrel, while the explosive was generating a greater volume of gas. It was noticed that the elongated bullet fired from such a gun was apt to tumble or lose its balance, and this was overcome in a measure by giving the grooves in the barrel a spiral turn, at the rate, in the earlier guns, of one complete turn in about seventy-eight inches. This added much to the stability of the bullet, keeping its point foremost for a longer time in its flight, thereby adding to its range and effectiveness. This principle in ballistics should be specially remembered, aside from the development in the use of explosives, because it is really the initial point in the great strides that have been made in the effectiveness of bullets. The act of loading with the ramrod and hammer was very laborious. To overcome the difficulty Delvigne, a French army officer, hollowed out the base of the projectile next to the powder. The expanding gases pressed the sides of the cup so formed into the metal grooves in the barrel, thus causing the bullet to take the rifling. Later, in 1847, Captain Minié made a still further advance by suggesting the use of an iron disc in the cup. The harder metal being forced against the sides of the cup insured greater expansion than the gases alone, so that the accuracy of fit between the ball and the barrel was more completely secured. The so-called Minié rifle used in the Crimean War, and our own Springfield used in the Civil War, were loaded with such bullets. The following were the principal features of the Minié rifle which correspond with those of our earlier make of the Springfield rifle.

Minié-Rifle, 1851 to 1866.

Weight with bayonet	10 pounds 8¾ ounces.
Diameter of bore	.702 inches.
Number of grooves	4
Twist	1 turn in 78 inches.
Diameter of bullet	.690 inch.
Weight of bullet	680 grains.
Charge of powder	150 "

Sighted for 100 to 1,000 yards.

The old Minié ball formed the section of a cone, so that the accuracy of fit in the barrel was confined almost entirely to the base of the bullet. The resulting inequality of its different sectional areas disturbed the balance of the projectile to such an extent that its stability in flight was soon lost. Instead of rotating on its long axis, it was apt to tumble or to commence to rotate on its short axis, at right angles to its line of flight. To overcome this difficulty the body of the projectile was made cylindrical; the base was cupped, the metal stopper was replaced by a boxwood plug, and the head was made hemispherical instead of conical in shape. This was the missile used in the Enfield of the English foot troops till 1871, as well as in our old pattern Springfield rifle, which formed the armament of our infantry from 1855 to 1873. The calibre of the latter at this time was reduced to .58, its weight to 500 grains, and the charge of powder to 80 grains.

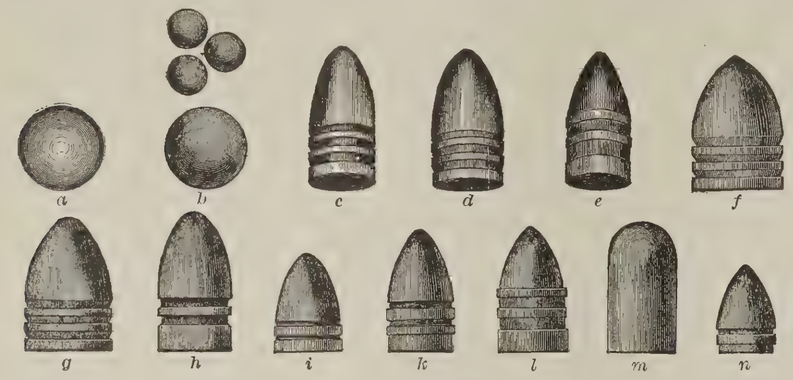

FIG. 2353.—Different Kinds of Projectiles. *a*, United States round musket ball, calibre .69, weight 387 grains; *b*, buck and ball, calibre .69, weight of ball 387 grains; *c*, Springfield rifled musket ball, calibre .58, weight 500 grains; *d*, Enfield rifled musket ball, weight 450 grains; *e*, Austrian rifle ball, weight 460 grains; *f*, elongated bullet, calibre .71, weight 675 grains; *g*, elongated bullet, calibre .69, weight 760 grains; *h*, elongated bullet, calibre .577, weight 517 grains; *i*, Burnside rifle bullet, calibre .54, weight 400 grains; *k*, Spencer rifle bullet, calibre .56, weight 434 grains; *l*, Sharp's carbine ball, calibre .52, weight 450 grains; *m*, Green's rifle ball, calibre .53; weight 575 grains; *n*, Colt's army pistol bullet, weight 207 grains.

3. Breech-loaders. The great desire of military men to increase the rapidity of fire led to the introduction of breech-loaders. Although loading by the breech had been practised since the reign of Henry VIII., the mechanism of the earlier weapons was so uncertain and clumsy that they were not used by armies until about 1866, when the Germans demonstrated the superiority of their needle gun in the Austro-Prussian war.

In 1866 the United States Government modified the muzzle-loading Springfield rifle by adding the breech-block which permitted loading by the breech. It was at this time that the calibre was reduced to .50. In 1873 the calibre of this same weapon was further reduced to .45, the twist was shortened to 1 turn in 22 inches, the charge was reduced to 70 grains of black powder, while the weight of the bullet was still retained at 500 grains. These improvements increased the velocity at the muzzle to 1,301 foot seconds, and the maximum effective range to 2,000 yards. Compared to the effectiveness of a generation before the advancement was certainly very great, yet those who marvelled at these rapid strides in the manufacture of the engines of war were hardly prepared for the rapid advances that were soon to follow.

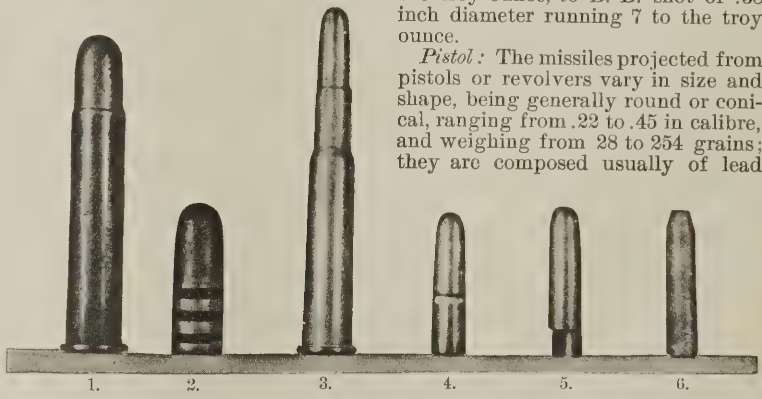

FIG. 2354.—Projectiles for Rifles. 1, Complete cartridge .45 calibre Springfield rifle; 2, projectile of cartridge .45 calibre Springfield rifle, 480 grains; 3, complete cartridge .30 calibre Krag-Jörgensen rifle; 4, steel-jacketed projectile, Krag-Jörgensen rifle, 220 grains; 5, steel-jacketed projectile, Krag-Jörgensen rifle; 6, the lead nucleus of Krag-Jörgensen projectile.

4. *Magazine Breech-loading Rifles, with Reduced Calibre.* The modern tactics in war involve rapidity in movements, and with these rapidity in fire. The latter led to the introduction of the magazine rifle, an arm that carries a reserve of ammunition in some part of its mechanism. Increased expenditure of ammunition with the new arm necessitated a greater number of rounds per man. But the soldier was already loaded to the maximum of weight, so that the number of rounds could be increased only by reducing the calibre and thereby the weight of the bullet. The calibre of military rifles has thus been reduced as far as .26, and the weight of their projectiles as low as 156 grains, thereby nearly doubling, for the same weight, the number of rounds that soldiers usually carried. This reduction in calibre of the rifle increased the difficulty incident to fouling, *i.e.*, to the lodgment of the unconsumed residue of the old black powder on the inner wall of the barrel, and eventually led to the introduction of so-called smokeless powders that leave little or no residue, and that possess the further advantage of conferring upon the projectile a greater initial velocity (owing to the fact that the gases which they emit are relatively more voluminous than those resulting from the ignition of the old black powder). This increase in velocity added quite a complication. The lead bullet instead of keeping point on, tumbled, to prevent which, a shorter twist was given to the grooves in the barrel. Instead of one complete turn in 22 inches, the twist was shortened to 1 in 10 inches. The old lead bullet became refractory under the bidding of such a sharp turn. Instead of following the new twist it was apt to strip through the barrel without properly revolving, a difficulty which was obviated by coating the lead with some harder metal.

Generally speaking, the classification of gunshot wounds is based on the character and size of the missiles that caused them.

Shotgun: The missiles from ordinary shotguns vary from fine round lead projectiles running from 2,020 to the troy ounce, to B. B. shot of .38 inch diameter running 7 to the troy ounce.

Pistol: The missiles projected from pistols or revolvers vary in size and shape, being generally round or conical, ranging from .22 to .45 in calibre, and weighing from 28 to 254 grains; they are composed usually of lead hardened with antimony in the proportion of 95 parts of the former to 5 parts of the latter. The missiles from the remainder of the hand weapons should be divided into two classes, viz., those of the smoothbore guns and those of the rifles. Those of the latter should be further divided into the lead and jacketed projectiles.

Smoothbores.—The missiles of the smoothbore guns were round, made of soft lead, ranging from .68 to .75 in calibre, and weighing from 465 to 555 grains.

Lead projectiles for rifles were conoidal in shape and composed of lead, generally hardened with antimony; they ranged from .45 to .71 in calibre, and weighed from 387 to 675 grains.

Jacketed projectiles for rifles are made of a lead core enclosed in a mantle of harder metal, like copper, German silver, white metal, or cupro-nickel steel—generally of the latter. Their calibre is much smaller, .26 to .31, and their weight ranges from 156 to 244 grains.

Aside from the foregoing there are other missiles and substances concerned in the production of gunshot wounds. These are principally employed in warfare, and they may be considered under the following heads:

LARGE PROJECTILES OR THEIR FRAGMENTS.—These are the large solid shot, and large hollow shells provided with a charge of some explosive used to generate expansive gases that break the projectile into fragments at or about the time of impact. The large solid shot from cannons is used to penetrate armor and to demolish fortified positions. The hollow shells are used to develop positions, and this is done by observing the distance at which bursting occurs, thereby establishing the range

Shrapnel.—The use of shrapnel is largely restricted to the artillery arm in war, a typical example of which is found in the Frankford Arsenal Shrapnel in use by our field artillery. It is a hollow steel projectile composed of a head, body, and base. The head contains 2¾ ounces of black powder; the body holds 162 lead and antimony balls, 41 to the pound, disposed in circular layers and held by cast-iron separators. The shell and separators are deeply grooved to invite separation into corresponding fragments at the time of bursting. The head is provided with a fuse which is so timed that explosion is made to take place at any interval of 60 yards or one-sixth of a second. As many as 202 missiles have been counted after an explosion. The maximum effective range of this projectile is 7,000 yards. The flight of the fragments represents an extending cone for 400 or 500 yards, the diameter of which is 30 feet at a distance of 25 yards from the place of bursting.

Canister.—Canister, sometimes called caseshot, is a projectile not unlike the shrapnel. It is cylindrical in shape, the walls of the cylinder being composed of a thinner metal and enclosing 200 or 300 round lead balls hardened by antimony. The projectile is ruptured close to the muzzle at the moment of discharge by the force of the explosion in the gun, and not by the liberation of gases from an explosive within the shell, as occurs in the case of the shrapnel. Such a projectile is of use only at close range, from 300 to 500 yards, depending upon the calibre of the gun.

EXPLOSIVES.—The modern advance in conferring extended range, velocity, and penetration upon projectiles, is due to the development in the use of explosives. They are employed not only to propel missiles into space, to explode projectiles, etc., but also to explode mines, fugases, and bombs in offensive and defensive warfare; and, by evil-doers, in the destruction of life and property. A consideration of these various chemicals and the manner of their action in the creation of wounds naturally falls under the subject of gunshot wounds. Among the more familiar explosives may be mentioned: gunpowder, fulminates, and certain chemical compounds.

Gunpowder.—Gunpowder is the most ancient of all explosives. It is generally referred to as black gunpowder to distinguish it from certain chemical compounds which vary in color from brown to black and which are usually designated as smokeless powders. The composition of black gunpowder has remained almost constant for centuries, viz., saltpetre, charcoal, and sulphur in percentages of something like 75, 15, and 10 in the order named. In this mixture saltpetre furnishes the oxygen, carbon supplies the fuel, and sulphur promotes the rapidity of the explosion. Gunpowder explodes when

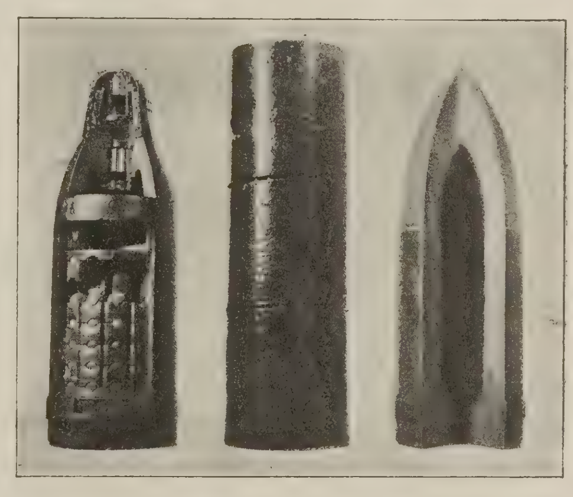

FIG. 2355.—Larger Projectiles. Shrapnell (1), Canister (2), Shell (3), Used with 3.2 inch Breech-Loading Rifle-Filled Batteries.

heated to 700° F. The volume of the gas which it generates occupies 250 times the bulk of the charge employed. It is this resulting expansion which serves to propel the missile from a gun barrel and which confers upon it such velocity as to enable it to penetrate tissues, thereby causing gunshot injuries. The temperature of the flame which is noticed at the time of ignition has been variously estimated at 2,000° to 4,000° F., a fact which doubtless has had much to do with spreading the old-time notion of the searing and burning effects of bullets upon the tissues. The chemical results of the disintegration of gunpowder are 32 per cent. of gaseous products, and 68 per cent. solid residue. The gases generated are carbonic oxide, carbonic acid, and nitrogen, with some aqueous vapor. The pressure which the gaseous products exert on the gun barrel is said to be more than 4,000 atmospheres for 1 gm. of the powder ignited.

Fulminate Powder.—Fulminate of mercury is principally used as a detonator in exploding guncotton and other explosives, and also in charging percussion caps and primers. The volume of gas generated for the amount of substance is relatively very large. Disintegration of the substance into gases is so rapid and the pressure exerted by the sudden displacement of air is so violent in all directions that the term detonate has been employed to characterize the explosion. Thus we say that it detonates instead of saying that it explodes. The gases formed are carbonic acid. nitrogen, and vapor of mercury. As an example of the tremendous force exerted by the sudden displacement of these gases, it may be stated that in the attempt to assassinate the French Emperor in 1858, three tubes, each containing two ounces of the fulminate, were exploded, and from these explosions there were produced 511 wounds upon 51 persons.

Smokeless Powders.—So called because they emit very little smoke as compared to black gunpowder; and unlike the latter they exhibit neither flame nor burning at the time of explosion. As to their exact composition it may be stated that they are secret compounds. In a general way we know that they are composed of guncotton (cordite), dynamite, or picric acid (melinite). Some of the smokeless powders that have been analyzed show ninety-four per cent. guncotton, five per cent. nitroglycerin, one per cent. castor oil. Melinite is made up of picric acid with collodion jelly. Aside from those composed of guncotton or picric acid as a base, there is a class known by various names, such as roburite, rock-a-rock, hellofite, securite, etc., which explode only upon mixing two or more substances, as chlorinated dinitrobenzole with ammonium nitrate, chloride of potassium impregnated with liquid hydrocarbon, naphthalin, phenol, or benzin in fuming nitric acid, etc.

The causes that influence the character of gunshot wounds may be treated under the following heads:

MECHANICS OF PROJECTILES.—The character of gunshot wounds has been as much influenced by the discovery of high explosives as it has by the perfection attained in the manufacture of firearms. These two essential particulars involve a study of the motion of bullets in flight in order that the lesions inflicted on impact may be properly interpreted. It is only with such knowledge that penetration, smashing, and mutilation of tissues can be explained in a given case.

Trajectory.—The trajectory of a projectile is the curve which it describes in space from the muzzle to the first point of impact.

Velocity.—In speaking of the flight of a projectile in space we employ the term velocity, and this in turn is usually divided as follows:

1. Initial Velocity.—The initial velocity of a projectile is its rate of motion as it issues from the muzzle of the gun, that is, the number of feet it passes over in one second of time, known in mechanics as the foot-second system. For revolvers this rate is seldom more than 700 foot seconds, whereas, with the more perfect hand rifles, it is as much as 2,400 foot seconds.

2. Remaining Velocity.—The remaining velocity is the rate of speed which a bullet still possesses at any given point in its flight. Thus, for instance, the projectile that may issue from the muzzle of a given weapon at the rate of 1,800 foot seconds, is so influenced by the gravity of the earth and friction against the air that its flight is impeded in proportion as the distance from the gun increases, so that, on reaching a distance of 500 yards, the velocity, instead of being 1,800 foot seconds, will have fallen to 900 foot seconds.

Energy.—The energy of a bullet has always been of interest to surgeons, because its power to do work is measured by the energy which it possesses of overcoming resistance at the moment of impact. In olden times when the manufacture of firearms was imperfect and our knowledge of explosives was restricted to black gunpowder, we sought to increase the energy of a projectile by increasing its mass, but to-day superior knowledge in manufacture and modern advance in the use of explosives enable us to attain the same end by increasing the velocity. The latter method is more effective in this, that formerly if we chose to double the energy of a projectile we doubled its mass, whereas to-day we double the velocity and thereby increase the energy fourfold. The following table illustrates the two velocities, and the energy of our present service bullet and that of the Springfield rifle at varying ranges up to 2,000 yards.

The velocity and energy of the projectiles of the two weapons at different ranges are as follows:

TABLE II.—VELOCITY OF THE PROJECTILES OF THE TWO GUNS.

Name and calibre of weapon.	Initial velocity.	500 yards.	1,000 yards.	1,500 yards.	2,000 yards.
Springfield, calibre .45	1,301	873	676	531	429
* Experimental Springfield, calibre .30	2,000	1,103	804	627	495

ENERGY OF THE PROJECTILES (IN FOOT POUNDS).

Name and calibre of weapon.	Initial velocity. F. S.	Weight, grains.	Muzzle.	500 yards.	1,000 yards.	1,500 yards.	2,000 yards.
Springfield, calibre .45	1,301	500	1,879	846	507	313	204
* Experimental Springfield, calibre .30	2,000	220	1,954	594	315	192	120

* Which corresponds in ballistic value to the Krag-Jörgensen rifle.

Rotation of Bullets.—As a bullet issues from a gun two motions are imparted to it: one of translation and one of rotation. The former is due to the pressure of the powder gases which impel it onward into space, the latter is either accidentally or purposely given. In the first instance we have the rotation that was observed with old spherical bullets from smoothbores, in which the direction of the rotation was marked by the last point of contact of the projectile with the inside of the gun barrel. The axis of rotation was always at right angles to the line of flight, and its rapidity was always variable. In the latter instance we have the rotation that is purposely conferred by the gunmaker in grooving the inside of the barrel with from two to five or six spiral grooves, the direction of which, usually to the right, is followed by the bullet as it issues in a rotatory motion from the muzzle. This rotation is purposely conferred on elongated bullets to keep them moving point on. The axis of rotation with them is parallel to the line of flight, and not at right angles, as it is with spherical bullets. The velocity of rotation is determined by the sharpness of the twist in the barrel. In our present service rifle the twist describes one complete turn in about ten inches.

Shape and Density of Projectiles.—The character of a gunshot wound is often influenced by the shape and density of the missile that inflicts it. The tendency with the old spherical ball from smoothbore guns upon impact with resistant bone was to smash or comminute the bone at the point of impact, doing little or no damage to the shaft above or below. As the bullet was composed of soft lead, a resistant bone usually caused it to mushroom or otherwise lose its shape, thus adding to the amount of comminution. Later, as the rifle came in vogue, the cylindro-conoidal bullets were introduced. The effect of these wedge-like missiles was to penetrate and produce splintering above and below the point of impact, thus causing displacement of larger fragments of bone beyond the foyer of fracture. The deformation of the leaden missile added to its sectional area, thereby magnifying the destructive effects. The tendency to penetrate was still further increased by the employment of jacketed projectiles. The hard envelope preserves the shape of the projectile, so that the additional amount of destruction consequent upon deformation, so often noticed with the old leaden bullet upon impact with resistant bone, is seldom noted. The tendency with it is to perforate and fissure bone rather than to cause extensive comminution.

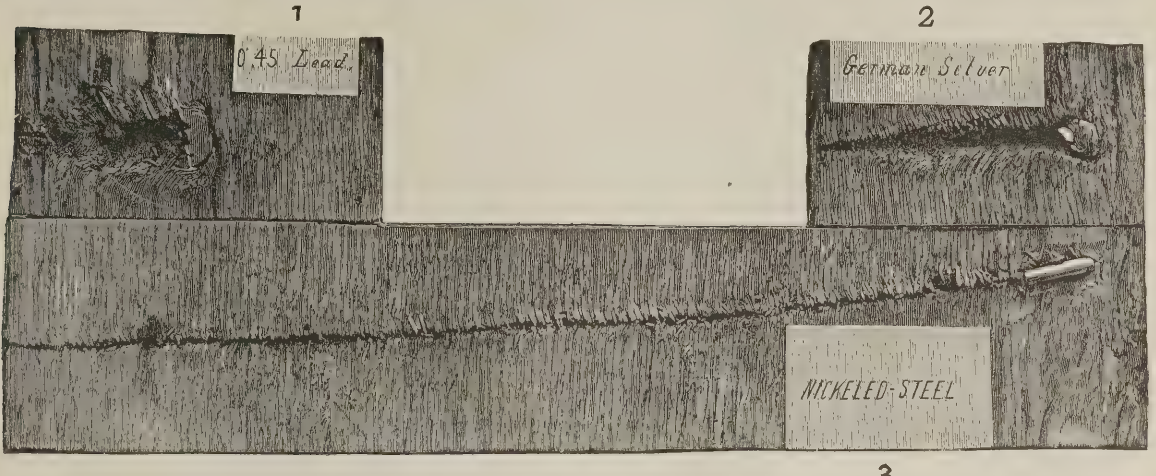

FIG. 2356.—Shows the Penetration in Hard Oak, against the Grain, Three Feet from the Muzzle, of the following Projectiles: 1, ."45 calibre leaden projectile, weight, 500 grains; I. V., 1,300 f. s., 3."2. 2, ."30 calibre German-silver jacketed projectile, weight 220 grains; I. V., 2,000 f. s., 5."3. 3, ."30 calibre nickel-steel jacketed projectile, weight 220 grains; I. V., 2,000 f. s., 19."5. The latter was not deformed.

The introduction of the modern rifle of reduced calibre at a time when the world was at peace rendered experimental evidence necessary to show what might be the difference in destructive effects between it and the older weapons of larger calibre and lower velocities. At no time in the history of firearms has the subject of the mechanical effects of projectiles been so thoroughly studied as it has during this so-called experimental stage. The experiments of military surgeons in the different countries of the civilized world and their studies of the injuries caused by gunshot have been conducted in such a thorough fashion, and they have entered so minutely into the mechanics of projectiles generally, that a report of what has been learned cannot fail to be of practical value to the civil as well as to the military surgeon.

Our knowledge of the rifles of reduced calibre propelling armored projectiles dates from the publication of Professor Hebler's pamphlet in 1882. In his original monograph Hebler claimed certain advantages for the reduced calibre rifle, among which were the following: (1) lighter ammunition; (2) flatter trajectory and greater dangerous space; (3) less deviation by wind; (4) less recoil; (5) greater penetration; (6) greater accuracy; (7) the wound produced, while being sufficient to disable, is much more humane.

Some of these advantages were so apparent that they could not be refuted, while the others required the proof which could be obtained only by experiments or by observation of the actual conditions in the field.

That the ammunition is lighter there is no doubt, since a soldier who carries 100 rounds of the older ammunition can carry for the same weight about 180 of the new ammunition. That the trajectory of the new rifle is flatter, and that the dangerous space is consequently greater, is also apparent, since those versed in ballistics have shown us that the point-blank range of the older gun of the Springfield pattern is 300 yards, while that of the Krag-Jörgensen rifle, our present service gun, is about 570 yards.

The advantage of less recoil is perfectly apparent to any one who will shoot the two last-named weapons one after the other. The remaining advantages claimed by Hebler were not so readily determined. Greater accuracy and less deviation by wind had to be determined by comparison at target. Although the small-bore guns and ammunition have been perfected very much of late, it is yet a fact that, in the remote ranges, the smaller and lighter projectile is more influenced by wind than the heavier and larger leaden bullet, and that for these ranges it is not so accurate.

Greater penetration was another important advantage claimed by Hebler, and this claim was sustained by experiment. In unseasoned oak, firing across the grain three feet from the muzzle, the old leaden .45 calibre bullet from the Springfield rifle penetrates but five or six inches, while the steel-jacketed bullet of our present service rifle at the same distance will penetrate nineteen or twenty inches.

The last of the advantages claimed by Hebler, and the one of greatest interest to mankind, was that *the wound produced, though sufficient to disable, is much more humane.* This claim could be determined only by experiments on cadavers, and on the lower animals, and by observation of the actual conditions in battle. In all the leading countries of the world, from 1886 to the present time, competent men have been experimenting upon the lower animals and upon dead human bodies, for the purpose of ascertaining the character of the wounds inflicted by the different missiles employed in warfare. The Surgeon-General of the Austrian army, Johann Habart, Chauvel and Ninier, of the French army, Bruns, of Germany, and many others have furnished us important data upon the effects of the new arm. In this country the subject was first undertaken in 1893 when the change in our armament took place.*

Although there was some difference in the mechanism of the guns used by the different experimenters, the projectiles which they propelled differed but little as to calibre and destructive effects. The most of the experiments were conducted at simulated ranges. That is to say, if the work at Frankford Arsenal be taken as an example, all of the firing was done at fifty-three feet. When it was desired to obtain the effects of a bullet at a certain range, the charge of powder was reduced in quantity enough to give the bullet the remaining velocity for that range. The results thus obtained were generally uniform, and, as far as the experimenters were concerned, sufficiently conclusive. Some critics refused to accept the results of the experimenters as final, upon the ground that the simulated velocities of the projectile, and the dead tissues fired into, did not represent the conditions that must obtain in war. It is specially gratifying to those who labored upon the problems involved to find that their deductions have been amply justified by clinical evidences in war, and especially by the revelations of the *x*-ray. When one reflects that it has been the usage of French military surgeons for generations to study gunshot wounds by firing into cadavers, and that it is done by order at Val de Grâce to this day, the practice has this claim to recommend it at least.

---

* Annual Report, Surgeon-General United States Army, 1893.

In order to make the results more apparent we adopted the following plan at Frankford Arsenal: We noted (1) the effects of a projectile of larger calibre and lower velocities upon different parts of the human body at various ranges; and (2) the effects of a projectile of the smaller calibre and greater velocities upon similar parts of the human body, or upon parts offering about the same resistance at similar ranges. The larger calibre weapon selected was the Springfield rifle, calibre .45, the gun which had formed the armament of our foot troops since 1873. The smaller calibre weapon employed, and to which the experiments were especially directed, is known as the Experimental Springfield rifle, calibre .30.

The following is a description of the more important ballistic properties of these weapons: "The Springfield rifle is a .45 calibre gun, the projectile of which has an initial velocity of 1,301 foot seconds. Its projectile is made of compressed lead, cylindro-conoidal, cannelured, and lubricated, weighing 500 grains, impressed by 70 grains of black rifle powder. The Experimental Springfield rifle is a .30 calibre gun, the projectile of which has an initial velocity of 2,000 foot seconds. Its projectile is made of a German silver jacket filled with a core of lead, and is not cannelured or lubricated."

It will be seen by Table II. that the initial velocity of the smaller calibre projectile is far greater than that of the larger calibre, and that the striking velocity at all the ranges is greater.

The penetration of a bullet is proportional to the square of its striking velocity; for equal velocities the penetration is proportional to the density of section. The form of the bullet and its power to resist deformation have a powerful influence. The penetration of the 220-grain bullet is greater at all ranges. This quality of penetration in projectiles is always of great interest to surgeons, and it becomes especially so in this instance, since it depends to a material extent, as far as the human body is concerned, upon the almost indestructible hardness of the projectile.

In the experimental work referred to, the penetration at the different ranges was obtained as follows: A Le Boulenge chronograph was used, the distance between first and second targets being 100 feet, and the first target being 3 feet from the muzzle. The remaining velocities of both bullets used (500 grains, .45 calibre, and 220 grains, .30 calibre) were computed for the desired ranges by the methods given in Ingall's "Exterior Ballistics." To find the penetration at a given range, say 1,000 yards, the procedure was as follows: The remaining velocity at this range computed as above, was found to be 676 foot seconds for the 500-grain bullet. The charge of powder was successively reduced until a charge was found which gave at 53 feet from the muzzle a velocity of 676 foot seconds. Cartridges were made up with this charge, and the cadaver to be fired at was placed at 53 feet from the muzzle. The striking velocity of the bullet being the same as that of a bullet fired with the full charge and striking an object at a distance of 1,000 yards the penetration would also be the same. At the ranges of 1,500 and 2,000 yards respectively, it was found necessary, in order to record the low velocities obtained, to reduce the distance between targets to 50 feet, which caused the velocity to be determined at 28 feet from the muzzle. At these ranges, therefore, the cadavers were placed 28 feet from the muzzle. A tackle was provided for traversing the cadavers and bringing a portion of the body to be fired at into proper position. Barrels filled with sawdust were placed behind the cadaver experimented with, to catch the bullets and preserve them from deformation other than that received in their passage through the body. Each bullet was marked on its base with a number or letter, for the purpose of identification, and after firing at each range the bullets were collected and examined.

Before proceeding to the observation of gunshot injuries proper, some facts were noted on impact and explosive effects, as follows:

Impact.—The shock as shown by the oscillation of the limb, when a resistant bone was hit, was always greater with the leaden bullet of .45 calibre than with that of the smaller-bore gun; on the other hand, the difference was reduced to a minimum when the soft parts alone were hit. It often happened that the occurrence of a fracture from the impact of the smaller projectile was determined only after a careful examination of the wound. This difference in shock was noted at all the ranges, but especially so after the 500-yards range.

The minimum amount of shock for the smaller projectile depends upon the superior penetration, which, as stated already, is due to its smaller calibre, greater velocity, and last, but not least, because it preserves its shape unaltered. The fact that the calibre of the Springfield was greater sufficed to explain the greater amount of shock. This was added to by deformation. Part of the energy was consumed in the flattening of the bullet, while the remainder was conveyed to the part hit in the form of shock. The difference in the amount of shock is at once suggested in Table II., already cited. It will be seen that the striking energy in foot pounds for all the ranges is greater with the projectile of the .45 calibre Springfield rifle.

Explosive Effects.—The explosive effects caused by the projectile of the Springfield rifle were noticed up to 200, and in some instances up to 250 yards, while the explosive effects of the projectile of the experimental Springfield rifle extended in some instances as far as the 350-yards range.

The term "explosive effects" is somewhat confusing, as it is apt to convey the idea that the wound was caused by an explosive bullet. It is a term that doubtless owes its origin to the similarity in the appearance of the two wounds. When we say that a wound shows explosive effects, we mean that it appears as though it had been caused by an explosive bullet. As a rule, the wound of entrance presents no special features to which attention should be called. In only a few instances is a certain amount of bone sand found in the tract leading to a fractured bone. When a resistant bone has been hit, the foyer of fracture will show great loss of substance, the bone will have been very finely comminuted, the pulverized bone will have been driven not only in the direction in which the projectile was travelling, but in all directions, and the pulpification of the soft parts will not only be limited to the track of the bullet, but utter destruction is noticed for some distance into the surrounding tissues. The wound of exit appears like a bursting forth of the skin; the track leading to the bone is conical in shape, the base of the cone corresponding to the wound of exit in the skin and the apex to the seat of fracture.

The degree of explosive effects corresponds to the velocity of the projectile at the moment of impact and the resistance offered by the part hit.

The bony structures are not alone in showing explosive effects with high velocities. Explosive effects have been noted with the projectile of the reduced calibre weapons up to 500 metres in "very vascular tissues, cavities filled with liquid or semi-liquid or viscous masses, such as the skull, heart, liver, spleen, kidneys, stomach, intestines, and bladder, which have been attributed by some observers to hydraulic pressure."

In order to test the influence of hydraulic pressure in causing explosive effects, some interesting experiments were conducted at Frankford Arsenal.

1. Empty powder cans were fired into at various ranges. The orifices of entrance and exit were found proportional to the size of the projectiles employed. The cans were not deformed, showing no explosive effects.

2. A half-dozen or more powder cans from the same lot were filled with wet sawdust. The cans were fired into at various ranges. The orifice of entrance in each case presented no special features. The orifice of exit, however, for both projectiles was marked by a bursting forth of the tin and loss of the contents. The cans had been expanded as if by an internal force, which had been exerted in all directions. The explosive effects were about the same for both bullets.

3. Another lot of powder cans of the same size and dimensions was filled with water and fired into. The results were quite similar to those observed in the case of the wet sawdust, only more extensive, and they were about equal for the two projectiles.

The following observations upon the explosive effects of projectiles at relatively short ranges picture in a marked degree the wounds that surgeons have to treat, as a result of high velocities, and unless one is prepared to interpret their true cause he is apt to fall into very erroneous conclusions.

Notes of Gunshot Injuries on the Human Body; Experiments Conducted at Frankford Arsenal, Pennsylvania, on March 18th, 1893, with the Large and Small Calibre Projectiles, for the Purpose of Noting the Explosive Effects at Relatively short Ranges.

1. Gunshot injury, left humerus, at junction of middle and lower thirds; bullet No. 4, calibre .45; range, 17 yards. The wound of entrance is oval, .55 inch in its greatest diameter. The wound of exit is marked by a chasm on the back of the arm four inches in length, 2.36 inches in width, the edges of which are ragged. There is eversion of muscle and fat. The soft parts contain minute fragments of bone, which have been driven some distance into the tissues. The bullet struck the humerus at the junction of the middle and lower thirds. The foyer of fracture shows a loss of substance of the shaft 1.60 inches in length. There is extensive comminution. The fragments (twenty-three being readily counted) are greatly displaced, and the majority of them are free from the periosteum. The bullet is very much mushroomed, having lost about one-half in weight.

2. A gunshot injury by the .30 calibre projectile, at the same range, on the opposite arm produced a wound of entrance which is round, .35 inch in diameter. The wound of exit is 4.30 inches in length, and 2.36 inches in width. It is marked by pulpification of the muscular tissue, which contains bone sand. The missile struck the shaft of the humerus above the middle, comminuting the bone extensively, but not to the extent observed in the preceding injury with the .45 calibre leaden projectile. Fourteen principal fragments were readily counted. They are large and not so much displaced as in the injury on the left humerus. The larger fragments are retained in place by their periosteal attachment. The fissures are not so extensive in the shaft above and below the seat of injury. The projectiles were recovered, the leaden nucleus having escaped from the harder metallic mantle. The cylindrical part of the envelope is intact, the conical end having split in four pieces, one of which is entirely detached from the shell.

3. Gunshot injury of the left tibia, middle third; bullet No. 5, calibre .45; range, 17 yards. The wound of entrance is round, .45 inch in diameter; the wound of exit is marked by a longitudinal tear in the calf 3.16 inches in length and 1.18 inches in width. The bullet struck the shaft of the tibia at the junction of the middle and upper thirds, shattering the bone extensively. The seat of comminution measures 4.30 inches; the fragments, which are all detached, have been displaced backward. Large numbers of fine spicula of bone have been driven into the muscle of the calf. The soft parts are reduced to a pulp-like mass for some distance beyond the walls of the chasm-like opening. The fibula is broken at the same level. The projectile was split into two lateral halves at the conical end, one of which was lost, whilst the other remains attached to the cylindrical portion.

4. A gunshot injury by the .30 calibre projectile at the same range on the opposite tibia shows a wound of entrance which is round, .30 inch in diameter, and a wound of exit which is marked by an oblique tear extending from the lower part of the popliteal space to the lower part of the calf, measuring 6.66 inches in length and 2.36 inches in width.

The bullet collided with the tibia at its inner border 4.30 inches below the knee-joint, comminuting the shaft. Upon removing the skin the wound of entrance is seen to be filled with bone sand, the periosteum over the crest of the shaft is partly torn; on the outer side several large, sharp splinters of bone remain attached to the periosteum; the posterior wall of the shaft below the popliteal space, two inches in extent vertically, has been entirely destroyed and spicula of bone and medulla are seen in the lacerated muscle of the calf. The fibula is fractured in two places just above the level of the fracture in the tibia. The muscle of the calf has been reduced to pulp.

The projectile was very much deformed; but one fragment of the metallic mantle was recovered; it measured .79 inch in length and .39 inch in width. The leaden nucleus was mushroomed and is only half the original length.

It will be seen from the foregoing that the explosive effects at short range differ but little for the two projectiles, and that they are always enormous.

Notes on the Effects, on the Human Body, of the Projectiles of Large and Small Calibre Impressed by the Velocity Common at 350 yards; Experiments Conducted at Frankford Arsenal, Pennsylvania, January 12th, 1893.

1. Gunshot injury of the left ankle; bullet No. 2, calibre .30. The wound of entrance is 1.18 inches below the tip end of the internal malleolus; it is star-shaped, .39 inch in its greatest diameter. The projectile entered the astragalus at the lower margin and at its articulation with the os calcis. A portion of the bone belonging to the astragalus at this point, .59 inch long by .39 inch wide, is lying in the wound, attached by periosteum. The posterior portion of the trochlear surface of the os calcis, .59 inch long by .39 inch wide, is partially detached. The missile passed between the os calcis and the astragalus and emerged through the upper portion of the os calcis next to the outer margin of the articulation. There are several free fragments from the latter bone in the wound of exit. The tip of the external malleolus was crushed by the projectile. The projectile was not deformed.

2. Gunshot injury of the left ankle joint; bullet No. 3, calibre .45. The wound of entrance is round, 3.54 inches in diameter, and torn, the tears radiating from the edges of the wound. The wound of exit is irregularly quadrilateral in shape, .79 inch in its greatest diameter. The bullet entered through the internal malleolus and made a grooved fracture of the astragalus; there is complete pulverization of the inner half of the articular surface of the tibia. The missile then passed out, piercing the posterior portion of the external malleolus, the anterior portion remaining attached to the shaft. The projectile was mushroomed.

3. Gunshot injury of the right foot; bullet No. 4, calibre .30. The wound of entrance is .35 inch in diameter, 1.18 inches in front of the external malleolus. The wound

of exit was found, after several minutes of patient searching, to be located in the sole of the foot, 1.38 inches from the internal malleolus. It is marked by a slit-like opening .28 inch in length. The edges of the slit approximate each other thoroughly, hence the difficulty experienced in locating the wound. The projectile entered the os calcis near its articulation with the cuboid and below the head of the astragalus, fracturing the calcaneo-cuboid articulation, splintering the bone in three fragments, near which a small amount of pulverized bone is found. All the bones of the tarsus are intact except the os calcis. The projectile was recovered unaltered in shape.

4. Gunshot injury of the left tibia and fibula near knee-joint, bullet No. 5, calibre .30. The wound of entrance is round, .39 inch in diameter; the wound of exit is marked by a longitudinal slit, measuring .39 inch in length. The projectile entered the anterior portion of the head of the tibia, .39 inch from the joint, in the middle line, passing obliquely toward the outer side, and emerged from the posterior surface of the head of the fibula. The orifice of entrance in the bone is equivalent to the diameter of the missile; the orifice of exit is irregular, .39 inch in its greatest diameter. There is no comminution of bone. The knee-joint was not perforated, but the articular surface adjacent to the outer tuberosity shows a fissure which in the recent state was not apparent. The projectile was lost.

5. Gunshot injury of the lower shaft of the right femur; bullet No. 3, calibre .45. The wound of entrance is 1.57 inches above the outer condyle, round, and .45 inch in diameter. The wound of exit is in the upper part of the popliteal space, irregularly quadrilateral in shape, .79 inch in its greatest diameter. The bullet entered the lower shaft, 1.57 inches above the margin of the articular surface, .39 inch outside the middle line. Nine large splinters are detached, measuring from .6 inch to 3.50 inches in length. There are a number of deep vertical fissures in the upper and lower fragments; those in the lower do not invade the joint. The projectile was very much set up.

6. Gunshot injury of the right hip joint. Bullet No. 6, calibre .30. The wound of entrance is .35 inch in diameter, over the femoral vessels, 1.57 inches below Poupart's ligament; the wound of exit is in the middle of the gluteal region of the corresponding side, oval in shape, and exceeds very little the diameter of the projectile. The bullet entered the capsular ligament at its inner margin and traversed the head of the femur, .79 inch below the ligamentum teres, producing a grooved fracture. The course of the projectile was horizontal and clear-cut; a fracture, 1.57 inches in length, is noticed extending downward through the ischium. The compact bone adjacent to the track of the bullet shows fissures not apparent in the fresh state. The missile entered the acetabulum, 1.97 inches from the lower margin in the cotyloid notch. The orifice of entrance corresponds nearly to the diameter of the projectile; the orifice of exit is irregular, 1.97 inches in its two diameters. A fragment of the outer plate of bone, .39 inch in length, hangs attached by periosteum. The projectile was not in the least deformed.

7. Gunshot injury of the left hip joint; bullet No. 7, calibre .30. The wound of entrance perforated the skin on the anterior aspect of the thigh, external to the large vessels, 1.57 inches below Poupart's ligament. The wound of entrance is round, .30 inch in diameter; the wound of exit is also round, in the middle of the gluteal region, and it barely exceeds the diameter of the missile. The projectile entered the anterior convexity of the head of the femur, after passing through the capsular ligament; the acetabulum was not involved until after the bullet had passed through the head of the femur. The projectile traversed the head of the femur in a horizontal direction, .30 inch above a horizontal line drawn through the centre of the head, and emerged at its posterior surface 1.28 inches external to the ligamentum teres. A fissure is seen connecting the points of entrance and exit, and extending outward along the upper margin of the attachment of the capsular ligament; there are smaller fissures that radiate from the orifice of entrance. No splinters are detached. The outer lip of the acetabulum, however, was split, and is held in place only by the capsular ligament. The bullet at the orifice of exit penetrated the acetabulum, .59 inch from the outer margin, emerging without detaching any splinters, excepting as noted, and left clean-cut orifices upon entering and leaving the bone. The orifices of entrance and exit in the globular head of the femur are round and equal to the diameter of the projectile. The orifice of entrance in the pelvis is round, and exceeds by only a fractional part the diameter of the projectile; the orifice of exit is .59 by .39 inch in diameter, with the margins of the orifice slightly elevated. The bullet was not deformed.

8. Gunshot injury of the right elbow joint; bullet marked "E," calibre .30. The wound of entrance is on the external aspect of the arm opposite the bend of the elbow, 2.36 inches from the olecranon; it is round, and equal in diameter to that of the projectile; the wound of exit is .59 inch below the tip of the olecranon; it is star-shaped, and .30 inch in its greatest diameter. The projectile passed through the head of the radius, permitting the outer and posterior aspect of the forearm to receive the wound; the head is split in two portions, one half of which is finely comminuted, while the outer half, together with its portion of the neck and .79 inch of the shaft, remains in place without much damage to the periosteum. The pulverized bone, comprising the inner half of the head, lies free in the joint. The projectile entered the ulna .20 inch below the joint, near the posterior margin of the lesser sigmoid cavity; the olecranon is completely crushed; fissures extend through the greater sigmoid cavity, and the posterior portion of the articular surface. There are seventeen small splinters detached from the periosteum about the foyer of destruction. The projectile was slightly dented on one side in the cylindrical portion; otherwise it sustained no deformation.

9. Gunshot injury of the right shoulder joint; bullet No. 6, calibre .30. The wound of entrance is round, .30 inch in diameter; it perforated the skin well up on the anterior aspect of the shoulder, .39 inch below the acromion; the wound of exit is irregular in shape, .59 inch in its greatest diameter, on the posterior aspect of the shoulder, 4.72 inches from the wound of entrance, measuring over the shoulder. The projectile entered the bone in the bicipital groove between the two tuberosities and traversed the head of the humerus, crushing the head in passing out posteriorly. One large splinter, 1.18 inches by .98 inch, was carried through the orifice of exit in the bone and found embedded in the infraspinatus and teres minor muscles. Four other splinters comprising the globular head of the humerus lay about the seat of fracture; the central portion of the head is pulverized and discolored by lead. The bullet was not recovered.

NOTES ON THE DESTRUCTIVE EFFECTS ON THE HUMAN BODY, OF THE PROJECTILES OF LARGE AND SMALL CALIBRE IMPRESSED BY THE VELOCITY COMMON AT 1,200 YARDS. EXPERIMENTS CONDUCTED AT FRANKFORD ARSENAL, PENNSYLVANIA, MARCH 9TH, 1893.

1. Gunshot injury of the lower third of the left femur; bullet marked "J," calibre .45. The wound of entrance is round, .45 inch in diameter; the wound of exit is in the upper part of the popliteal space, marked by a slit running obliquely, 1.38 inches in length. The missile struck the shaft of the left femur 2.36 inches above the articular cartilage on the inner side of the median line. The bone immediately behind the point of impact, covering an irregular space 1.5 by 2 inches in diameter, was carried away and lies finely comminuted in the track of the bullet; only a fraction of the number of the splinters of bone could be recovered. Some fragments of lead were found with the bone sand. The projectile was very slightly flattened in the cylindrical portion near the base; one-third of the conical portion of the bullet was severed

laterally and lost; the remaining two-thirds are flattened laterally.

2. Gunshot injury of the head of the right tibia; bullet marked "K," calibre .30. The wound of entrance is .30 inch in diameter, and .59 inch below the patella; the wound of exit is in the upper part of the calf; it is quadrilateral in shape, .30 inch in its largest diameter. The projectile perforated the head of the tibia in the middle line, .39 inch below the articular surface. The diameter of the track of the projectile corresponds to the diameter of the missile; the orifice of exit is on the posterior surface, .39 inch distant from the articular facet for the fibula. No large fragments were found in the tissues. The fibula and the articular surface of the head of the tibia are uninjured. The projectile was not deformed.

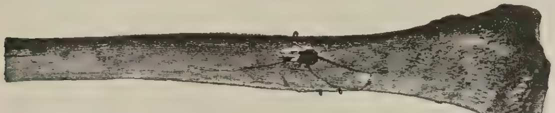

FIG. 2357.—Gunshot Injury of the Right Tibia, at the Junction of the Upper and Middle Thirds, by the ."30 Calibre German-Silver Jacketed Projectile with the Velocity Common at 1,200 Yards. The projectile penetrated the shaft six inches below the knee joint. Examination immediately after the shot was fired revealed no mobility, although upon dissection a distinct fracture was observed. The displacement of the principal fragments is very slight.

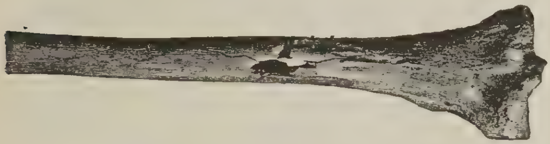

FIG. 2358.—A Posterior View of Fig. 2357.

3. Gunshot injury of the lower end of the right femur; bullet marked "D," calibre .30. The wound of entrance is round, .30 inch in diameter, .79 inch above patella; the wound of exit is in the internal and upper part of the popliteal space, marked by a quadrilateral orifice having a punched-out appearance, .79 inch in its greatest diameter. The projectile perforated the anterior face of the bone about its middle, immediately above the upper margin of the articular surface. A small quantity of finely pulverized bone was found in the wound of exit. There was no fissuring, and the articular surface was uninjured. The projectile sustained a slight flattening of its tip at the conical end.

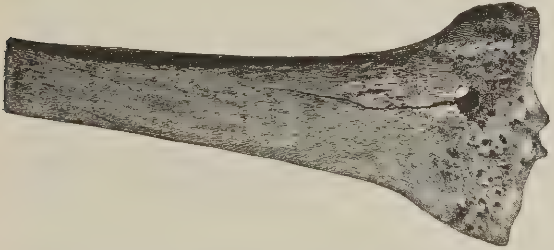

FIG. 2359.—Gunshot Injury of the Head of the Right Tibia by the ."30 Calibre German-Silver Jacketed Projectile with the Velocity Common at 1,200 Yards. The projectile perforated the head of the tibia in the middle line ."39 below the articular surface. The diameter of the track of the bullet in the bone corresponds to the diameter of the missile.

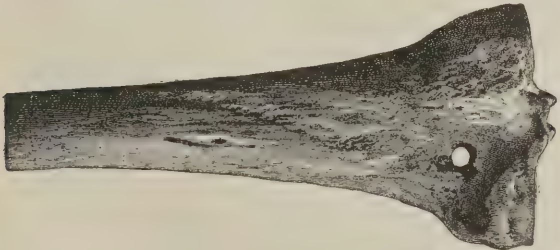

FIG. 2360.—A Posterior View of Fig. 2359.

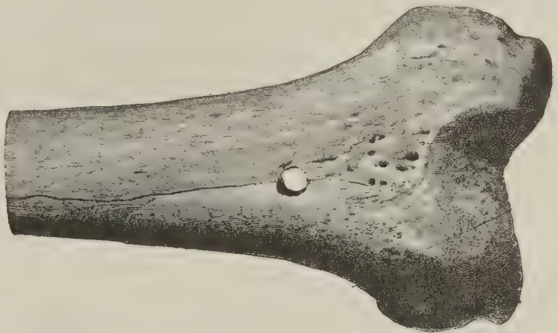

FIG. 2361.—Gunshot Injury of the Lower Third, Right Femur, by the ."30 Calibre German-Silver Jacketed Projectile with the Velocity Common at 1,200 Yards. The projectile perforated the anterior face of the bone about its middle, immediately above the upper margin of the articular surface, making a clean-cut perforation. The fissure occurred in drying; it was not present in the recent state.

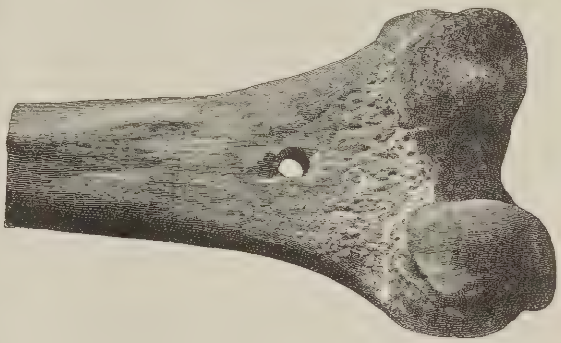

FIG. 2362.—A Posterior View of Fig. 2361.

4. Gunshot injury of the left knee-joint; bullet marked "B," calibre .45. The wound of entrance is round, .45 inch in diameter, a little internal to the middle of the patella; the bullet ranged downward, backward, and outward, inflicting, in the fleshy part of the

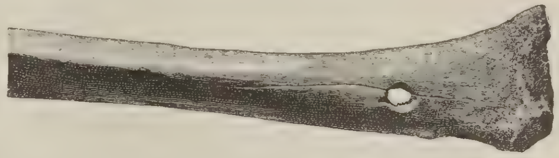

FIG. 2363.—Gunshot Injury, Right Tibia, near the Ankle, by the ."30 Calibre German-Silver Jacketed Projectile with the Velocity Common at 1,200 Yards. The bullet perforated the tibia on the anterior aspect in the middle line 2."17 above the ankle joint. The orifice of entrance has a punched-out appearance equal in diameter to that of the projectile. The fissure occurred in drying; it was not present in the recent state.

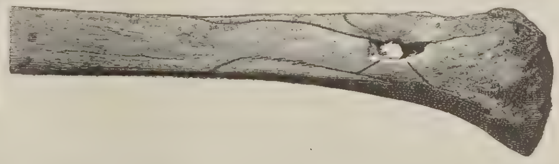

FIG. 2364.—A Posterior View of Fig. 2363. Fissures are exaggerated by drying.

calf, a wound of exit which is quadrilateral in shape, .79 inch in length. The bullet entered the patella on the inner side of the median line and passed through the outer condyle, emerging .79 inch from the point of entrance, splitting the outer tuberosity. A slight outward displacement of the fragments shows a fissure extending upward to the margin of the articular cartilage. The patella is broken into a number of fragments. Passing downward the bullet entered the left tibia, carrying away a portion of the outer cartilage and grazing the top of the fibula. The bullet was flattened laterally along its cylindrical and conical portions on one side, and flattened at the conical end alone on the opposite side.

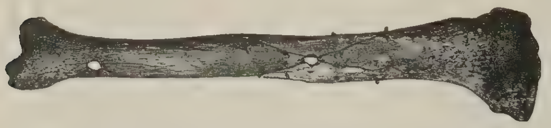

FIG. 2365.—The Specimen Shows Two Perforations of the Right Tibia by the ."30 Calibre German-Silver Jacketed Projectile with the Velocity Usually Possessed at 1,200 Yards. The perforation in the middle of the shaft shows two fissures crossing each other in the form of an "×." There is a complete fracture. The lower perforation is attended with less fissuring. There is no solution of continuity.

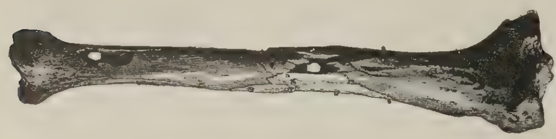

FIG. 2366.—A Posterior View of Fig. 2365.

5. Gunshot injury of the left tibia and fibula near the ankle joint; bullet marked "G," calibre .45. The wound of entrance is over the ankle in front, round, .45 inch in diameter. The wound of exit is just above the external malleolus between the tendo Achillis and the fibula. It is marked by a longitudinal slit, 1.38 inches in length. The bullet entered the tibia 1.18 inches above the ankle joint in the median line; the missile struck the tendon of the tibialis anticus muscle, displacing it to the outer side. The inner portion of the shaft and internal malleolus remain intact. The shaft of the outer side is fissured irregularly; a zigzag line extends between the points of entrance and exit. The fibula is fractured at the same level. The bullet is flattened in the cylindrical portion near the base, and flattened laterally at the conical end, the flattened surface at the latter point being very irregular.

6. Gunshot injury of the right tibia near the ankle; bullet marked "H," calibre .30. The wound of entrance is over the lower part of the leg anteriorly, round, .30 inch in diameter. The wound of exit lies in the same place posteriorly; it presents a punched-out appearance, is triangular in shape, .30 inch in its greatest diameter.

The bullet perforated the tibia on the anterior aspect in the median line, 2.17 inches above the ankle joint. The orifice of entrance has a punched-out appearance; it is .30 inch in the vertical and .24 inch in the horizontal direction. There is a fissure 3.75 inches long, extending upward from the perforation; it is seen through the periosteum, the latter being intact. Posteriorly between the foyer and the wound of exit in the skin many fine splinters of bone are distributed, the fibula is uninjured. The bullet is very little flattened at the conical end.

7. Gunshot injury of the right knee; bullet No. 1, calibre .45. The wound of entrance is .30 inch internal to and above the patella; it is round, .45 inch in diameter; the wound of exit is in the middle of the popliteal space, star-shaped, .59 inch in its greatest diameter. The bullet entered the bone 1.18 inches above the articular surface. The diameter of the perforation corresponds to the diameter of the missile. The orifice of exit posteriorly admits the index finger and is situated in the popliteal space above the trochlear surface of the inner side of the median line. The bullet was recovered, very little dented at the conical end.

8. Gunshot injury of the upper third of the left femur; bullet No. 2, calibre .45. The wound of entrance is round, .45 inch in diameter; the wound of exit is marked by a slit-like opening running longitudinally, 1.18 inches in extent. The projectile entered the anterior aspect of the femur and shattered the bone above its middle. Nine large splinters, from 4 inches to .40 inch in length, are found in the foyer of fracture, and only partially held by the periosteum. The bullet was set up and dented at one side at the conical end.

9. Gunshot injury of the upper third of the right femur; bullet No. 1, calibre .30. The wound of entrance is round, .30 inch in diameter; the wound of exit is in the fleshy portion of the thigh, quadrilateral in shape, .79 inch in its greatest diameter. The bullet entered the bone 5.50 inches below the trochanter major, comminuting the shaft. The largest fragment is 4 by 1.18 inches, and is firmly adherent to the surrounding tissues. The specimen shows an old united fracture of the upper shaft passing obliquely and immediately below the trochanters. The bullet was flattened at the conical end and distorted to one side; the leaden nucleus protrudes from the mantle at the base.

10. Gunshot injury, right tibia, middle of shaft; bullet marked "T," calibre .30. The wound of entrance is round, .30 inch in diameter; the wound of exit is marked by a slit in the calf, .35 inch in its greatest length. The bullet struck the subcutaneous surface of the tibia at its middle, splintering the bone into several large fragments; the largest one, embracing the crest of the tibia, is 5 inches long. Viewed from the inner side the fissures cross at the point of impact, so as to form an "X." The periosteum is intact and binds the fragments together so that, as the dissection would indicate, there is no reason to suppose that the fracture would not unite readily. A large number of fine splinters of bone were found in the muscular tract of the calf, near the seat of fracture. No great laceration of soft parts was observed. The fibula was not injured. The projectile was dented at the conical end.

11. Gunshot injury, right tibia near the ankle joint; bullet marked "C," calibre .30. The wound of entrance is round, .30 inch in diameter; the wound of exit is marked by a slit .30 inch in length. The bullet perforated the shaft 2 inches above the internal malleolus. On removing the skin the orifice of entrance in the bone presents sharply cut edges, and it corresponds in size to the diameter of the missile. The bullet passed out at the posterior aspect of the bone, the orifice at this point being irregular in shape and a trifle larger than the ori-

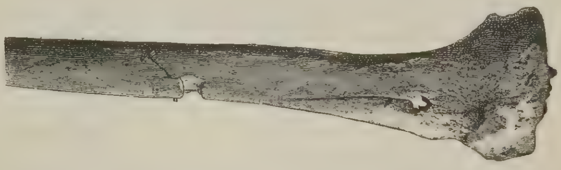

FIG. 2367.—This Specimen Shows a Complete Perforation in the Upper Part of the Shaft of the Left Tibia by the ."30 Calibre German-Silver Jacketed Projectile with the Velocity Common at 1,200 Yards. There is also an injury in the middle of the shaft by a ."30 calibre projectile at the same range. The bullet struck the crest of the tibia, passing wholly in front of the medullary canal, and producing a gutter in the crest. There is a complete fracture. There is no record of the injury near the ankle.

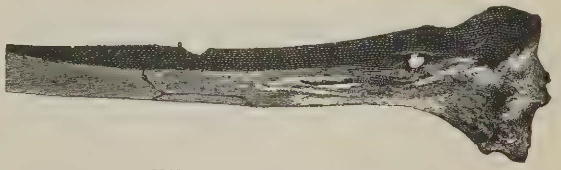

FIG. 2368.—A Posterior View of Fig. 2367.

fice of entrance. A few splinters of bone were found in the track of the bullet leading from the bone. The projectile was not deformed.

Notes on the Effects, on the Human Body, of the Projectiles of Large and Small Calibre Impressed by the Velocity Common at 2,000 Yards. Experiments conducted at Frankford Arsenal, Pennsylvania, March 16th, 1893.

1. Gunshot injury left tibia, middle third; bullet No. 1, calibre .45. The wound of entrance is oval in shape, .51 inch in its greatest diameter. The projectile remained lodged under the skin of the calf. The bullet entered the subcutaneous part of the shaft, 5.50 inches below the knee joint, causing extensive comminution of the bone at the foyer of fracture, including 2 inches of the shaft. Some of the fragments are free whilst others remain attached to the periosteum. The bullet was found under the skin of the calf; it was cleft longitudinally through the conical part, one-half of the cone having become detached from the cylindrical part. The detached fragment was found embedded in the tibialis anticus muscle.

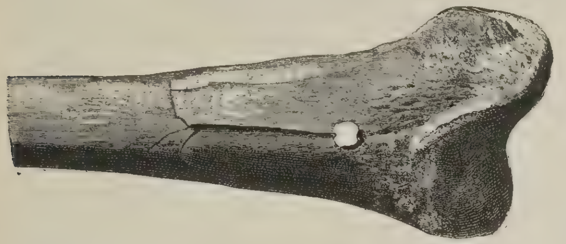

FIG. 2369.—Gunshot Injury, Lower Third, Right Femur, by the ."30 Calibre German-Silver Jacketed Projectile Propelled with the Velocity Usual at 2,000 Yards. The projectile entered the bone ."79 above the articular surface, making a perforation with long fissures.

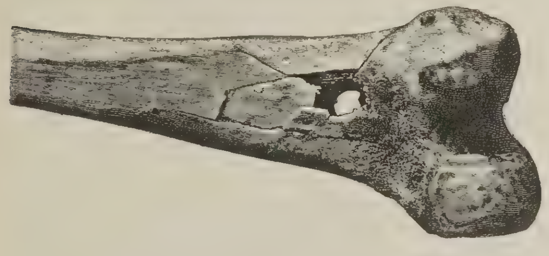

FIG. 2370.—A Posterior View of Fig. 2369.

2. Gunshot injury of the right tibia at junction of middle and lower thirds; bullet No. 4, calibre .30. The projectile entered side on, inflicting a wound of entrance which runs obliquely, .98 inch long and .39 inch wide. The bullet lies under the skin posteriorly in the lower part of the calf. The bullet guttered the inner side of the tibia 5.12 inches above the internal malleolus. On removing the skin several spicula of bone are seen in the wound; the outer border and crest of the tibia are uninjured; the posterior surface of the bone is splintered over a distance of 3.15 inches in lines which radiate from the point of emergence. The periosteum is not detached, excepting in the line of the passage of the projectile and over an area adjacent to the posterior margin of the groove, between .20 and .40 inch in diameter. The fibula was not injured. The bullet was embedded in the muscle of the calf with its point resting against the skin and its base presenting in the track through the muscle adjacent to the bone, a distance of .79 inch. The projectile is slightly flattened at the conical end, otherwise it is unaltered.

3. Gunshot injury of the left knee joint; bullet No. 2, calibre .45. The wound of entrance is round, .45 inch in diameter, above and internal to the patella; the wound of exit is in the lower part of the popliteal space, oval, and .59 inch in its greatest diameter. The bullet perforated the tibia 1.18 inches below the articular surface. The orifice of entrance in the bone is sharply defined, irregular in shape, .59 inch in the vertical and .39 inch in the horizontal line; the orifice of exit is also irregular, .59 inch in its greatest diameter. There is a fracture of the shaft marked by a fissure, which runs downward and backward; the compact tissue of the upper and posterior surface of the bone is broken by radiating fissures into six fragments. The muscular track from the bone to the wound of exit contains some fine spicula of bone. The projectile was not recovered.

4. Gunshot injury of the right knee joint; bullet No. 9, calibre .30. The wound of entrance is round, .30 inch in diameter and .39 inch from the internal border of the patella at its middle; the wound of exit is in the upper part of the popliteal space marked by an oblique slit-like opening .39 inch in length. The projectile entered the bone .79 inch above the articular surface, making a perforation of the femur; the missile passed out in the median line in the popliteal space, perforating the popliteal vein, but leaving the artery uninjured. The wound is full of venous blood clots. Very fine spicula of bone were found in the track of the projectile leading to the wound of exit. There is a fissure 4.72 inches in length, which extends from the orifice of entrance in the direction of the shaft, and a number of smaller radiating fissures are observed to start from the orifice of exit. The projectile was recovered from the sawdust very much deformed. The metallic jacket was ruptured at the conical end, having a slit running along the side of the cylindrical portion at the end of which a transverse slit occurs, which includes one-half of the cylindrical part of the envelope; the leaden nucleus has parted entirely from the jacket; it is flattened at the conical end, bent upon itself in the cylindrical portion, and scooped out on one side.

5. Gunshot injury of the left femur, upper third; bullet No. 3, calibre .45. The wound of entrance is round, .45 inch in diameter; the wound of exit is on the outer and posterior aspect of the thigh, marked by a longitudinal slit, .59 inch in length. The projectile made a glancing shot, striking the outer aspect of the shaft of the femur 4.72 inches below the trochanter major, and producing an oblique fracture of the shaft from above downward and inward; the fragments are considerably displaced, the lower shaft lying to the outer side; the periosteum is detached about the point of impact, but the fragments of bone are not loosened to any very great extent; there is a fissure extending from the trochanter minor downward a distance of 6 inches. Particles of lead were found in the foyer of fracture. The bullet

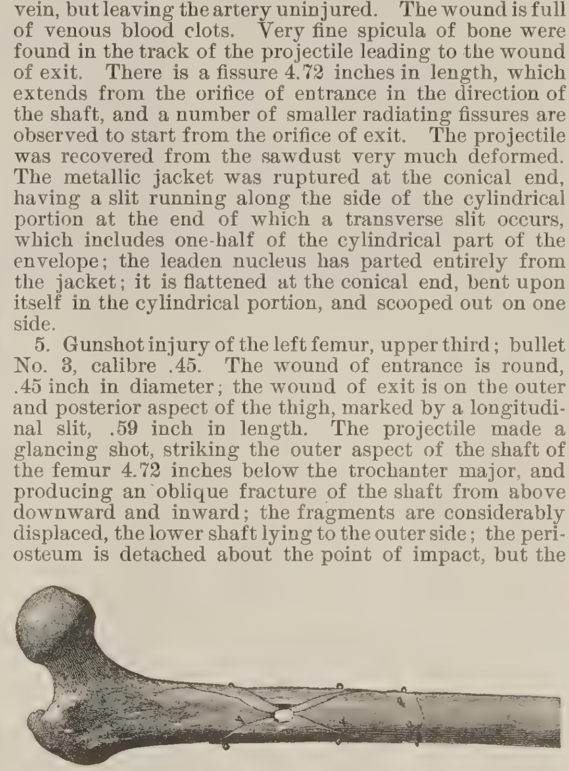

FIG. 2371.—Gunshot Injury of the Right Femur at Junction of Middle and Upper Thirds by the ."30 Calibre German-Silver Jacketed Projectile with the Velocity Common at 2,000 Yards. There is a well-marked perforation with extensive fissuring.

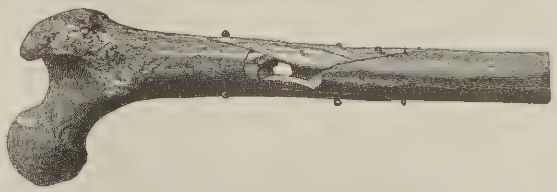

FIG. 2372.—A Posterior View of Fig. 2371.

was seemingly split in two lateral halves nearly equal in weight; the greater half only was recovered.

6. Gunshot injury of the right femur, upper third; bullet No. 0, calibre .30. The wound of entrance is round, .30 inch in diameter; the wound of exit is triangular in shape, .39 inch in its greatest length. The bullet struck the shaft of the femur in the middle line anteriorly, 7 inches below the anterior superior spine of the ilium, comminuting the bone into a number of fragments, which are held by periosteum. The bullet was flattened at the conical end; otherwise it is unaltered.

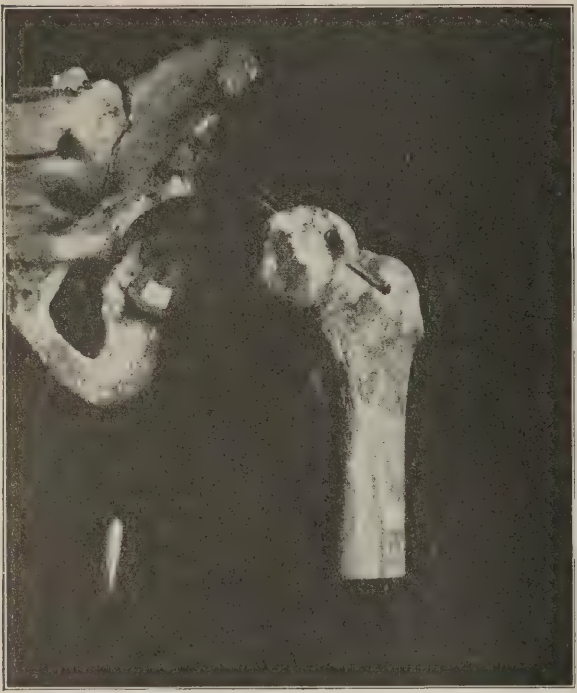

FIG. 2373.—Gunshot Perforation of the Head of Left Femur and Acetabulum by the ."30 Calibre German-silver Jacketed Projectile with Velocity Common at 1,200 Yards. The bullet appears in illustration undeformed.

OBSERVATIONS UPON THE FOREGOING RESULTS.—*Soft Parts.*—The wound of entrance corresponds in diameter as a rule to the diameter of the projectile. In the middle and remote ranges the entrance wound measured less at times than the diameter of the projectile, but the difference was only apparent since the wound invariably admitted a projectile of like calibre to the one having inflicted it. In the short ranges it was often noted that skin overlying bone and resistant aponeurosis was apt to show a wound of entrance actually exceeding in diameter that of the missile. The edges of the wound of entrance were at times clear-cut, but more often they were rolled in, and often blackened for a distance of a line about the circumference. The latter circumstance gave rise to the notion formerly that the discoloration was due to burning, but from experiments to be cited later this fallacy has been forever set at rest.

The wound of exit of the .30 calibre rifle was generally larger than the wound of entrance, and beyond the zone of explosive effects especially, it was generally round, marked at times by a mere slit; again it was star-shaped, T-shaped, semicircular, etc.; the edges were generally turned out. When a wound of exit exceeded in diameter that of the projectile to any extent the circumstance was generally regarded as indicative of bone lesion.

Effects upon the Shafts of Long Bones.—Up to 350 yards the destructive effects of the two projectiles are alike severe. Unless guided by the wound of entrance or other circumstances it is difficult within this range to determine, by the appearance of the injury alone, which of the projectiles has caused the injury. After this range the destructive effects of the smaller projectile become less than those of the larger missile. The fissuring is less, the spicula of bone are larger, and they are more apt to be attached to the periosteum. These differences are especially noticeable from the 500- to the 1,500-yard ranges. At 2,000 yards the smaller bullet again shows rather extensive comminution. This fact has been noted by all observers, and it has been variously explained, though not in a very satisfactory manner. It has been said that the projectile has lost so much of its velocity of translation, when it reaches this part of its course, that it is apt to lodge, and that the velocity of rotation causes such a disturbance, when it is about to engage, that comminution is the result. The angle of impact which is rarely vertical at this range, has been brought forward as a possible cause. Certain it is that a number of the projectiles were observed by us at this range to impinge side on at the moment of impact.

Effects upon Joints.—Before engaging upon this part of the subject it may be stated that the humane wound of the small-bore gun is especially observed in the joints and soft parts. Owing to the reduction in calibre the wounds in the latter partake more of the nature of subcutaneous wounds, and experience shows that they heal very kindly under appropriate treatment.

It is not necessary in this instance to dwell especially upon the destructive effects of the larger leaden projectile upon joints. Suffice it to say that the greater frontage, which it naturally possesses, is made greater still by deformation, and that these facts, in combination with a velocity sufficient to penetrate a joint, serve to convert the .45-calibre projectile into a very destructive missile.

The experiments conducted at Frankford Arsenal show in a striking manner the difference between the two bullets in their destructive effects upon the spongy ends of bones. In order to appreciate this difference it is necessary to go beyond the zone of explosive effects for the .30 calibre projectile, namely 350 yards; even within the latter range perforation with slight fissuring will at times be noticed. From the latter range to the 1,500-yard range perforations and gutterings with little or no fissuring are almost invariably seen. Between 1,500 and 2,000 yards the specimens show perforations still, but there is a tendency to fissuring again, as noted in the shorter ranges (see Figs. 2363 and 2364).

Deformation of Projectiles.—The different kinds of deformation of projectiles represent nearly every form of alteration known. Those of the leaden projectiles are sufficiently familiar and require no comment. The deformation of the jacketed projectile is most common at the conical end which consists usually in a slight dent or flattening, and partial separations of the metallic mantle

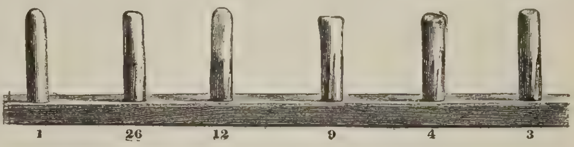

FIG. 2374.—Specimens Showing the More Common Deformations of the ."30 Calibre German-silver Jacketed Projectile. No. 1, A normal ."30 calibre German-silver jacketed projectile which was never fired. No. 26, A ."30 calibre German-silver jacketed projectile showing the deformation sustained upon fracturing the middle of the shaft of the tibia, when propelled with the velocity usual at 1,200 yards. No. 12, A ."30 calibre German-silver jacketed projectile showing the deformation sustained upon causing a fracture with slight comminution of the lower half of the humerus, while propelled with the velocity common at 1,500 yards. No. 9, A ."30 calibre German-silver jacketed projectile showing deformation after fracture of the middle half of the femur, when propelled with the velocity common at 1,500 yards. No. 4, A ."30 calibre German-silver jacketed projectile showing the deformation upon colliding with the upper third of the femur while propelled with the velocity common at 2,000 yards. No. 3, A ."30 calibre German-silver projectile showing the deformation sustained upon fracturing the middle third of the tibia when propelled by the velocity usual at 2,000 yards.

from the leaden nucleus are occasionally seen; complete separation between the jacket and nucleus is a very rare occurrence. It occurs principally with high velocities at close range, when the projectile encounters resistant bone. Separation of the envelope and nucleus was noticed very seldom in the middle and remote ranges.

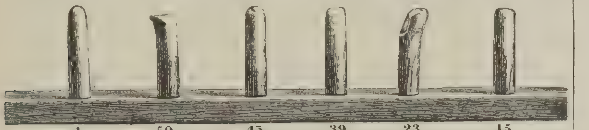

FIG. 2375.—Specimens Showing the More Common Deformations of the ."30 Calibre German-silver Jacketed Projectile. No. 4, This is a normal ."30 calibre German-silver jacketed projectile which was never fired. No. 50, A ."30 calibre German-silver jacketed projectile after inflicting a comminuted fracture of the tibia and fibula with the velocity common at 150 yards. No. 45, A ."30 calibre German-silver jacketed projectile which caused perforation of the astragalus with the velocity usual at 350 yards. No. 39, A ."30 calibre German-silver mantle projectile which inflicted a perforation of the surgical neck of the humerus with little comminution with the velocity common at 350 yards. No. 23, A ."30 calibre German-silver jacketed projectile after inflicting a perforation with slight fissuring of the middle of the shaft of the tibia, when propelled with the velocity usual at 1,200 yards. No. 15, A ."30 calibre German-silver jacketed projectile after inflicting a complete fracture with extensive fissures of the middle of the shaft of the femur, while propelled with the velocity usual at 1,500 yards.

Before we leave the subject of the work done by experiments as to the character of gunshot wounds, for the more practical one in the clinical field, it may be well to admit that the deductions of the experimenters have been questioned by a number of surgeons. On the other hand, the experimenters themselves, the great majority of whom have largely dealt with gunshot injuries as actually observed in accidents and in war, are satisfied to believe that the experimental wounds tally in the main with those which we meet in the actual conditions, and that their judgment has been amply confirmed by the accumulated experience in the Spanish-American and South-African wars.

The Heat Imparted to Projectiles.—The heat imparted to projectiles by the ignition of the powder, the resistance in the barrel, etc., has been very much exaggerated. Some have gone so far as to claim that the small jacketed bullets are rendered aseptic thereby. In a series of experiments conducted at the Pathological Laboratory of the Johns Hopkins University and Hospital, and also at Frankford Arsenal some years since, we were able to show that this claim is false. In order to arrive at some definite conclusion in the matter a series* of experiments were undertaken for the purpose of obtaining answers to the two following questions:

(1) Are projectiles from portable hand weapons sterilized by the act of firing?

(2) Can a septic bullet infect a gunshot wound?

As a preliminary to the work of noting the effects of firing bullets that had been previously contaminated it was considered proper to ascertain the condition, bacteriologically speaking, of bullets in their original packages. After a number of observations it was found that fifty-three per cent. of all cartridges in their original packages were absolutely free from germs. This is to be ascribed to the cleanly methods which are necessary in their manufacture.

The literature of gunshot wounds shows that the majority of surgeons of the past and present times believe that the act of firing destroys any infection that might have been accidentally or otherwise placed upon the projectile.

In order to ascertain the facts in the matter we fired projectiles, after they had been sterilized by heat, from revolvers that had been similarly sterilized. The projectiles were recovered from sterilized cotton and dropped into gelatin tubes. The latter revealed no growth.

Projectiles covered with dust were then fired from sterilized revolvers into sterilized cotton. As each projectile was recovered it was dropped into a gelatin tube. Colonies appeared in every instance.

In a series of experiments with the .22 and .38 calibre revolvers, the .45 calibre Springfield rifle, as well as the .30 calibre Experimental Springfield rifle, whose ballistic qualities correspond to the Krag-Jörgensen, Männlicher, improved Mauser, Lebel, etc., the projectiles were in all instances infected with the germs of anthrax and fired into sterilized materials and into animals. The tables of results show that anthrax bacilli or spores are seldom, if ever, destroyed by the act of firing.

Bullets infected with the streptococcus of erysipelas, with some of the same culture of tetanus mentioned below, and with the bacillus pyogenes soli of Bolton, were fired through the ears of rabbits with a .45 calibre Colt's revolver. The erysipelas coccus was communicated to one animal, and the bacillus pyogenes soli was recovered from the wound of another; tetanus was not communicated.

A bullet infected with a culture of the bacilli of tetanus was fired into a horse with the modified Springfield rifle with negative results; rabbits inoculated with some of the same culture died promptly. At the suggestion of Prof. Meade Bolton, of the Johns Hopkins Hospital, a bag of tetanus earth was placed against the hip of another horse and the projectile of the .30 calibre Experimental Springfield rifle was fired through the earth into the fleshy part of the ham without result.

Later, a series of experiments were conducted to show the effects of firing infected bullets into animals at 300 and 500 yards.*

Whether bacteria might remain on a projectile in transit through the air for such a number of yards had often been questioned, but the evidence at a distance was identical with that obtained at the proximal ranges.

The foregoing results have justified the following conclusions:

(1) The majority of cartridges in original packages are sterile and free from septic germs.

(2) The sterile condition of cartridges is due to the thorough disinfection and absolute cleanliness observed in the process of manufacture.

(3) The majority of gunshot wounds are aseptic because the vast majority of the projectiles inflicting them are either sterile or free from septic germs.

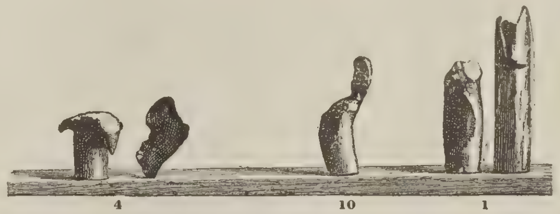

FIG. 2376.—Specimens Showing Unusual Deformations of the ."30 Calibre German-silver Jacketed Projectiles. No. 4, A ."30 calibre German-silver projectile showing separation of the nucleus from the envelope; the nucleus is badly mushroomed, and only a fragment of the envelope was recovered. The projectile was fired into the arm at 17 yards with the full charge of powder. The humerus was pulverized 3 inches in extent, and the soft parts showed extensive explosive effects. No. 10, A ."30 calibre German-silver jacketed projectile showing deformation after causing extensive comminution of the femur, when propelled with the velocity common at 500 yards. The nucleus alone was recovered. No. 1, A ."30 calibre German-silver jacketed projectile showing the deformation sustained after perforating the lower shaft of the femur, when propelled with the velocity usual at 2,000 yards. The nucleus has escaped from the envelope through a rent in the conical end. The concavity in the nucleus was probably sustained by colliding with another projectile in the sawdust.

(4) Anthrax spores or bacilli when applied to the projectile of a portable hand weapon are seldom if ever entirely destroyed by the act of firing.

(5) When a gunshot wound is inflicted upon a sus-

---

* N. Y. Med. Journal, vol. lvi., No. 17, p. 458, October 22d, 1892.

* New York Med. Journal, vol. lvi., No. 17.

ceptible animal by a projectile infected with anthrax bacilli the animal becomes infected with anthrax and dies in the vast majority of instances from said infection.

(6) The streptococcus of erysipelas and the bacillus pyogenes soli, when placed upon the projectile of the .45 calibre Colt's revolver, are certainly not always destroyed by the act of firing, and they are liable to cause infection.

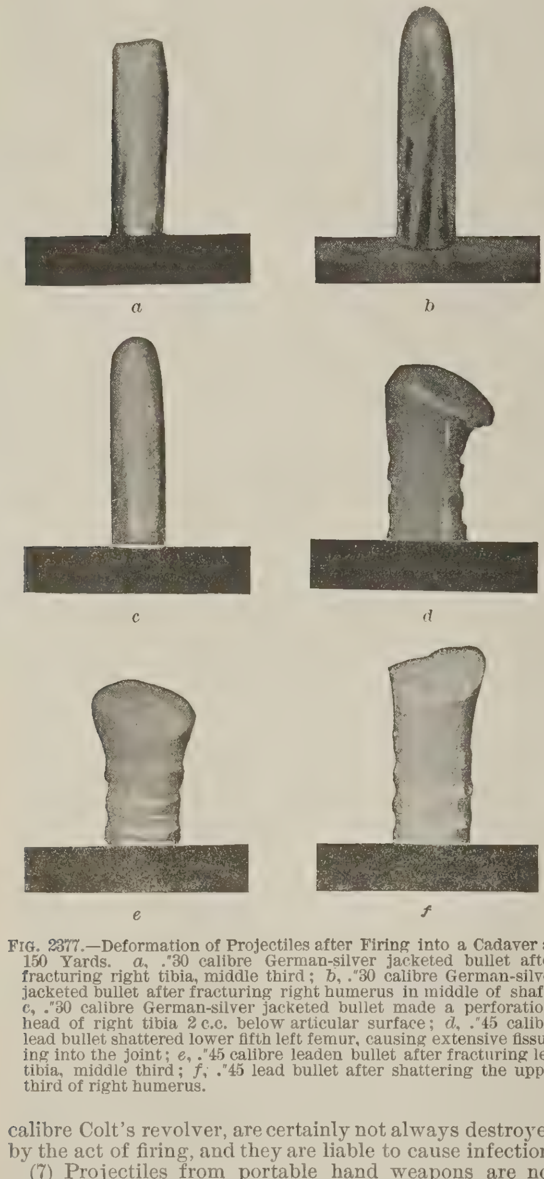

FIG. 2377.—Deformation of Projectiles after Firing into a Cadaver at 150 Yards. *a*, ."30 calibre German-silver jacketed bullet after fracturing right tibia, middle third; *b*, ."30 calibre German-silver jacketed bullet after fracturing right humerus in middle of shaft; c, ."30 calibre German-silver jacketed bullet made a perforation, head of right tibia 2 c.c. below articular surface; *d*, ."45 calibre lead bullet shattered lower fifth left femur, causing extensive fissuring into the joint; *e*, ."45 calibre leaden bullet after fracturing left tibia, middle third; *f*, ."45 lead bullet after shattering the upper third of right humerus.

(7) Projectiles from portable hand weapons are not sterilized by the act of firing.

(8) A septic bullet can infect a gunshot wound.

PRIMARY SYMPTOMS OF GUNSHOT WOUNDS.—The symptoms usually noted in gunshot wounds are (1) pain, (2) shock; (3) primary hemorrhage; (4) thirst; (5) lodgment of the bullet; (6) powder burn, and (7) multiplicity of wounds or, more properly speaking, complications of a primary nature.

(1) *Pain.*—The amount of pain, as an early symptom of gunshot wound, is variable. Indeed it may be said that save in some cases of nerve injury it is not a symptom that reflects the extent or gravity of the injury sustained. The remembrance of the amount and character of the pain at this time of injury is usually vague. Some liken it to a smart tap from a cane, others to a thrill across the tissues, or to a slight sting. During moments of great excitement, in the case of soldiers in battle or of antagonists in duels, the absence of pain is not uncommon. In a certain percentage of cases there is the very opposite of pain, namely a local anæsthesia; the parts about the area of injury have lost their sensibility, the surface is numb to the sense of touch, or to efforts at primary dressing of the wound. Stevenson says that such wounds are apt to give rise to septic discharges. Probably in these cases the vitality of the parts is so lowered that the tissues fall an easy prey to pyogenic micro-organisms. Inquiry among the wounded at Santiago showed that pain was largely related to the idiosyncrasy of the individual. Makin* relates, as a striking instance of absence of entire pain, the case of a man shot through the buttock, the bullet then traversing the abdomen. He was unaware of the fact until he found blood on his trousers on undressing, when he exclaimed, "Why I have got this bloody dysentery." It is related that he died in thirty-six hours.

(2) *Shock.*—Constitutional shock without special tendency to loss of consciousness is generally present. The evidences of shock are most marked in the facial expression. Mr. Harold Schwartz was able by the expression of the face alone to distinguish the cases requiring immediate attention after battle. Before Santiago, in the cases of Mauser wounds from the Spanish rifle, the greatest amount of shock followed hits in the upper part of the femur, the spinal cord, and viscera. Although local shock, as shown by experimental evidence, is much less from reduced-calibre bullets, the assertion on the part of certain observers that men wounded would advance after being hit a number of times was not true of the wounded in Cuba. As a rule to which there were few exceptions, when hit, a man fell back.

(3) *Primary Hemorrhage.*—Primary hemorrhage which threatens life, from gunshot, may be divided into two kinds, internal and external. Of the internal variety, that resulting from injury to blood-vessels in the interior of the trunk, not very readily accessible to surgical aid, is said to cause the majority of deaths on the field of battle, although no one has yet offered statistics to substantiate such claim. Of the external variety, which might be easily stayed by the surgeon in time to save life, the percentage is not so obscure. Doubtless direct injury to a main vessel like the brachial or femoral by a bullet of large calibre, ends fatally in the majority of cases in battle. The cases of this character seen by the surgeon in time are generally acknowledged to be very few compared to the whole number of wounds. According to Longmore they constituted but 3 per cent. in the Crimea. Otis places the number at .05 per cent. in our Civil War. Aside from the internal and external kinds of hemorrhage in which life is immediately threatened, hemorrhage in gunshot wounds is not of special consequence. Much speculation has been indulged in by writers upon the supposed influence of the new high-velocity projectiles in causing additional hemorrhage in wounds hereafter. Happily the apprehensions in this quarter have not been realized. Speaking of the external variety which comes within the opportunity of the surgeon to correct, out of 1,400 wounded in the Santiago campaign the vast majority of which were inflicted by the Mauser bullet, no death took place from this cause nor was a single ligation necessary. The evidence from South Africa is in keeping with our observations in Cuba. Makin† states that hemorrhage was rarely of a dangerous nature except when the larger visceral vessels were involved. From limb wounds the general tendency was to spontaneous cessation of hemorrhage. The English surgeons had ample opportunity to observe this point in over 18,291 wounded exclusive of 4,355 deaths, occurring on the field.‡ Lesion of vessels without tendency to fatal primary hemorrhage from reduced calibre bullets is one of the interesting revelations from this projectile that will be taken up later.

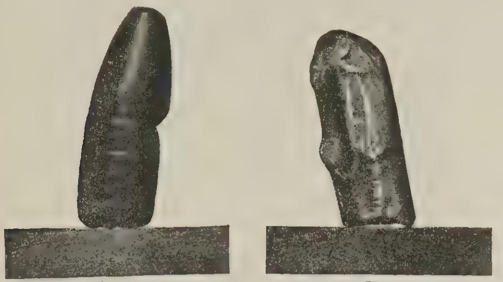
* "Experiences in South Africa," 1901. † *Op. cit.*
‡ American Medicine, vol. ii., No. 6, 1901.

(4) *Thirst.*—This symptom is of no special importance.

(5) *Lodgment of Bullets.*—With low-velocity weapons like pistols, and the old-fashioned smoothbore guns, the lodgment of the missile is very common. The development of higher velocities has done away with this complication very largely except in long range firing and in those instances in which the momentum of a projectile has been lessened by striking or traversing objects in its line of flight. The number of cases of lodgment in the Santiago campaign was surprisingly large, being about ten per cent. on the side of the United States troops. The Spanish surgeons as well had occasion to wonder at the frequency of lodgment of our bullets in their men. Still when the nature of the field was taken into consideration the cause was readily understood. The Americans had to advance through a country rich in jungle-like vegetation so that the remaining velocity of the projectiles of the two armies was very much reduced, thus favoring arrest in the tissues. It is safe to say that a rifle of lower velocity, like the Springfield, would have exhibited a very much higher percentage of lodged balls. This is confirmed by the English surgeons in the Boer War. There were more lodged balls, everything considered, from the large-calibre Martini-Henry and Snider.



1. 2.

FIG. 2378.—Lodged Bullets. 1, Brass-jacketed ."45 cal. Remington bullet; 2, Filipino ."30 cal. leaden bullet moulded in bamboo stick.

(6) *Powder Burn* is one of the complications of gunshot wounds, at close range upon exposed parts of the body. Grains of powder unconsumed at the moment of ignition lodge under the skin causing tattoo marks, and at relatively close range there is superficial burning of the tissues, by the flame of the ignited powder. Powder burn has received special consideration of late in its medico-legal and pathological bearings. Thus the degree of powder burn is very much modified by the distance of the injured part from the muzzle, the calibre and length of barrel, the amount, standard, and variety of powder, the velocity and direction of the wind, etc. Experiments[*] have shown, as originally pointed out by Dr. D. B. N. Fish, that the burning, scorching, or powder brand as he calls it, is always located on the hammer side of the weapon when the wound has been inflicted by revolvers especially. That is, if the hammer is held up the powder brand will be above the wound of entrance of the bullet; if the weapon is held with the hammer to the left the powder brand will appear to the left of the wound of entrance, if to the right, the powder brand will be to the right of the wound of entrance, etc. The location of the powder brand as described is explained by the action of the recoil upon the point of support, which in the case of a revolver is the hand. This recoil or force tends to cause the weapon to revolve about this point. The ball, which precedes the gases, inflicts the wound of entrance before the barrel has had time to change its direction. By the time the powder gases issue from the muzzle the recoil has partially revolved the weapon, and they necessarily follow the new direction of the barrel which will point above, to the right, or left, as already described. The position of the powder brand has already figured in the courts of justice in distinguishing a suicide from a homicide and vice versa.

The introduction of certain kinds of smokeless powder which produce neither flash nor burning, as shown by our experiments at Fort Logan, tend to destroy the value of the powder brand in medical jurisprudence. Further, if it is true that a homicide can be recognized in the dark by the flash of the igniting black powder from his weapon, the use of smokeless powder will here again furnish negative evidence.

Of the pathological conditions that may arise from the lodgment of grains of unconsumed powder under the skin, so common in so-called powder burn, it is a fact, ascertained by experimentation,[*] that such grains of powder when contaminated by septic cocci purposely or otherwise are not purified by the act of firing. Repeated experiments with black powder purposely inoculated with specific micro-organisms, gave positive results when fired into media and lower animals. The results were not so constant with certain brands of smokeless powders; for instance, the Peyton brand used in our service rifle in 1894, when contaminated with the less resistant organisms and fired into media, gave rise to no growth whatever; nevertheless, when it was treated with Bacillus anthracis and fired into media and animals the results were positive. Taken as a whole the evidence thus obtained tends to confirm the opinion that gunpowder may be at times the medium for conveyance of septic influences like tetanus, malignant œdema,[†] etc. Cases of the former disease reported by H. Nimier of the French Army can hardly be explained otherwise.[‡]

(7) *Multiplicity of Wounds.*—Multiple wounds from the same bullet are recorded in all works on military surgery more as surgical curiosities. The liability to such occurrences have of course increased with the velocity and penetration of projectiles. Now that the velocity of the present service-rifle projectile has recently been doubled and its penetration trebled, multiple wounds are more frequent than heretofore. Instances of this kind from the Mauser bullet were very frequently seen in the Santiago campaign. Thus a man entered the hospital at Siboney with six wounds inflicted by one Mauser bullet, implicating the right shoulder and both breasts. There were a number of instances in which wounds of the body were associated with wounds of the arm or forearm or both, the latter being in a state of flexion at the time of injury. Wounds of entrance and exit in the lower extremity were several times complicated by wounds of the scrotum or penis by the same bullet. Captain —— 7th Infantry received wounds of the face followed by no disfigurement. The projectile, a Mauser, entered the right cheek below the outer canthus, emerged on the nasal side, entered the nose and again emerged at the left side. The linear scars are noticeable only on close inspection. Had these wounds been inflicted by a leaden bullet of larger calibre, the resulting disfigurement would doubtless have been most distressing.

Poisonous Influence of Projectiles.—The experimental work already alluded to demonstrates that there is liability to infection from an infected bullet. It does not necessarily follow that the gunshot wounds inflicted by dirty bullets will suppurate. The virulence of the micro-organism and the resistance of the patient fix the liability very largely. The danger of infection more often arises from particles of clothing or dirty skin carried into the wound by the bullet. Instances of such infection are seldom seen, not because infected material has not been carried into the wound, but more often because the virulence of the organisms so carried is very weak. Formerly the great source of infection lay in the introduction of dirty fingers and probes into all gunshot wounds, a practice reprehensible to-day even under aseptic conditions.

DIAGNOSIS.—The wound of entrance will nearly always give information of the calibre of the bullet; if elongated, whether the angle of incidence with the surface was a right angle or not. When the bullet's remaining velocity is reduced from ricochet or extended range, the so-called keyhole character of the wound of entrance will often suggest the fact. A bullet that sustains deformation by colliding with a hard substance like rock and subsequently inflicts a wound will often fail to give definite evidence of its original diameter, and it is apt to upset thereby the calculations made from the size and shape of the wound of entrance. The appearance of the wound of exit and of the area around it often gives evidence of the extent of damage sustained by a resistant bone. When the wound of exit is two or three times as large as the entrance wound, a bone lesion may be taken for granted. With the employment of armored projectiles we sometimes find smaller multiple lacerations around the exit wound. In the case of close shots these may be due either to fragments of the mantle and lead core of the bullet, when these separate, or to small pieces of bone which, having received the transmittal energy from the projectile, have shot forth acting as secondary missiles.

[‡] Archives de Médecine et de Pharmacie Militaires, No. 23, 1894.

Bullet extractors, detectors, and probes were formerly used to locate balls, estimate bone lesions, and to trace the direction of the channel made by the missile. It is needless to state that these have given way to the more advantageous methods—fluoroscopy and skiagraphy with the Röntgen ray. The experimental evidence already quoted establishes the fact that there is no such a thing as an aseptic gunshot wound. The shreds of clothing, particles of skin, and the bullet itself infect the channel tract at once. That the infection is generally of a low order, unattended with marked systemic disturbance in the vast majority of cases, is due, first, to the state of quietude in the channel tract; second, to absence of virulence on the part of the organism; and third, to the resistance of the individual. If we violate number one by invading the channel tract with probes, or if two and three are not propitious, suppuration is sure to follow. We will revert to this subject under treatment.

PROGNOSIS.—The prognosis of a gunshot wound depends (1) upon the amount of destructive effects sustained, (2) upon the nature of the anatomical parts traversed, (3) upon the environment, (4) upon the management of the case when it falls under the care of the surgeon, and (5) upon the fatality due to different armaments.

1. Destructive effects are proportional to velocity and resistance on impact; that is to say, when a projectile impressed by a maximum velocity collides with a tissue, like the shaft of a long bone, having a maximum amount of resistance, the result is a maximum amount of destruction. On the other hand a projectile travelling at a maximum amount of speed through tissues like muscle having a minimum amount of resistance will not exhibit destructive effects beyond the area of the channel wound; and conversely, in the case of a projectile travelling at a minimum amount of speed, although it may collide with a resistant structure, the destructive effects will be reduced to a minimum. In estimating the probable amount of destructive effects we should also bear the following in mind, viz.: everything being equal, destruction of tissue increases with the sectional area of the projectile, whether natural or whether it be acquired by ricochet or impact. Projectiles of certain manufacture are purposely made to acquire deformation on impact, and they cause extensive mutilation of tissue when they collide with resistant structures. They are used by sportsmen under the name of express bullets, or soft-nose bullets. They have been used in war under the name of explosive bullets although the name is erroneous, since they do not disintegrate by the action of explosives in them as we find in the shells of field guns or cannons. The soft nose bullet is one that has the armored steel jacket covering the lead core except at the point. On impact the absence of the steel envelope at the point invites disintegration of the projectile so that the core and casing break up into many pieces upon striking resistant bone. Wounds caused by such bullets are murderous in the extreme and not permissible in war by the comity of nations. Their use is tantamount to that of an explosive bullet for hand weapons—a thing which was proscribed by the articles of the St. Petersburg Convention of 1868 (Fig. 2379).

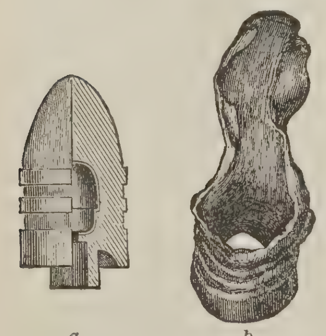

FIG. 2379.—Examples of Explosive Bullets in our Civil War, with Old Calibres. *a*, Gardner's explosive bullet; *b*, fragment of explosive bullet extracted from thigh.

The following illustrations from Dr. Makin's book* are given to show the normal bullets used in South Africa, those that were deformed by ricochet, and also the appearance of the soft-nose bullet before and after impact. Fig. 2380 shows how jacketed bullets may be filed or otherwise tampered with by the soldier on the field, and 3 on the same figure shows an express bullet used in hunting large game. The result with such bullets on impact against resistant structures is the same as that described for soft-nose bullets (Figs. 2375 to 2377).

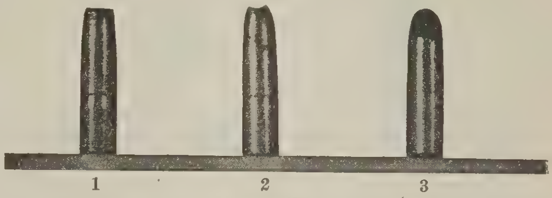

FIG. 2380.—1 and 2 show the steel jacketed projectile with impairment of the steel envelope by filing sufficient to invite deformation on impact; 3, copper-jacketed express bullet, the lead being exposed at the end, used by sportsmen in hunting large game.

FIG. 2381.—Normal Mauser Bullet.

FIG. 2382.—Normal Lee-Metford Bullet. (Makin.)

2. The gravity of gunshot wounds is measured by the nature of the parts traversed. Those of the head, large vessels, spine, and viscera are the most serious.

3. In military practice environment plays a great rôle in the prognosis of gunshot wounds. In the fixed hospitals of civil life, equipped with every necessary appliance, with ample help of the most intelligent kind, the civil surgeon has entire control over his cases at all times; in other words he dominates the environing conditions as they present themselves; whilst, on the other hand, the military surgeon is movable and moving field hospitals.

---

* *Op. cit.*

are ever at the mercy of endless conditions far beyond the surgeon's control. The confusion incident to the turmoil of battle renders it impossible to do more than apply a first-aid dressing to a dirty wound. When the battle waxes fiercely there is as much need for help at the front as at the rear, to say nothing of all the labor that is constantly required of the relief corps in transporting the wounded from the fighting line to the field hospitals, oftentimes several miles to the rear. Under these circumstances it is difficult to provide an adequate amount of help to the three places at the same time. Deficiency in help for the wounded is the result—a fault that has existed in large and sudden engagements in all wars. Again, military necessity compels the movement of the wounded so often that the patient is robbed of needed rest, it is a difficult matter to keep his dressings clean, and the dangers of sepsis are thereby magnified. In spite of the best efforts of the military surgeon in times of peace, when he himself has but few opportunities of treating sick and wounded, it is impossible for him to convert the relief corps under his orders into nurses having the same efficiency that one finds in civil life; so that this valuable adjunct to the care of the wounded is far below the standard. If one undertook to picture the reverse of the conditions that prevail around the civil surgeon he could not do so more aptly than by pointing to the predicament of the military surgeon in active campaign. Hence the influence of environment on prognosis.

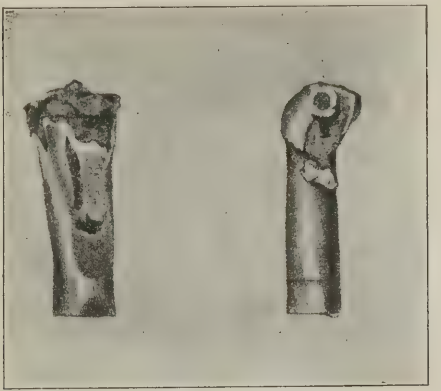

FIG. 2383.—Apical Lee-Metford Ricochets. From Hythe targets. Tendency of cupro-nickel envelope to tear in transverse direction. (Makin.)

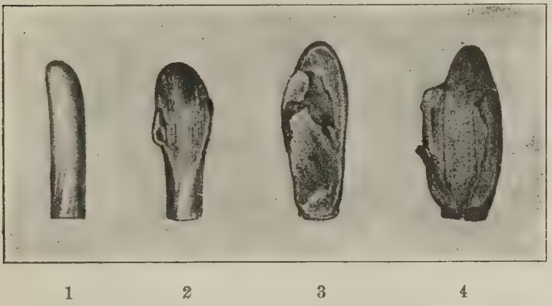

FIG. 2384.—Four Common Types of Lateral Mauser Ricochet Bullets. From left to right. 1, Slipper form; slight broadening and turning of tip. 2, More pronounced degree of form 1, with laceration of the mantle opposite the shoulder of the bullet. This is the weakest spot, for two reasons: the alteration in curve at this position, and the junction of the thickened point of the mantle with the thinner sides. 3, Lateral ricochet involving nearly the whole length of bullet. Rupture of mantle from broadening of core opposite shoulder. 4, Similar lateral ricochet with extensive longitudinal rupture of mantle, the latter being turned out and forming a cutting "flange." (Makin.)

4. The significance of the management of a gunshot wound when it falls under the care of the surgeon was never so thoroughly expressed as by Nussbaum's trite saying: "The fate of the patient with a gunshot wound lies in the hands of the surgeon who applies the first dressing." That this should be done under strict antiseptic precautions goes without saying. More than that, the caution against the unnecessary use of probes should be strictly adhered to. Even in gunshot fractures presenting extensive comminution, there is less danger in a *laissez faire* policy than there is found in an attempt to clear out the wound without adequate preparation. There are certain wounds that need close investigation as soon as possible. This should be thoroughly done, but not before the proper antiseptic precautions are available.

5. The evolution of the military rifle has witnessed some change in the general mortality on the field of battle, but contrary to expectations the mortality has not kept pace with the efficiency in firearms; if anything, it has diminished. This is due partly to the humane character of the armored projectiles, partly to fighting in open order and while lying down. This is well brought out in the subjoined table if we compare the number of killed and wounded to the force engaged in battles with the old armament and in the more recent ones fought with reduced calibres and superior velocities, like the assault on Santiago, and two of the prominent battles of the Kimberley Relief Force, viz.: Belmont and Magersfontein. It should be borne in mind that the armies concerned in the last three engagements were always on the offensive against an enemy well entrenched on heights. The wounds from the artillery arm were less than one per cent. at Santiago, and according to press reports they did not exceed five per cent. at Belmont and Magersfontein, so that the casualties as a whole may be regarded as a fair index of the comparative deadliness of the new military rifle.

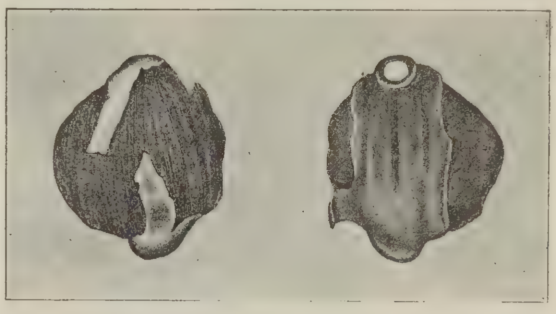

FIG. 2385.—"Disc"-shaped Lateral Ricochet. This form is of little practical importance, as the velocity retained by the bullet is low, and no perforating power would be retained. It is inserted separately in order to complete the series shown in Fig. 2384. (Makin.)

TABLE III.—MORTALITY ON THE FIELD OF BATTLE FROM THE OLD AND NEW ARMS.

	Nation.	Strength.	Killed.	Wounded.	Ratio of killed to wounded.

Occasional Complications.—In former times the complications of gunshot wounds constituted by far the most important clinical picture of this class of wounds; they consisted of inflammation, gangrene, secondary hemorrhage, aneurism, hospital gangrene, pyæmia, tetanus, erysipelas, traumatic delirium, etc. With the exception of those resulting from injury to blood-vessels, the complications that follow gunshot wounds in our day are exceptional. They will be taken up later under the heading of Wounds of the Blood-Vessels, etc.

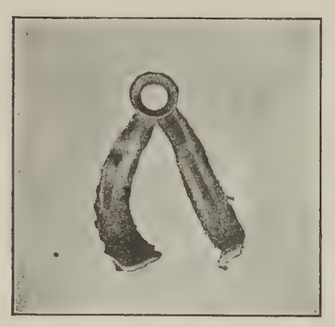

Fig. 2386.—Ruptured Mauser Mantle, to Illustrate the Tendency to Complete Longitudinal Fissuring. (Makin.)

Remote Effects of Gunshot Wounds.—The ulterior and disabling effects of gunshot wounds as treated by authors have reference to conditions that have remained after the healing of the wound has been accomplished. In the past, the amount of invaliding resulting from the ulterior effects of gunshot wounds among the soldiery has been a cause of great expense to the state, and of much pain and protracted suffering to the wounded. Pain and the ills that ensue after the lodgment of foreign bodies have been a fruitful source of the protracted suffering referred to. As one might suppose, the disabling effects are often correlated with the anatomical structure or bodily region involved. A source of remote effects not hitherto described—plumbism from lodged missiles—has recently been touched upon* by Nimier and Laval. In this article they refer to what seems to be a well-authenticated case by Küster and Lewis in *Arch. für Chir.*, t. xliii., p. 221, 1892. Cases of lead poisoning from this source are seen only when the projectile has divided into many fragments, or when the wound has resulted from fine shot that remains embedded in bone, and preferably in the bone marrow and under the periosteum, both of which possess, to a remarkable degree, the property of absorbing materials into the general circulation. In the cases mentioned the symptoms from lead intoxication disappeared as soon as the missiles were removed. Plumbism as a remote effect, already rare, will be very exceptional hereafter in military surgery because of the use of the steel-jacketed bullets, and of the x-ray in diagnosis. The lead core of the latter bullet very seldom separates from its envelope, so that the opportunity for absorption under the most favorable conditions will very seldom occur. The use of the Röntgen ray in diagnosis will point out the location of bullets so exactly that few bullets will be allowed to remain in the tissues long enough to produce any kind of remote effects.

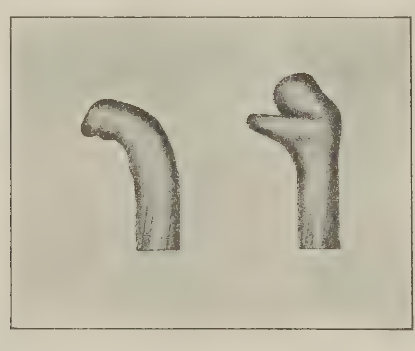

Fig. 2387.—Two retained Mauser bullets which had produced comminuted fractures of the femur of moderate severity. Each has given way at the shoulder, but the mantle developed creases without rupture, and the bullets are correspondingly bent. Both bullets were travelling at a moderate, if not low, degree of velocity. (Makin.)

The amount of suffering from remote effects in gunshot wounds diminished very largely with the introduction of clean surgical methods. Again, the use, in war, of hard steel-clad bullets, that seldom deform or disintegrate on impact with hard bone, have materially curtailed the after-effects in wounds. Projectiles of this class seldom lodge, and when they do, their lighter weight and polished exterior favor permanent encystment with few or no symptoms. It may be stated also to the credit of the reduced-calibre projectiles that they seldom carry clothing or pieces of the accoutrement into the wound track, whereas formerly, with the employment of projectiles of larger calibre, this complication was of common occurrence. Lastly, the use of the x-ray in localizing projectiles and defining the amount of bone injury has played a prominent part in curtailing the remote effects of gunshot wounds. The following skiagrams explain some remote effects before and after operation (Figs. 2390 to 2398).

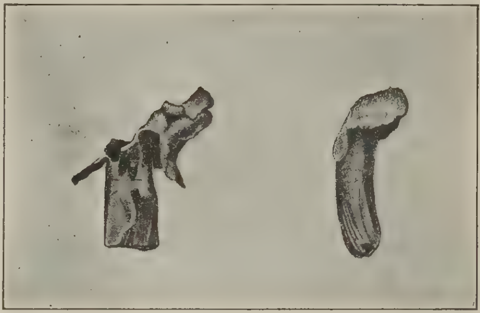

Fig. 2388.—Apical Ricochet Mauser Bullet (see text). The mushrooming of the core is moderate, but the destruction of the anterior part of the mantle very considerable. (Makin.)

General Treatment.—The treatment of gunshot wounds has been very much simplified in late years. The civilian treats them as he would other infected wounds, in accordance with the rules of strict antisepsis. He does not invade the channel tract except for special reasons to be indicated later. In simple uncomplicated gunshot wounds a clean dressing and rest in bed constitute about the necessary measures of treatment. In military practice, when the lack of transport and sudden accessions of large numbers of wounded are thrust upon an inadequate corps of helpers, the medical department resorts to the expedient of furnishing each man, upon going into battle, with a first-aid dressing composed, in our army, of a package five and one-half inches long, one-half inch thick, and two and one-half inches wide. Contents of package: Two antiseptic compresses of sublimated gauze in oiled paper; one antiseptic bandage of sublimated cambric with safety pin; one triangular bandage and a safety pin. The mode of application is illustrated on the bandage. This dressing is

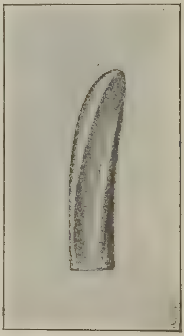

Fig. 2389.—Grooved Mauser Bullet Removed from Anterior Abdominal Wall after Crossing the Ribs. I saw several such removed from the thoracic wall, and am inclined to attribute the grooving to impact with the margin of the ribs. (Makin.)

---

* Le Caducée, September 7th, 1901.

usually applied by a comrade or officer who has been instructed in first-aid work by the medical department; or by a member of the hospital corps, and less often by a medical officer. The want of water and time seldom permits more than the application of the dressings without first cleansing the hands of the operator or cleansing the skin about the wound. It is needless to state that a lacerated wound, already infected, dressed in this way will invariably suppurate unless redressed very soon. The fact that the simple wounds, which predominate so largely in war, have heretofore done well under this treatment has caused many observers to attribute the happy results in gunshot wounds to the value of the first-aid dressing. The most that one can say in favor of the practice is that it adds no infection to an already infected wound, which would certainly occur if nothing intervened between the wound and the dirty clothing of the soldier. The simple wounds, and many that included perforations and fractured bones, brought to the Reserve Divisional Hospital, Siboney, from the line near Santiago, exhibited, as a rule, no evidence of suppuration. The loose state in which the dressings were found when they reached us—having oftentimes been imperfectly readjusted by the wounded soldier himself—made it difficult to believe that the happy result was to be ascribed solely to the dressing. These wounds were generally covered by dry blood, and the more reasonable explanation suggested was that healing was taking place under the protective influence of a blood clot. Until we are furnished with something better the military surgeon will have to continue the use of first-aid packages at the dressing stations; later, at the field hospitals, where the appointments are better, wounds are dressed when necessary under such asepsis as field conditions ordinarily permit. Here, also, necessary explorations and surgical operations can be done with some degree of safety. Wounds undergoing suppurative processes can here be thoroughly washed with antiseptic solutions and drained; the dressings can be changed as often as necessary, and with persistence, to the end that suppurative cases shall be kept at the very minimum of number, for once suppuration sets in among the wounded in a hospital the task of preventing its spread becomes doubly difficult, and this is especially true when campaigns are prolonged. The soldiers in prolonged field work lose their normal resistance, while from frequent transmission, pus microbes are ever acquiring virulence as they go from host to host. We are speaking here of field conditions where the military surgeon is not always sure of carrying out an aseptic technique.

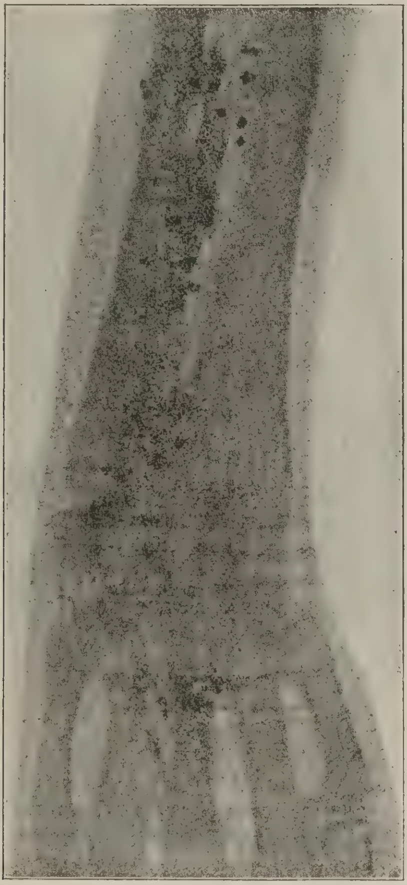

FIG. 2390.—Radiograph. In the case of a marine officer who received a charge of fine shot at close range in the palm of the left hand August, 1900. Wound of exit was on dorsal surface of forearm at junction of lower and middle thirds. During the next four months he had four attacks of lead colic and suffered from plumbism. In December, 1900, the shot was removed. One month later he was free from all symptoms of plumbism. (Nimier.)

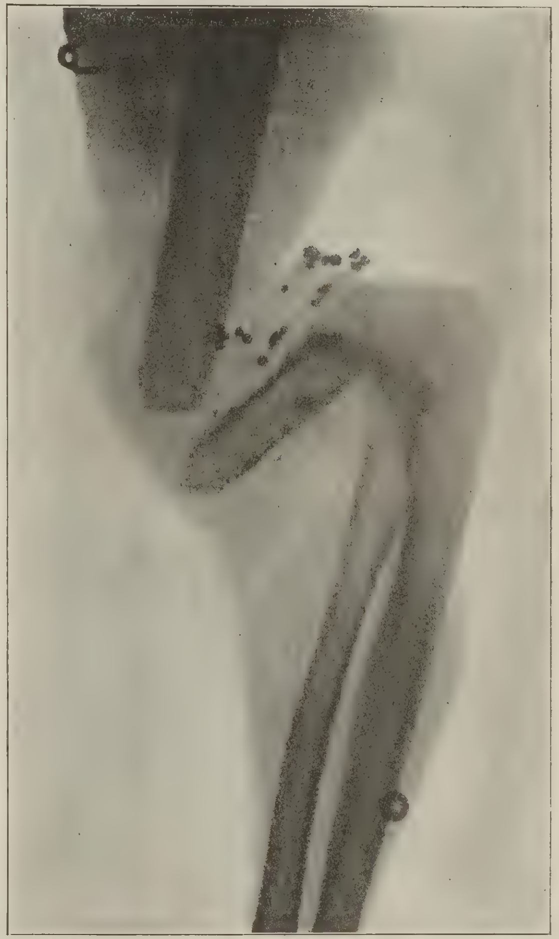

FIG. 2391.—Radiograph. In the case of J. M—— showing ununited fracture of humerus and lodged shot. Wounded June 25th, 1860, by accidental discharge of shotgun within a distance of two feet. Forearm and hand totally paralyzed for three years. Remote effects: flail joint in humerus causing weakness and impairing motion of arm. Radiograph taken October 2d, 1901.

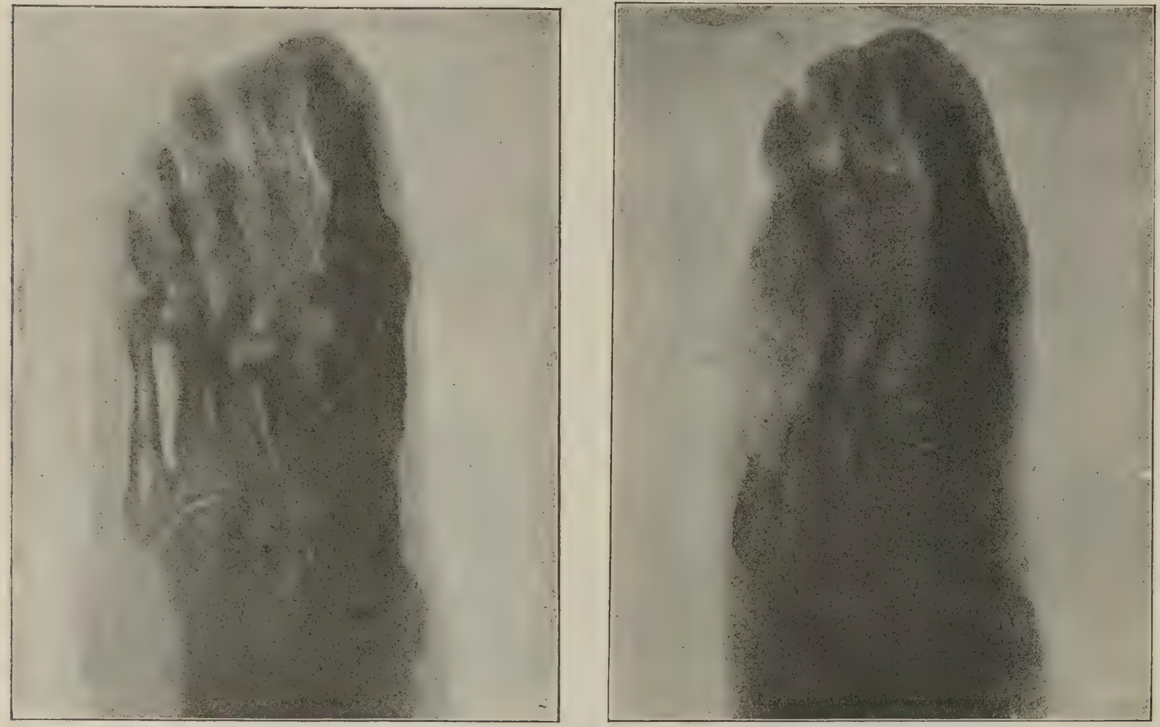
Lodged Balls.—The questions as to whether it is necessary, in any given case, to remove a lodged ball or other missile, and as to what is the proper time for accomplish-



FIGS. 2392 AND 2393.—Radiographs in the case of C. M——, showing the course of a Mauser bullet through the metatarsal bones. Wounded July 1st, 1898, at a distance of 300 yards. The ball ranged transversely across the foot, grating the metatarsal bones in transit. In the process of healing osseous bridges formed uniting the bones. Remote effects: pain at site of wound and limping due to the bony union. Radiograph taken May, 1900. Operation June, 1900. Excision of fourth and fifth metatarsal bones. Result: no pain; the man walks without limping. The second radiograph was taken in August, 1900.

ing this, call for more than a passing notice, at least in military practice. Save in cases of actual necessity (and they are very rare), when time is a factor as it often is in the rush of field practice, bullets should be let alone. An incision for a bullet requires time and an additional dressing, and it exposes the patient to an additional danger of infection amid doubtful surroundings. The morbid curiosity of the laity to find the ball, the restlessness of the patient, and the lack of resolution on the part of the surgeon are only too often exhibited in this late day. At Siboney it was impossible to restrain the surgeons from the practice of cutting out bullets, notwithstanding the strict orders to the contrary, at a time when the dressings were running short, and military necessity was keeping the wounded almost constantly on the move. The necessity and the time for the extraction of a lodged missile are questions which should as a rule be left to the surgeons who are located at those points on the line of communication where the hospitals are fixed and provided with *x*-ray machines. In time of peace the military surgeon should take occasion to explain to the soldiery the evil effects of probing for bullets, and of haste in operating for balls whose location is not exactly defined, and the utter harmlessness that comes from bullets that lie embedded in tissues. If a bullet is lying immediately under the skin, or has already partially protruded through an exit wound, it should be at once removed. Those lying at the bottom of infected tracts should also be removed, as they are generally met with in the special effort to disinfect the wound by irrigation, etc. Those interfering with function or that cause pain by pressure on a nerve should be removed as soon as definitely located; the same is true of projectiles lodged in joints or in close proximity to the joint structure. An effort should be made to remove all missiles of irregular, sharp contour like those which have been deformed through ricochet or by fragmentation, and also pieces of shells, unless they lie in inaccessible regions very near or in the large cavities. Figs. 2400 to 2404, which give skiagraphic views of the head and thorax, illustrate how bullets can remain

FIG. 2394.—Captain K——, United States Army; lodged bullets from whole charge of No. 6 shot four feet from muzzle, entering outer aspect of upper thigh from below upward. There is a distinct bruit emanating from the external circumflex artery, possibly due to shot lodged in or around arterial coats.

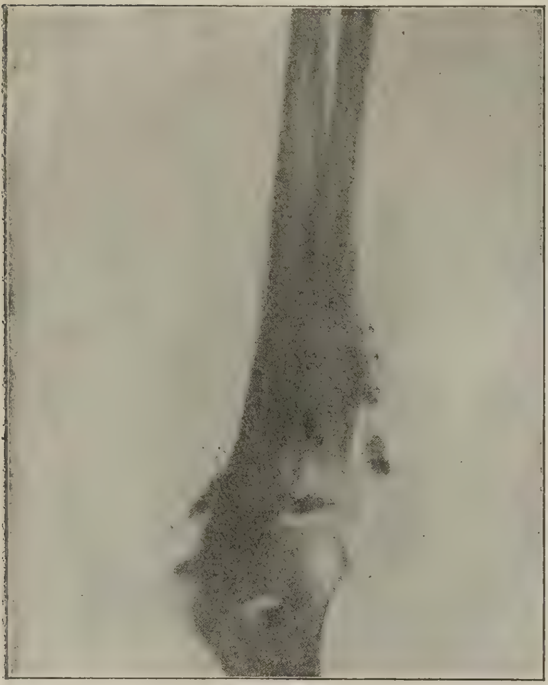


FIG. 2395.

The four fragments united in a solid callus. Remote effects: total paralysis of wrist and hand with loss of sensation over fingers.

lated* that but 27 such cases—.007 per cent.—occurred out of 36,508 wounds in the army of the Potomac from the Rapidan to the James, 1864. In the Crimea (Longmore) of 4,434 wounds recorded, 15 wounds of arteries, or .03 per cent. of the whole, came under observation. The wounds in those days were inflicted by a leaden bullet prone to deformation. There has been much speculation on the part of experimenters as to what would be the effect of the new military rifle upon blood-vessels. We are now in a position to give some facts that have been gathered from the actual conditions in war. Whether the percentage of deaths from fatal primary hemorrhage on the field has increased must still remain doubtful. The superior velocity of the new bullet, its direct course through tissues, and pointed form, increase the chances of its wounding vessels in its path. On the other hand the smaller calibre of this missile, its tendency to preserve its shape unaltered, and the simpler bony lesions which it inflicts, diminish the likelihood that any of the blood-vessels will be wounded by secondary projectiles—either portions liberated from its own substance or fragments of bone to which the bullet itself had communicated its own momentum.

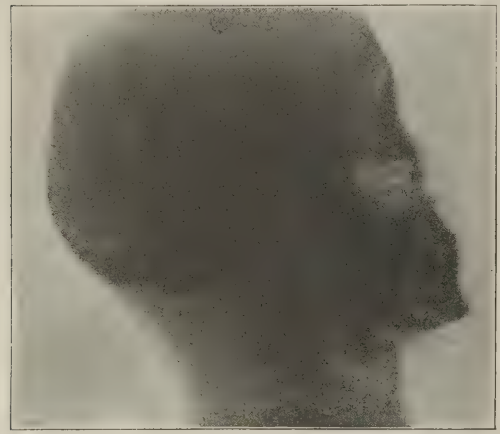

FIG. 2399.—Radiograph. Case of G. W. G——, showing leaden slug lodged in base of tongue. The ball entered behind the left ear Radiograph taken fourteen months after injury. Remote effects: left hemiparalysis of tongue, also loss of taste on left side; loss of hearing in left ear; left optic neuritis; partial ankylosis of lower jaw and painful deglutition.

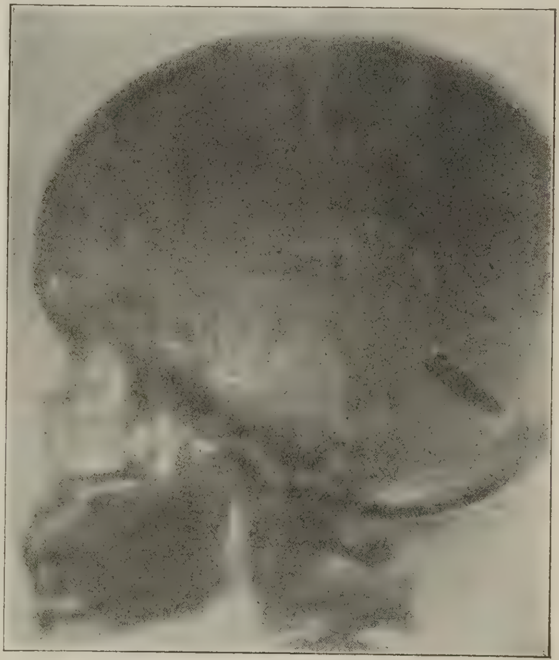

FIG. 2400.—Lodgment of Mauser 7 mm. Bullet (Long Range) in the Brain. Recovery. Private J. G——, 1st Nebraska Volunteers, wounded at Mariboa, P. I., March 27th, 1899. A 7 mm. bullet entered the forehead 2 cm. above the orbital ridge and 3 cm. to the left of the median line, passed directly backward and downward, and lodged about on the tentorium, well within the skull. He was carried one mile to a field hospital, and reached Manila twelve hours after the injury. Complete loss of consciousness for several hours; gradual return to consciousness. In bed four weeks. Primary healing of wound. Returned to quarters June 13th, 1899, cured. First few days of illness were marked by severe pain in head, nausea, and vomiting. More or less pain existed for some weeks, increased by mental or physical exertion, but gradually disappeared. Returned to San Francisco with his regiment in August, quite well. Radiograph taken August 20th, 1899. No history of paralysis other than a slight weakness of right arm and leg, now nearly gone. Some confusion of ideas and slowness of expression existed for a time, but no convulsions or epileptiform seizures occurred. No loss of vision of left eye, but slight ptosis, diplopia, and photophobia were present. Senses of smell and taste more acute on the right than on the left side. Reflexes active; sphincters not involved. Entered mail service, and went back to Manila on duty.

Of fourteen hundred wounded among the United States forces at Santiago by the Mauser bullet there was no instance of a wound of a large vessel requiring ligation on the field. While we have no figures to quote from the South African war, Makin† informs us that "deaths from external primary hemorrhage were rare." Those that recover from injury to blood-vessels form a very interesting class to the surgeon on account of the primary, secondary, and recurrent hemorrhages; as well as on account of the various kinds of aneurisms that are apt to occur in their clinical history. The lesion present in any of these conditions may be contusion or laceration without perforation, partial or complete perforation causing complete division of the vessel. Of the fourteen hundred wounded above mentioned there is no note of either recurrent or secondary hemorrhage. The femoral, the external iliac, and the ulnar were each tied once for diffuse aneurism, the radial and subclavian were tied twice for the same cause, and there were five cases of gangrene that were caused by an injury to blood-vessels and that required amputation. That secondary hemorrhage should be absent in the clinical record of these cases points to the great boon that asepsis has conferred upon the wounded in war. In the days when the surgeon welcomed the appearance of "laudable pus," "no wounded patient was considered to be safe from secondary hemorrhage so long as his wound remained open to suppuration" (Longmore). Disintegration of the arterial coats from septic arteritis was the main cause of secondary hemorrhage in the pre-antiseptic era, and now that we exclude suppuration almost entirely by clean surgical methods we are in a position to appreciate the frequency of secondary hemorrhage from other causes. These causes are in a measure peculiar to gunshot wounds, and they are more apt to be seen in military practice. A projectile, some of its fragments, or spicula of bone, may injure the external coats of an artery at the time of the injury without causing immediate hemorrhage. A few hours or days later, in transport, when rest to the part cannot be secured, hemorrhage occurs by breaking down of the inner coat, unconnected with suppuration. Makin (*op. cit.*) mentions a number of cases of this kind in his South African experiences. He saw only two cases of acute traumatic gangrene, both following gunshot fracture of the thigh. Among the very interesting features of his experience may be mentioned the number of traumatic aneurisms observed "and most frequently of all, perhaps, aneurismal varices and varicose aneurisms. The statement is made of the increase of the number of aneurisms from gunshot wounds in direct ratio to diminution in the size of projectiles employed." We should not forget that our knowledge of the occurrence of traumatic aneurisms with the large calibres was obtained in pre-antiseptic days. We have reason to believe that suppuration, which was so universal in gunshot wounds at that time, played a marked rôle in terminating the cases long before the lesions of vessels referred to had time to develop—say in death from secondary hemorrhage, in ligation of vessels on the proximal side, or in amputation.

* REFERENCE HANDBOOK OF THE MEDICAL SCIENCES, first edition, vol. vii., p. 18.

† *Op. cit.*

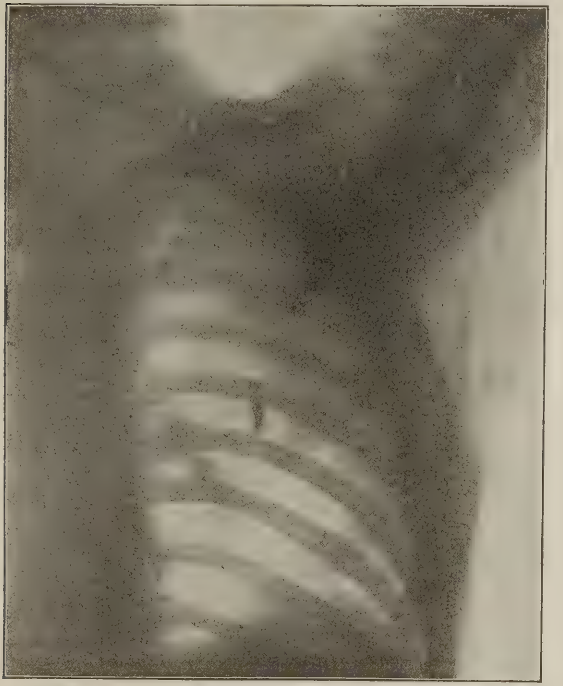

FIG. 2401.—Radiograph Showing Mauser Bullet, Deformed by Ricochet, lodged in Right Back opposite Seventh Intercostal Space.

Until we learn the frequency of aneurisms from the effect of the larger calibres under our present methods of wound treatment, we are hardly in a position to estimate their relative frequency from the smaller calibres under the same conditions.

Injury to nerves has been referred to under Remote Effects of Gunshot Wounds.

Wounds of Joints.—In point of gravity, until recent years, gunshot wounds of the larger joints like the knee and hip, ranked next to those of the larger cavities. For the civil practitioner antisepsis has upset all the statistics of former times, and for the military surgeon antisepsis and the use of armored bullets have operated to make joint wounds among the most humane in war. That this should be so was appreciated by all the military surgeons who entered the experimental field with the new military rifle long before it was put to actual test in battle. As already stated, the destructive effects in a gunshot wound are measured by the velocity of the projectile and the resistance it encounters. The spongy structure of the epiphyseal ends of bones offers a minimum of resistance compared to the compact substance of the diaphyses, and for that reason the lesions of joints even with the high velocity weapons at the proximal ranges are very limited (Figs. 2403 to 2409). The tendency of the armored bullet in passing through the joint ends of the long bones is toward a clean-cut perforation. Fig. 2405 shows that even close by, the tendency to inflict a perforation remains the same. At the remote ranges or from ricochet, when the projectile has lost its balance, it is apt to make an irregular impact, in which case the bone suffers more or less comminution. The joint wounds inflicted by the old leaden bullet of larger calibre are always serious because the projectile meets enough resistance to flatten, thereby increasing its sectional area; the wounds of entrance and exit are larger, rendering more likely the introduction of septic matter; the comminution and fissuring in the bone are more extensive; and, the remaining velocity being always less, the ball is more apt to lodge. If we take as an example wounds of the knee joint as observed in previous wars and compare them with those which occurred in the Spanish-American war, the value of the modern treatment as well as the more favorable lesion inflicted by the jacketed bullet, in point of economy to the State, in saving life and limb, is very striking. A study of all the gunshot wounds of the knee, in war, in which the bones were implicated, gives a mortality of 57.3 per cent.* The Surgeon-General's Report for 1900 records "24 injuries implicating the knee joint, 1 proved fatal . . . after amputation of the thigh. The missile was removed in 4 cases, and amputation was performed in 1 case, the patient recovering." The character of the missile in this group of 24 cases is not stated, but we know that the large majority of the bullets were fired from reduced-calibre rifles. Of 17 cases of gunshot wound of the knee joint reported by the Surgeon-General in 1899, from the Santiago campaign, 14 were returned to duty, and 3 were invalided.

Wounds of the Long Bones.—The injuries inflicted upon the diaphyses by the jacketed bullet do not make so favorable a showing because of the great resistance which compact bone offers to the projectile on impact. At close range the bone is finely comminuted, bone sand being driven into the channel wound and in all directions. The wound of entrance is about the calibre of the bullet, whilst the wound of exit is much larger, showing explosive effects. The bony fragments are apt to be detached from their periosteum and fissures extend vertically above and below the area of comminution. In the mid ranges the fragments of bone are larger and are still attached to the periosteum; the explosive effects are absent and the fissures longer. Guttering of the bone and complete perforations without solution of continuity are not infrequently seen; subperiosteal fractures with little or no tendency to displacement of fragments are also not un-

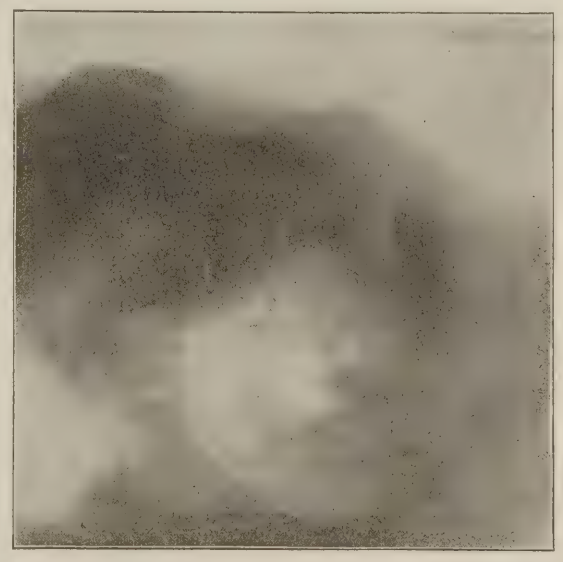

FIG. 2402.—Radiograph. Case of T. H——, showing Mauser bullet lodged above and posterior to the hip-joint. Wounded July 1st, 1898. Radiograph taken October, 1901. The ball entered base first, passing through upper left arm and entering body opposite sixth rib in the mid-axillary line; it passed down to position seen in radiograph.

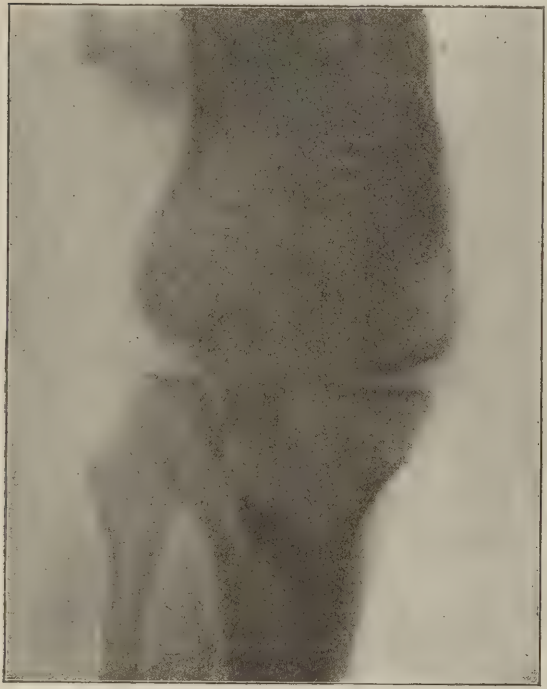

FIG. 2403.

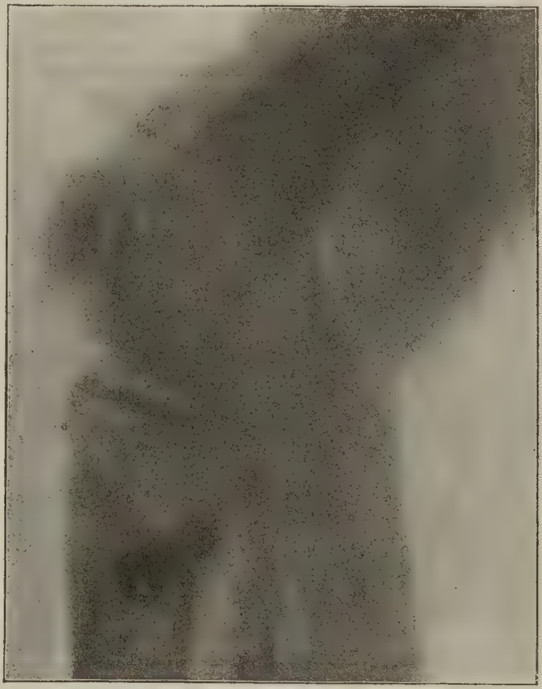

FIG. 2404.

FIGS. 2403 AND 2404.—Radiographs from two different directions. Fig. 2403, antero-posterior view; Fig. 2404, lateral view. In case of E. K——, showing gunshot wound of knee with ball lodged in tibia. Wounded October 23d, 1899, by a Remington bullet which had ricochetted. Distance about 250 yards. The ball entered outer aspect of knee joint 1 cm. above the articular surface, passed down and in through the joint, and lodged in the tibia. Remote effects: chronic arthritis of the joint with weakness and partial ankylosis. The bullet was removed in May, 1900.

common. The results of the treatment of gunshot fractures in the shaft of the long bones bring out more forcibly the value to be credited to our present method of wound treatment than do those which are obtained in any other class of wounds. As stated before, the destructive effects of the old and new bullet are alike severe, and the so-called humane factor so constantly observed in wounds inflicted by the small calibre in other regions is absent in, for instance, the case of the femur. Six thousand five hundred and seventy-six gunshot fractures of the femur in the Civil War gave a mortality of 46.2 per cent., upper third 49.7 per cent., middle third 46.1 per cent., lower third 42.8 per cent. Of 43 cases reported in the annual report of the Surgeon-General, United States Army, for 1900, in which 16 are known to have occurred from small-bore bullets, 11 were returned to duty, 5 died, and the remainder were discharged from the service, a few still remaining under treatment. It is apparent, therefore, that

TABLE IV.—NUMBER, REGIONAL DISTRIBUTION, AND MORTALITY OF GUNSHOT WOUNDS IN THE WOUNDED WHO CAME UNDER TREATMENT IN THE AMERICAN CIVIL WAR AND THE SPANISH-AMERICAN WAR.

	Seat and character of injury.	Number of cases.	Percentage.	Per cent. of all wounds.		Recoveries.	Deaths.	Undetermined results.	Per cent. of fatality.

	Fractures	130	23	8.91					

the general mortality has dropped from 46.2 to 11.1 in favor of antisepsis. At the present time the death rate of this class of wounds increases as the injury nears the greater trochanter, just as it did in the preantiseptic era From the Anglo-Boer war, Makin reports 32 fractures of the shaft of the femur. Of these 18.7 per cent. needed amputation, 15.6 per cent. were fatal. The missile noted was principally the jacketed bullet from the Mauser rifle.

Wounds of the Head.—Gunshot wounds of the head are usually divided into flesh wounds and fractures. The latter are necessarily very fatal. In the Civil War the fatality among all head wounds that reached the hospitals was 28.93 per cent. The fatality of the same class under similar conditions in the Spanish-American war was about the same, 26.09 per cent. The figures concerning the relative number of the two are shown in the preceding table.*

The figures illustrate the frequency of glancing shots with the slow-velocity leaden bullet of the Civil War as compared to their infrequency with the high-velocity steel-jacketed bullet in present use. The latter as a rule travels in a straight line from the point of impact, being seldom deflected from its course by resistant bone. The relative increase in the number of fractures from the use of the modern military rifle augments the fatality in head wounds, so that the humane features attributable to this weapon already referred to do not apply to wounds of this region. These results were foretold by the experimenters before the opportunity to observe the effects of the new arm in the actual conditions of war had presented itself.

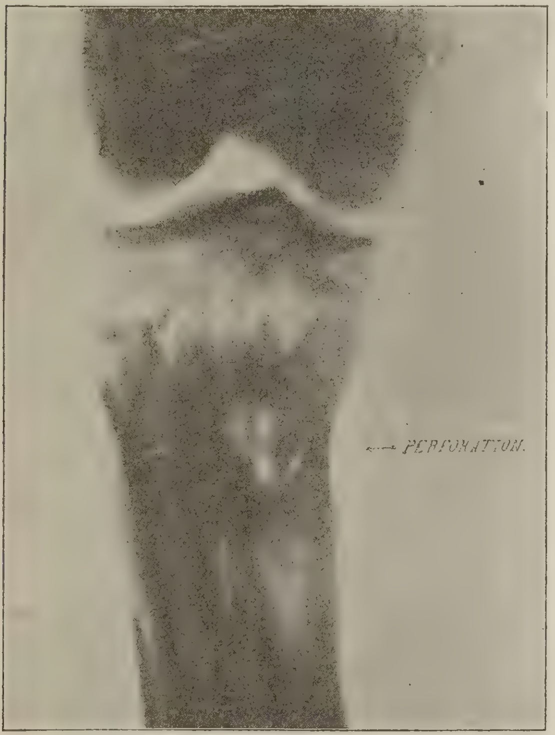

FIG. 2405.—Radiograph. In case of W. K——, showing perforation of upper end of tibia. Wounded June 25th, 1899, by a Krag-Jörgensen bullet at a distance of 10 feet. The fracture extended up into the knee joint, as shown by the escape of synovial fluid after injury. Radiograph taken six months after injury. Remote effects: slight weakness and pain at site of wound.

Stevenson (*op. cit.*), writing in 1897 upon the proportion of flesh to fractured wounds of the skull, states as follows: "In future wars the proportion will be very different. Omitting indirect and grazing hits, almost every bullet which hits the skull, up to a range of 2,200 yards, will perforate it, and at about 2,900 yards they will penetrate and remain lodged. The destruction produced in the skull and brain by modern bullets is so extreme, even at long ranges, that comparatively few patients will survive long enough to reach the field hospital for treatment, and for the large majority of those who do, treatment will be unavailing."

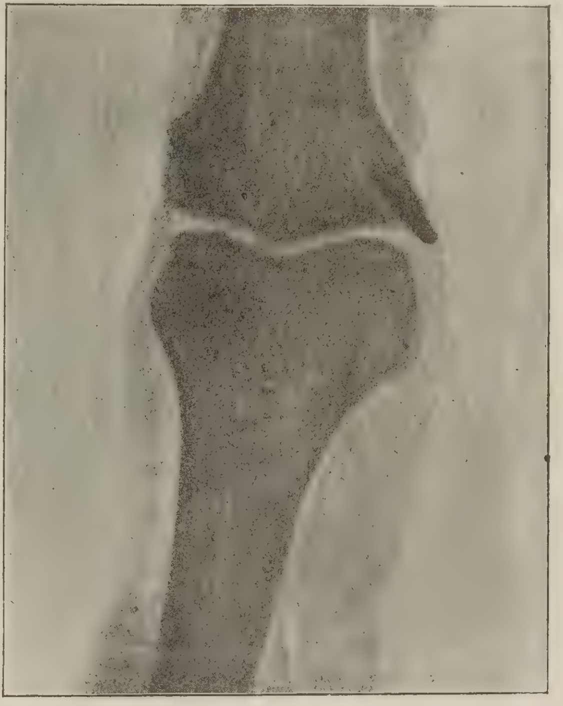

FIG. 2406.—Case of Lodged Bullet in Knee Joint. A cavalry man was shot by a ricochet bullet which passed through the left thigh and into the right knee joint, where it lodged. When admitted two days later he was found to be in the second week of typhoid fever. The bullet was removed six weeks after injury. The adhesions were broken up. Result: the joint became perfectly sound and useful. (From "A Civilian War Hospital.")

Concerning the results in the Anglo-Boer war, Makin (*op. cit.*) states: "injuries to the head formed one of the most fruitful sources of death both upon the battlefield and in field hospitals." He mentions some "sensational immediate recoveries" among head wounds, and they doubtless were of the character of those noted by us in the Santiago campaign, viz., oblique perforations of the skull cap involving the brain tissue at a limited depth. The gunshot fractures about the base and those running deeply through the brain from base to vertex or vice versa were uniformly fatal. Of 68 cases of gunshot fracture which were reported in the Surgeon-General's Report for 1900, and which occurred during the two preceding years, 54.4 per cent. ended fatally as against 59.2 per cent. out of 2,514 cases noted in the Civil War. Unlike wounds of other regions those of the head, unless properly treated at once, undergo suppuration, a fact which is not surprising when the amount of dirt overlying the scalp is considered. The surgeons in the Cuban and South African campaigns are unanimous in recommending early and free exploration of all cases of fracture of the skull by gunshot. The aim should be to relieve pressure and to rid the wound of all dirt and loose pieces of bone as soon as possible.

Wounds of the Spine.—Gunshot injuries of the spine are the most fatal in war hospitals. Their gravity increases as the wound approaches nearer to the head.

---

* Borden: "Military Surgery"; Prize Essay, Proceedings Association Mil. Surg., 1900.

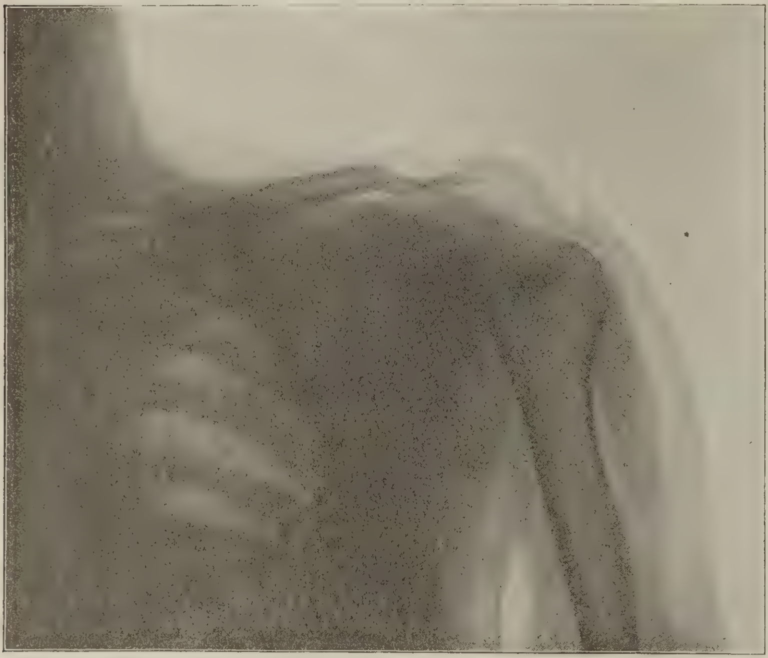

FIG. 2407.—Radiograph in Case of L. E. K——, Showing Gunshot Wound Involving the Shoulder Joint. Wound inflicted by a Mauser bullet at a distance of 6 feet. The ball passed directly through the shoulder joint, grooving the upper end of the humerus and emerging over the inner border of the scapula. Remote effects: paralysis of deltoid muscle and general weakness and impaired nutrition of the arm.

Otis, in the records of the Civil War, places the mortality in the cervical, dorsal, and lumbar regions at 70 per cent.; 63.5 per cent.; and 45.5 per cent. respectively. The fatality increases if the injury involves at the same time any of the organs in the neighboring large cavities. If the spinal column alone is injured the gravity of the case will depend upon the fact whether or not the cord is also implicated. In fractures of the body or laminæ, the cord is nearly always involved, and, sooner or later, the termination is in death. Injuries of the spinous and transverse processes are less likely to be attended with lesion of the cord, and this class therefore constitutes the bulk of recoveries among the wounds of the spine. Beyond the fact that the foyer of comminution is more restricted, as a rule, with the small-calibre bullets, wounds by them are as severe in their results as those from the large calibres of olden times. When the spinal medulla is implicated, Makin, in his experiences in South Africa, states that "the cases were proportionately the most fatal of any in the whole body to the wounded who left the field of battle or field hospital alive."

Wounds of the Chest.—The loss of life in battle from penetrating gunshot wounds of the chest, inflicted by bullets of the larger calibres, has been very great, varying between 62.5 per cent. in our Civil War and 91.6 per cent. among the French troops in the Crimea. When we consider the subsequent mortality from secondary involve-

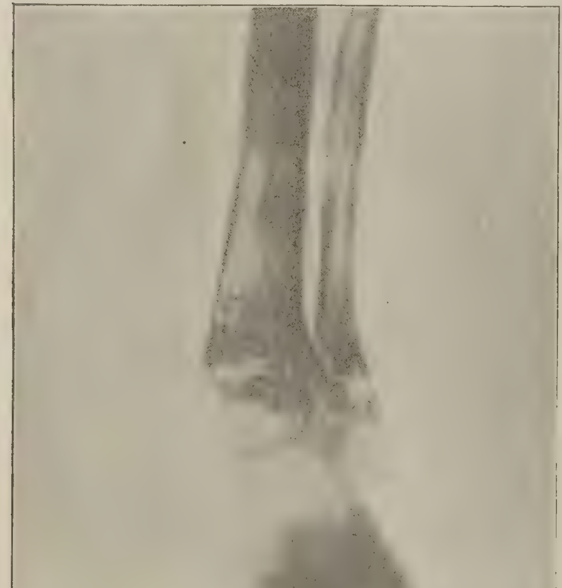

FIG. 2408.—Radiograph, showing track of bullet through lower ends of tibia and fibula. Wound was caused by a Mauser bullet February 2d, 1901, at a distance of 100 yards. The fracture extended down into the ankle joint. Remote effects: osteomyelitis of fibula; partial ankylosis of ankle; unable to bear any weight on foot. Radiograph taken nine months after injury.

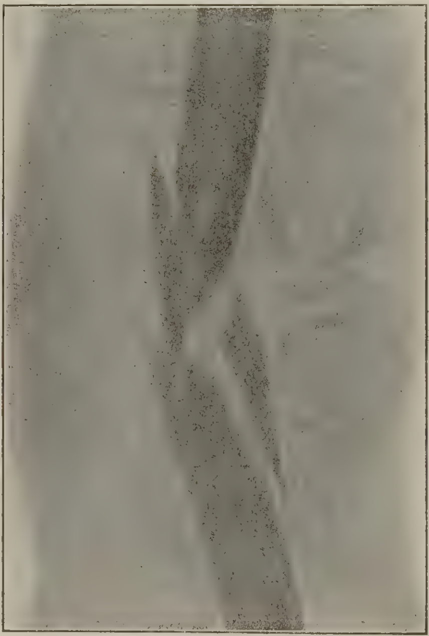

FIG. 2409.—Comminuted Fracture of the Humerus. Range about 300 Yards. The wound track took a directly antero-posterior course. Impact rectangular. The musculo-spiral nerve was completely divided. The plate affords a good example of the so-called "butterfly" fracture. Two long doubly wedge-shaped lateral fragments, and pointed extremities to both main fragments, are shown. The fracture healed well, with the deposition of a large mass of provisional callus. The musculo-spiral nerve was united by suture some three months later. (See Butterfly fracture, Fig. 2365, caused experimentally.) (Makin.)

ments like pneumonia, pleuritis, phthisis, etc., the mortality in the end is little less if any than that recorded in penetrating wounds of the head and spine. Happily, the humane features of gunshot wounds inflicted by the steel-clad bullets, as foretold by the experimenters, have already been satisfactorily shown in the Spanish-American and South African wars. If we recall the factors that are correlated to destructive effects in wounds—viz., velocity, sectional area, and resistance on impact—we find that the last two factors (sectional area and resistance) favor a limited amount of destructive effects. Since the Crimean war the calibre of the military rifle has been reduced nearly one-half. As to resistance, the lung, composed of elastic tissue and filled with air, invites but little lateral displacement; hence the great diminution in the mortality of this class of wounds. Of 198 cases of penetrating gunshot wounds of the chest (reported by the Surgeon-General of our army) which occurred during the years 1898 and 1899 in Cuba, Porto Rico, the Philippines, etc., 55, or 27 per cent., ended fatally. As to the results in South Africa, where the experience of the medical department was much larger, Makin states that "wounds of the chest furnished the most hopeful class of the whole series of trunk or visceral injuries. Cases of *wounds of the heart and great vessels*" [the italics are ours] "afforded the only exceptions to an almost universally favorable course, both as regards life and the non-occurrence of serious after-effects." Notwithstanding the favorable outcome of chest wounds, as inflicted by the new armament, it should be borne in mind that the clinical history of these cases is apt to be accompanied by complications like hæmothorax and pyothorax. The apparently trivial nature of the wound, in the majority of those who lived to reach the field hospitals, was exemplified at the Reserve Divisional Hospital at Siboney, in men who, though shot through and through a few days before, could be kept prone in bed only by the most watchful care over them of the nurses. Doubtless a number of the sequelæ observed afterward in these men* was due to imprudence on the part of the patients in disregarding the instructions to keep quiet.

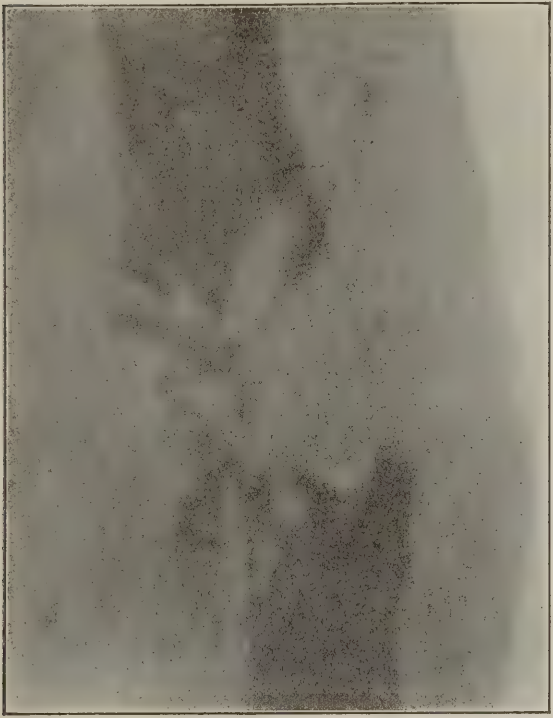

FIG. 2410.—Comminuted Fracture of the Humerus. Range 50 yards. Velocity extreme. Impact somewhat oblique. The bullet entered anteriorly about three inches above the elbow crease. The wound of exit was on the inner aspect of the arm and explosive in character; it still measured four inches by two inches three weeks after the injury was received. The wounds suppurated locally, but at the end of six weeks fair union of the bone had taken place and the wound of exit had contracted to a sinus. The musculo-spiral nerve was concussed, but not divided. The skiagram was taken three weeks after the reception of the injury. (Makin.)

As relating to this point it may be stated that Makin observed in South Africa, in the early part of the campaign when the patients were treated near the place of battle, and required but little subsequent transportation, that hæmothorax occurred only in probably thirty per cent. of cases. Later on, when it became necessary to transport the wounded for much greater distances—requiring in some instances journeys of two or even three days,—at least ninety per cent. of these patients "suffered with hæmothorax of varying degrees of severity." In referring to the only case of empyema seen by him during the whole campaign, he informs us that it followed the removal of a lodged bullet, and that the additional wound doubtless proved the source of infection because of the difficulty of maintaining asepsis in wounds treated under

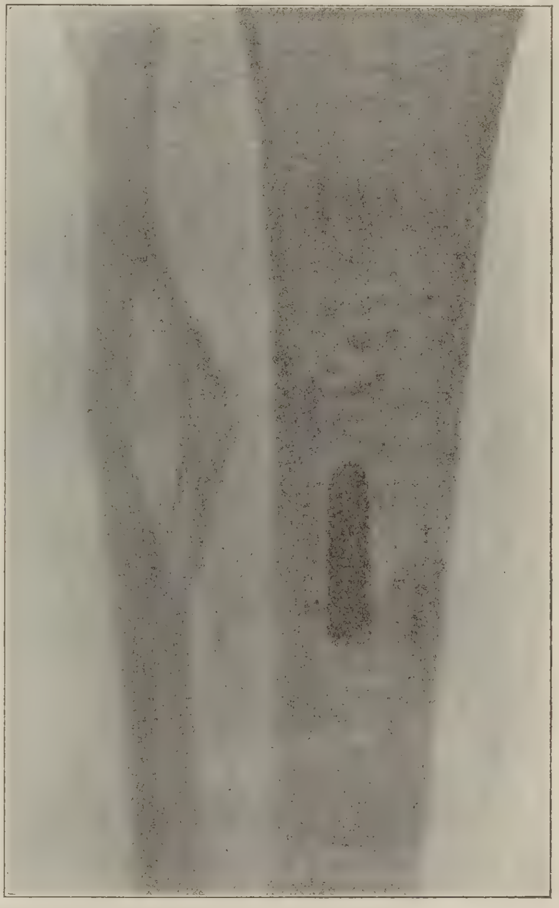

FIG. 2411.—Spurious Perforation of the Fibula. Moderate range about 1,000 yards. The injury was caused by an 8 mm. bullet, which entered base foremost and lodged in the calf. The fracture is really an incomplete stellate form, two well-marked transverse fissures extending from the point struck. The position of the bullet suggests its entry into the limb base foremost, and, as it is retained, a low velocity may be assumed. (From Makin's "Surgical Experience in South Africa.")

*Greenleaf: "Gunshot Wounds of the Lungs." N. Y. Med. Journal, vol. lxx.

such questionable surroundings as one encounters in the field. The moral which he draws from the circumstance is one to which we have already adverted—*remove no lodged missiles in the field save for exceptionally good reasons.*

Wounds of the Abdomen.—Penetrating gunshot wounds of the abdomen, under the expectant plan of treatment, were the most fatal of the regional wounds in both military and civil practice; the mortality ranging between ninety-five and ninety-nine per cent. Under a wise selection of cases and the employment of expert technique in operating, the statistics of fatality have been reduced by nearly a half in civil hospitals, while on account of unavoidable causes the death rate in military practice, in the field, still remains very high. In civil hospitals, where one finds all the modern conveniences and comforts to promote the well-being of the wounded, and where, further, the surgeon, almost from the moment of the receipt of the injury, holds absolute sway over his surroundings, the mortality, as shown by Grant's* statistics of operative cases, amounts to 52.5 per cent. in a series of 253 cases. Morton, of Philadelphia, reports 138 deaths after operation, or a mortality of 58.9 per cent., out of 234 cases collected from various sources in this country and Europe. Coley's statistics show a death rate of 53.8 per cent. in a series of 39 cases operated upon during the first twelve hours after injury; and a mortality of 77.2 per cent. in 22 cases operated upon at a later period. In military practice, in the conditions that obtain in active campaign, as already stated, the mortality has been very large, the death rate in the Crimea for the French and English troops being respectively 91.7 per cent. and 92.5 per cent. In our Civil War the fatality reached 90 per cent. When we remember that in many of those who are thus reported to have recovered, the abdomen was in reality not perforated, we are forced to the conclusion that the high mortality given would probably have to be made still higher if it had been possible to consider only perforative cases.

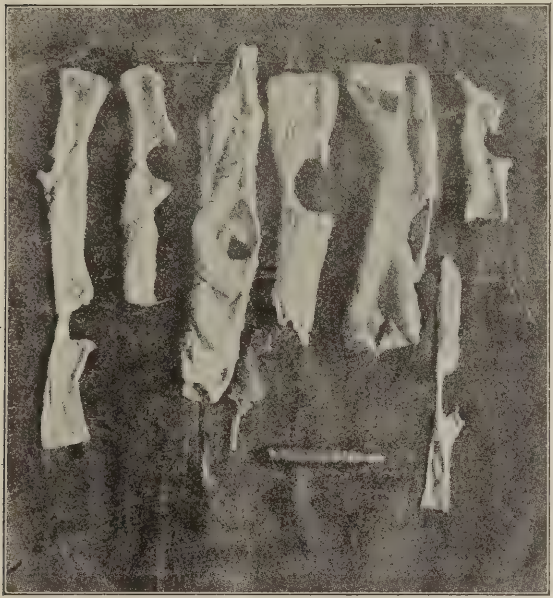

Fig. 2415.

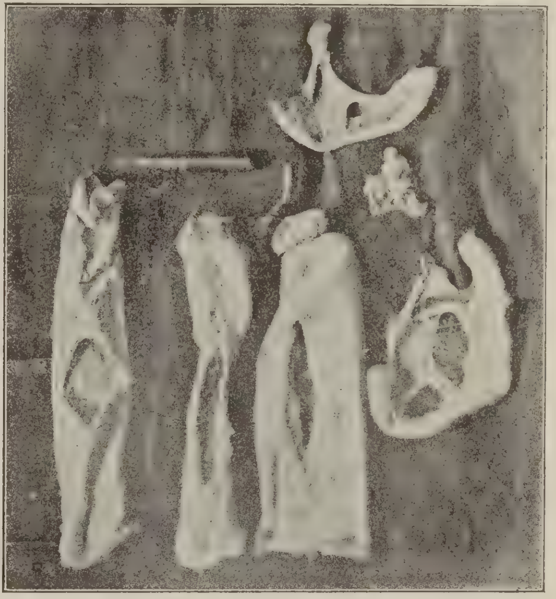

Fig. 2416.

Figs. 2415 and 2416.—The lesions of the intestines were inflicted on dogs by the .30 calibre Krag-Jörgensen bullet at 300 yards. (Griffith.)

nearly as good. These expectations, as the sequel shows, were not realized. Of 116 cases reported in the Annual Report of the Surgeon-General of the army for 1900,—cases which occurred in the Spanish-American war and during the Philippine insurrection,—there were 81 deaths, or a mortality of 70 per cent. The evidence of perforation was doubtless based upon the position of the apertures and the course of the ball in a straight line between these. It is fair to state that, of the 30 per cent. who recovered, the large majority sustained no injury to the intestine. The experiences of Makin in South Africa lead him to the belief that perforating wounds of the small intestine are very fatal*—"every patient in whom the condition was certainly diagnosed died." The table given below includes only those cases which survived longer than twenty-four hours, upon six of whom he operated. It will be seen that the prognosis varies largely with the anatomical structure involved in the perforation. It should be noted that of the ten cases of *possible* perforation of the small intestine there were ten recoveries, a fact that goes to show that in all probability few if any of them were perforative cases at all; and that, of the five cases of perforation of the "small intestine certain," death was the result in every instance. As far as prognosis is concerned, gunshot perforation of the small intestine, without operative interference, is as fatal to-day on the field of battle as it was during the Crimea. Some rare cases of recovery with few symptoms, cited by Makin, make it difficult to conceive how a projectile could plough its way through the abdomen from one flank to the other without cutting the intestine. Several cases of this kind were seen at Siboney from the line near Santiago, and they go to show that the small-calibre bullet is likely at times to traverse the intestinal area without inflicting injury of a fatal kind. Aside from the small sectional area of the bullet which would favor such an occurrence, it has been suggested that the intestinal lesion is apt to be minimized by fasting. The men before Santiago had been on scant rations for one week, and the remarkable recoveries among abdominal wounds were at the time attributed to the empty condition of the alimentary canal. We know by experimentation that the reverse condition would have been highly favorable to the infliction of extensive lesions. Resistance, among the three factors which conduce to destructive effects,—the other two being velocity and sectional area of the projectile,—is not confined to the compact substance of bone. The most extensive explosive effects are met in cavities filled with fluid or semifluid contents. Griffiths'* experiments upon dogs on the Fort Leavenworth range demonstrate that when all the conditions are favorable, the intestines will show rents varying from two to eight inches in their continuity. Men on the field of battle so wounded do not live to reach the relief stations; they die as a rule where they fell, from shock and internal hemorrhage. In gunshot wounds of the abdomen the vital question at issue is whether or not the wound is perforating in kind. If the evidence points with reasonable clearness to a wound of the former character, the treatment resolves itself into a cœliotomy either for the purpose of exploration or for that of remedying the injury done to the abdominal organs. Whether surgical aid of the latter kind is to be practised will largely depend on the confidence and skill of the operator and the nature of the environment. As stated before, owing to the unpropitious character of the latter, laparotomy on the field or in field hospitals in war has thus far been limited, and the results, when the

* Proceedings of the Association of Military Surgeons, 1893.

practice has been carried out, have been anything but encouraging. Of the three laparotomies done at one of the advanced hospitals before Santiago, the mortality was one hundred per cent. In order to accomplish successful abdominal work in war it will be necessary to use a great deal of forethought, so that the operators may not be hampered by the endless difficulties that are apt to occur in active campaign. It is possible to conceive of a field hospital so thoroughly equipped with material and personnel, and so favored by the condition of the weather, that in it a laparotomy may be performed with about the same safety as is experienced in a civil or fixed hospital. So far, the idea of establishing such a hospital has not been acted upon seriously. The subject is one replete with possibilities. *Louis A. La Garde.*

GURJUN BALSAM.—Wood Oil. A viscid, copaiba-like turpentine, obtained from half a dozen or more majestic Asiatic trees of the genus *Dipterocarpus.** The "balsam" is collected by making deep "boxes" or gashes in the trunk of the tree, scorching them, and fitting a bamboo spout to their lowest parts. The yield is very great, and the drug forms quite an important article of commerce in the East. It is officially recognized by the Indian Pharmacopœia, and extensively used there as a substitute for copaiba. In other countries it is considerably used to adulterate the latter drug.

It is an intensely fluorescent, thick liquid, of a mild, terebinthinous odor, and a bitterish, aromatic taste. By transmitted light it is of a deep sherry color, and perfectly transparent; by reflected light it appears opalescent and greenish-gray. It is soluble in chloroform and the essential oils, but not completely so in alcohol. It consists of thirty or forty per cent. of a mild-smelling essential oil associated with a composite resin, composed of a crystalline *gurjunic acid*, and an amorphous portion. As it is collected from several different trees, its appearance, and also probably its composition, are subject to considerable variation.

Uses.—In India and Asia generally as a substitute for copaiba in the treatment of gonorrhœa, etc., and as a varnish. It is occasionally to be got in this country, but is prescribed only as a novelty. *W. P. Bolles.*

GUTTA PERCHA.—The inspissated milk-juice of *Palaquium Gutta* (Hook. f.) Burck (fam. *Sapotaceæ*). (No longer official in the United States.) This remarkable substance is admitted into the pharmacopœias of most countries on account of the elastic varnish which can be made from it, and of its value in the making of plastic splints in surgery. The plant is a large tree growing, now or formerly, in many parts of Southern Asia, and in the great islands of the Pacific. Gutta percha was first brought into European use in 1842, having been previously employed by the aborigines in the manufacture of knife and weapon handles. From the vicinity of Singapore, where it was previously abundant, from Penang and other accessible places, the tree has been practically exterminated by the wasteful method of collecting its valued product. It still exists, however, in abundance in the Malay peninsula, whence most of the gutta percha now comes, in Borneo, Sumatra, and other places. The method of collection is as follows: The trees are felled and the bark is stripped off, when the milky product beneath it collects upon the surface of the wood, and is scraped off and put into a hollow leaf or other convenient receptacle. This juice quickly coagulates upon exposure to the air, and the putty-like curd is moulded while yet soft into blocks or cakes of various sizes and shapes. It is of a light or medium brown color, often gray upon the surface, sometimes, when nearly pure, white or ash-colored, of a peculiar rubber-like odor, and a rather flexible consistence at common temperatures. At something above 120° F. it becomes very plastic, and may be moulded into any shape and welded, resuming its hardness upon cooling. Ordinary gutta percha is an impure substance, containing inevitably, by the method of its collection, a considerable amount of coarse admixture of vegetable tissue, chips, etc., besides the residues of the evaporation of portions of the liquid juice, imperfectly separated from it in coagulating. It is soluble in chloroform, turpentine, carbon disulphide, etc., but not in water, alcohol, acids, or alkalies. Its purification may be effected by solution in one of the above, or by mixing with hot water and straining. The sheets, in which form it is generally sold for surgical use, are made by rolling it while hot between cylinders.

The principal portion, seventy-five per cent. or so, of good gutta percha, consists of an amorphous white mass or powder having the general properties given above, named *gutta.* It contains, further, from fourteen to sixteen per cent. of *alban*, a light flaky powder soluble in boiling alcohol, and from four to six and a half of *fluavil*, which is rather more soluble than either of the above (Payen).

Gutta percha is employed in medicine only on account of its physical properties. A nine-per-cent. solution of it in chloroform, with ten parts of carbonate of lead added mechanically to carry down coloring matters and impurities, is an excellent protective varnish for abrasions, excoriations, and small wounds, to be used in the same way as collodion. In sheets, from one-eighth to one-fourth of an inch thick, it is to be had of the instrument makers as a splint material. For cases in which there is a good deal of irregularity of surface to be fitted, as in fractures of the jaw, the bones of the thumb or great toe, or the metacarpal or tarsal bones, it is very useful; also in making splints that must be often taken off and reapplied. The form of the splint should be cut about one-fourth larger each way than the desired splint, as it shrivels when softened and when thrown into water at a temperature of about 130° or 140° F. or more. The limb having been prepared by adjusting the parts, shaving, bandaging, etc., as required, the softened splint is laid on the part and quickly moulded by the fingers to the desired form. A bandage where necessary is then applied, and cold water poured over all. When hardened the gutta-percha splint may be taken off, trimmed, and permanently reapplied. If it is desired to piece or weld the gutta-percha, it should be softened by dry heat, as over a lamp or gas. The fingers may be wet while handling it. Its use in submarine cables and other electrical apparatus is very extensive. *W. P. Bolles.*

GYNÆCOLOGICAL EXAMINATIONS.—History.—A proper history is a necessary preface to the diagnosis of every gynæcological case. It should not of necessity be lengthy, but certain facts in the life history of the patient, peculiar to her sex, which may have an especial bearing upon the condition of the female organs, should be carefully inquired into.

We will pass over the points common to all histories and simply emphasize those having a gynæcological bearing. The menstrual history should be thoroughly ascertained. The age at which the menses first appeared; the duration of the flow; the quantity and character; if accompanied by pain, whether it develops before, during, or after the flow; the regularity of the periods; and, finally, the history of the menopause—these are all subjects for inquiry.

In judging the condition of the menstruation as to duration, quantity, and regularity, it is well to remember that in this respect every woman is a law unto herself, and she must therefore be judged according to her own standard. But, her habit in this respect having once been established, she should not deviate from it.

The history of her pregnancies should be thoroughly investigated, as about two-thirds of all patients coming to the gynæcologist can trace their sufferings from a miscarriage, a difficult labor, or an abnormal puerperium.

Pain in some form or other is the most prominent gynæcological symptom, and is usually responsible for the patient's seeking the aid of her physician. The pain may be in the form of headache, backache, pelvic tenesmus, or a sensation of bearing down; or it may be referred to some particular part of the pelvis. Its character and location should be carefully ascertained. The condition of the bowels is a very important point for inquiry, as so many of the troubles in this class of patients are due to pelvic congestion induced by chronic constipation and irregular habits of going to stool.

---

* The following are mentioned in the Pharmacographia: *D. turbinatus* Gaertn., *D. incanus* Roxburgh, *D. alatus* Rox., *D. zeylanicus* Thw., *D. hispidus* Thw., *D. crispalatus*, and several others.

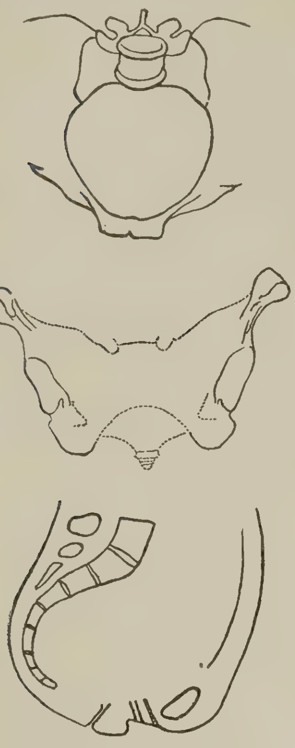

Fig. 2417.—Outline Diagrams for Recording Displacements, Growths, etc., in History-Taking.

Any bladder symptoms should be noted, especially burning or pain on micturition and frequency of the act, as they may be an indication of gonorrhœa, a disease which is now recognized as one of the most potent factors in the etiology of gynæcological cases.

The character, quantity, etc., of any discharge should be determined.

Finally, the presence of those symptoms known as neuroses, of a reflex character, should be recognized.

For the details of more extended history-taking the reader is referred to such works as those of Kelly, Reed, and Montgomery, the "American Text-Book of Gynæcology," etc. For ready reference, speed, and accuracy, we believe that the card-catalogue system, used in conjunction with outline diagrams of the various pelvic planes, in which it is possible graphically to note the size, situation, and shape of growths, displacements, etc., is of especial value in recording gynæcological cases. Rubber stamps of diagrams of the pelvis and abdomen have been devised by Dr. R. L. Dickinson, of Brooklyn, and their utility is testified to by many eminent gynæcologists (see Fig. 2417). Whatever system of history-taking is adopted it should be strictly adhered to, as routine habits will undoubtedly guard against error.

The novice will do well to remember, if he wishes to avoid embarrassment both to himself and to his patient, that all subjects of a delicate nature should be approached in an open, frank manner, devoid of subterfuge or insinuations of any kind, and coupled with the kindness and dignity of manner befitting a gentleman.

That the patient will submit to an examination should be taken as a matter of course, as at the present day most women know that such a procedure is a necessity and are prepared accordingly.

Anæsthesia.—In virgins it is desirable when possible to examine under anæsthesia, for as a rule, a first examination of such patients is very unsatisfactory, and therefore productive of no positive diagnosis. Nitrous oxide is an ideal anæsthetic for such a case.

If it is possible to avoid it, a vaginal examination should not be made in *virgines intactæ*. In the majority of cases a rectal examination will answer all purposes. The method of recto-abdominal palpation to be used will be described later.

Not infrequently in married women, if there happens to be an unusual rigidity of the abdominal muscles or a superabundance of fat, it is desirable to employ an anæsthetic, especially when the advisability of an operation is dependent upon an accurate diagnosis. When an examination is decided upon it should always be carried out in a thorough manner, and this necessitates that a systematic plan of procedure should be followed.

Nurse.—Whenever possible, a third party should be present, not only for the comfort of the patient, but as a protection to the physician from the malicious charges which the records show are by no means uncommon. If the physician can have a nurse at his disposal, this plan is by far the best, as the ready assistance and soothing influence of a trained female assistant go far toward rendering the ordeal less trying to the patient, and enable the physician to conduct his examination with much greater facility. When a nurse is not available, a female friend brought with the patient may often be of great assistance in holding a speculum, etc., but there will be many occasions when the general practitioner will have to conduct his examination unaided. While an assistant is certainly desirable, she is by no means indispensable.

Table.—The question as to what is the best table for gynæcological examinations is one that is often asked by the novice. The simpler the table the better. A costly complicated table or chair is not at all necessary, and a great many gynæcologists work with one of the simplest construction. An ordinary solid table, four feet long, two feet wide, and two and one-half to three feet high, will answer for all ordinary purposes. The foot of the table should be raised about two inches, and should be fitted with foot-rests. An extension arm or leaf attached to the right-hand corner is of great utility when employing Sims' position, as it allows the legs and feet of the patient to have a proper support, when the buttocks are drawn to the edge of the table.

A valuable adjunct, in the writer's opinion, is a pair of Edebohls' leg-holders.* They consist of two perpendicular rods that are attached to the corners of the table and have slings at their upper ends. The feet being fastened in the slings, are elevated to such an extent that the thighs are flexed upon the abdomen and rotated outward. This insures the greatest amount of relaxation of the abdominal muscles, and successfully prevents the approximation of the patient's knees. It is therefore of especial value in nervous patients.

Placing the Patient upon the Table.—If a nurse is not available, the physician should understand how properly to place the patient upon the table, so that he may not appear awkward or render the ordeal unnecessarily embarrassing. A screen should always be at hand, behind which the patient is instructed to retire in order to loosen all tight clothing about her waist, and especially to unfasten her corsets.

In all cases the patient should empty her bladder before going on the table. This is a detail that is frequently neglected, and it is the cause of an unsatisfactory examination in many instances. It is likewise of advantage that the lower bowel should be emptied, and when possible the patient should be instructed to take an enema before coming to the physician's office. The patient should be first placed in the dorsal position to permit of the bimanual examination. A stool or chair is placed at the foot of the table and the patient is directed to stand upon it, while the physician holds up a sheet between the patient and himself. She is then instructed to lift up all her skirts behind and sit down upon the edge of the table. She next lies down and the sheet is thrown over her, while her feet are adjusted in the foot-rests. The folds of the sheet are then wrapped about each leg so that there is no part exposed but the vulva.

The Examination.—The examination for purposes of diagnosis should consist of two parts—the first without instruments, and the second with instruments. It may be possible to arrive at a diagnosis by the bimanual touch alone, but an examination confined to this procedure alone cannot be considered thorough or complete; an actual inspection of the cervix, and an exploration of the uterine cavity are in many cases indispensable if an accurate opinion is to be given as to the conditions present.

---

* New York Jour. of Gyn. and Obstet., January, 1893.

The Examination without Instruments.—This should be conducted systematically. A good plan is to investigate the parts from without inward, commencing with the external genitals; then the vagina, cervix, uterus, ligaments, and the appendages are examined in order.

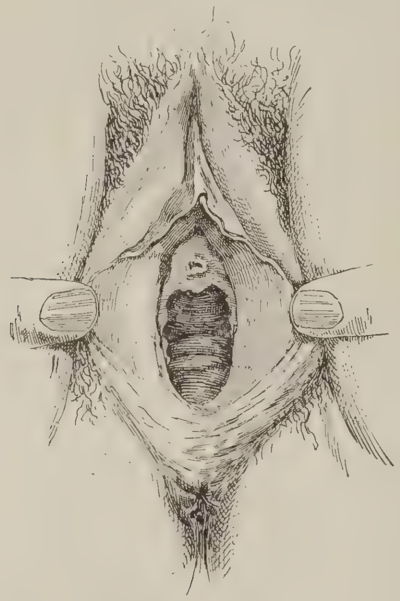

FIG. 2418.—Method of Separating the Labia for Inspection of External Genitals.

The Inspection.—This is an extremely important part of the examination, and it is too frequently omitted.

The labia majora are separated with the fingers of both hands, and the hood of the clitoris is retracted, so as to reveal any adhesions or retained concretions which may be the cause of irritation sufficient to produce neurotic disturbances. The meatus urinarius is examined for caruncle, prolapse of urethral mucous membrane, or urethritis. Skene's glands are to be observed for evidences of inflammation and discharge. These glands are very often the site of a latent gonorrhœa which would be overlooked unless they were carefully examined. The presence of a discharge in the urethra or from Skene's glands can best be determined by "milking" the anterior vaginal wall with the palmar surface of the index finger. A suspicious discharge should be stained for gonoccocci.

Prolapsus of the anterior and posterior vaginal walls (cystocele and rectocele) and procidentia uteri should be looked for, and so also should varicose veins of the vulva which are the result of some obstruction to the circulation and may be indicative of a tumor or growth blocking the pelvis.

The amount of prolapsus can be best judged by getting the patient to strain or bear down as if at stool, while the examiner's fingers separate the labia. This method shows the degree of relaxation of the vulvar outlet and the amount of supporting power of the pelvic-floor muscles. Injuries to the levator fibres and the pelvic fascia are thus accentuated. The degree of laceration of the perineum should never be estimated by a superficial inspection, as there may be an ample cutaneous covering, but with no body back of it. If the body of the perineum be grasped between the thumb and forefinger, after the latter has first been introduced into the rectum, the amount of muscular structure can be readily determined.

Bartholin's glands should always be examined for evidences of inflammation, which is almost invariably gonorrhœal in character. Latent gonorrhœa will be discovered by the careful examiner in the vicinity of these glands in a surprising number of cases. Normally the mouths of the ducts, which are situated on each side of the labia majora just below the centre, and usually behind a tag or ear of the remains of the hymen, are of the same color as the surrounding mucous membrane. The normal secretion which can be expressed from them is a glairy, colorless fluid like white of egg. Whenever the mouths of the glands seem to be much darker in color and to be eroded, suspicion should at once be aroused. If gonorrhœa is still present, the secretion expressed from the glands will be found to be turbid or purulent, and, if careful search is made, gonoccocci will usually be found. In such a case the gland itself can be felt between the thumb and finger to be decidedly enlarged and sometimes tender.

The anus and rectum should be searched for hemorrhoids, fissure, fistula, etc. The rectal mucous membrane can be readily everted by the finger placed within the vagina.

Any inflammatory condition of the vulvo-vaginal mucous membrane, if associated with copious purulent discharge, can hardly escape the notice of the careful observer, who will recognize it as a specific infection. Likewise the presence of condylomata, chancroids, venereal warts, etc., will readily be detected. It should always be borne in mind that an innocent wife is frequently a sufferer from diseases of this class through no fault of her own, and in utter ignorance of their nature.

The Bimanual Touch.—After completing the inspection, the physician will next lubricate the examining fingers with some lubricant, as vaseline, glycerin, or lubrichondrin. (The advantage of the latter is, that it is readily soluble in water, so that the hands can be speedily cleansed after they have been smeared with it.)

The examiner should accustom himself to the use of the fingers of either hand in the vagina, as it is easier to reach the left appendage with the left hand, and the right appendage with the right hand.

At first it is best to use the index finger alone in the vagina, but later, if the vagina will permit, the middle finger should be used in conjunction with the index finger. In introducing the fingers, they should be first flexed and the vulvar opening approached by sweeping the knuckles of the flexed fingers over the perineum from below, until the *knuckles* slip into the vaginal orifice, then the fingers are straightened until they find their way over the perineum into the vagina. By the employment of this method it will be possible to avoid touching the clitoris, urethra, and vestibule with the tips of the fingers, and should the circumstances of the case not permit of an inspection (as in an emergency examination, with the patient in bed), the entrance to the vagina can always be found with the greatest ease and without causing any pain or distress whatever to the patient.

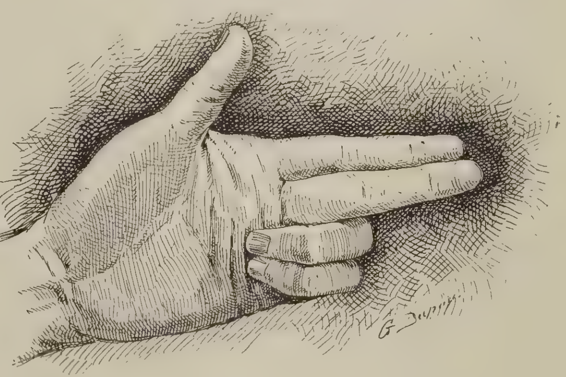

FIG. 2419.—Position of Fingers for Vaginal Examination

After the fingers have gained entrance into the vagina, the size, thickness, and sensitiveness of the organ are to be noted. The mucous membrane may present a smooth, velvety feel as when the rugæ are obliterated, or it may feel harsh and granular as in certain forms of vaginitis. Spasm of the vagina (vaginismus) may be observed as the fingers pass the introitus.

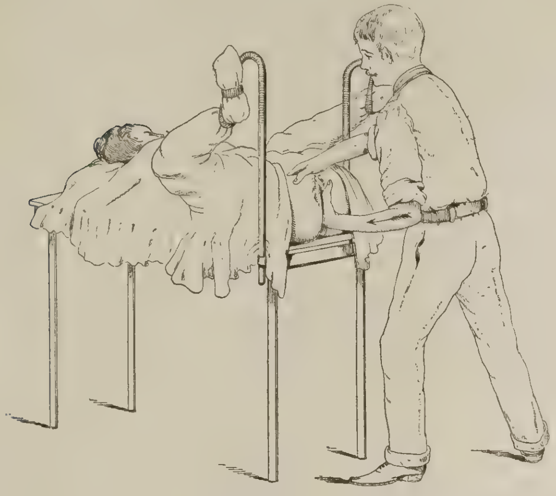

FIG. 2420.—Bimanual Examination, with the Patient on the Table.

It is important that the fingers should be held in a manner that will insure deep penetration into the pelvic cavity. The hand must be rendered as narrow as possible to permit its passage between the ischial tuberosities. When this is accomplished the whole pelvic floor can be pushed up or invaginated so as greatly to increase the penetration of the examining fingers, and thus render accessible to the touch parts which cannot otherwise be reached.

The hand should be held in a perpendicular position with the thumb extended so as to avoid the symphysis. The index and middle fingers rest in the vagina with the palmar surface of their tips inclining upward. The ring and little fingers are flexed upon the palm at the *middle* joint. It will be seen that this will give the minimum of breadth to the hand, allowing its passage between the tuberosities, while the perineum is pushed up on the knuckles of the ring and little finger (see Fig. 2419). The mistake is frequently made of flexing the fingers at their junction with the metacarpal bones. This will bring the whole length of the third phalanx of the fingers across the pelvic outlet which will render it impossible for the hand, which is then at its greatest width, to enter the pelvis. If necessary, the thumb may be closed upon the index finger so that it will pass under the pubic arch.

The elbow of the examining hand should rest against the examiner's hip, and all pressure should be made by throwing the weight of the body upon the elbow, thus allowing the muscles of the forearm and arm to be at rest, which greatly facilitates the vaginal touch (see Fig. 2420). As the fingers pass on toward the upper portion of the vagina, they should convey to the examiner a knowledge of the direction of the canal, of any abnormal relaxation of its walls, and of the presence of cysts or other abnormal growths. The presence or absence of fæcal matter in the rectum can be readily made out with the finger in the vagina. Sometimes hard scybalous masses may be mistaken for an abnormal growth by a careless observer, but they can usually be indented on pressure. However, if there is any doubt, an enema will promptly clear up the diagnosis. As soon as the cervix has been reached, the fingers should be rotated until their palmar surfaces are directed upward, and their tips should be slipped under the cervix until that organ rests upon them. The relation that the cervix bears to the axis of the vagina should be accurately noted. When the uterus is in its normal position, its axis is approximately at right angles to the axis of the vagina. Therefore the tip of the examining finger should touch the anterior wall of the cervix as it reaches the upper portion of the vagina. Should the examining finger directly enter the mouth of the cervix, it would be an indication that the uterus was displaced backward (retroverted), and that, therefore, the axis of that organ was parallel, or continuous, with the vaginal axis—unless further examination showed that the body of the uterus was flexed upon the cervix. In cases of extreme retrodisplacement, the cervix would be found to be pointing upward toward the symphysis, and the entering finger would encounter the posterior cervical wall (see Fig. 2421).

In anteversion the cervix will be found to point backward, its axis forming an acute angle with the axis of the vagina.

It must be borne in mind that the position of the uterus can be greatly influenced by the amount of urine in the bladder. A full bladder will throw the uterus into a position of retroversion. Errors will be avoided if the precaution is taken to have the bladder emptied before the examination.

The condition of the cervix itself can readily be determined by the sense of touch. The number, extent, and location of lacerations (if any are present) should be noted. It is important also to determine the degree of patulency of the os, and whether any granular erosion or carcinomatous induration exists. The presence of dense scar tissue in the angles of lacerations should be felt for, and the effort should be made to ascertain whether there is any hyperplasia of the cervix or any cystic degeneration of the Nabothian glands. Cysts of the glands of the cervix give to the touch the impression of the presence of buckshot under the mucous membrane.

The normal position of the cervix in the vagina is usually at a point corresponding to about the junction of the upper and middle thirds, and ordinarily it is not difficult to reach. In some cases, when there is a very deep vagina, or when the pelvic muscles are rigid and unyielding, it may be difficult to reach the cervix. It is a good plan to place the external hand gently upon the lower abdomen in commencing the examination; then, if the cervix cannot be readily reached, gentle pressure should be exerted in the direction of the axis of the pelvic inlet. This will depress the uterus and bring it within touch of the fingers in the vagina.

If the uterus is prolapsed, the cervix will naturally be found nearer the vulva than is normal. Care must be taken to differentiate a prolapsus of the uterus from an elongated or hypertrophied cervix.

After the examination of the cervix as above described, the next step will be to examine the uterus as a whole. The knowledge obtained by the simple vaginal touch of the cervix must be further amplified by the bimanual touch, if one wishes to arrive at a complete diagnosis of the position and condition of the uterus. It is obvious that if a flexion of the uterus exists, the position of the fundus, as indicated by the relation of the cervix to the vaginal axis, will be incorrect.

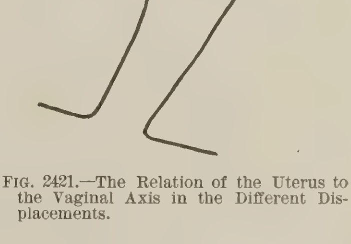

FIG. 2421.—The Relation of the Uterus to the Vaginal Axis in the Different Displacements.

In commencing the bimanual examination the physician should pass the tips of the vaginal fingers under the cervix, so that it shall rest upon their palmar surfaces. The external hand rests upon the abdomen midway between the symphysis and the umbilicus, ready to make counter-pressure from above.

The management of the external hand is a very important matter. Too vigorous pressure is the rule with the novice, and it will promptly insure failure. Such a procedure will cause the patient to resist to the utmost the rude invasion, by contracting her abdominal and pelvic muscles. It is therefore well to bear in mind, from the very beginning, that in the majority of cases more can be accomplished by gentleness of manipulation and skill, than by physical force. When it is necessary to use deep pressure, it must be done slowly and gradually, so as not to alarm the patient. By the exercise of strategy in distracting the patient's mind from the examination, as by asking questions and by getting her to take deep inspirations, we shall be able to seize the moment when the abdominal muscles are relaxed and gain the desired entrance into the pelvis with the external hand.

The four fingers of the external hand should always be kept close together, and the palmar surfaces of the fingers should be used as much as possible and not the tips. To separate the fingers and to use the tips is decidedly unpleasant to the patient, and will cause her to resist.

The first object of the bimanual examination should be to get the uterus between the two hands, so that it can be palpated. With the cervix resting upon the fingers in the vagina, slight upward pressure in the direction of the inlet of the pelvis is made, while the external hand makes gentle counter-pressure from above, gradually increasing until the fundus of the uterus is reached. This can be told by the fact that the pressure on the fundus is at once communicated to the fingers in the vagina, upon which rests the cervix (see Fig. 2422).

While holding the uterus in this manner, the size and shape of the organ can be judged, and also the amount of mobility that it possesses. The uterus should normally give the impression of being suspended between elastic ligaments. It is movable forward or backward, upward or downward, in response to moderate pressure. On the pressure being removed, the organ should promptly regain its normal position. In examining for the mobility of the uterus in this way, valuable knowledge can be gained as to the presence or absence of adhesions, or of infiltration of the vaginal vault or broad ligaments, which would cause various degrees of fixation of the uterus.

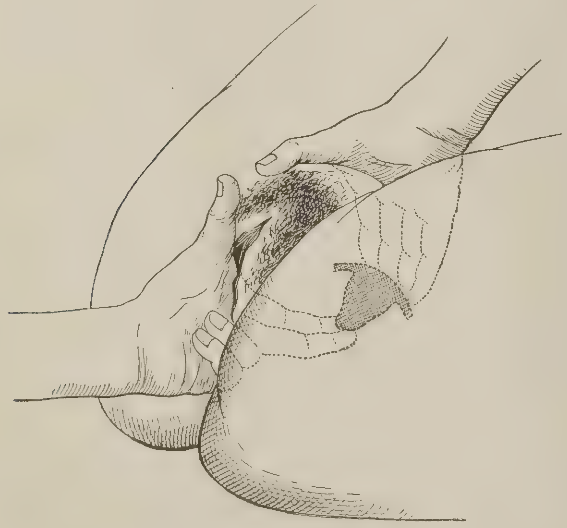

FIG. 2422.—Locating the Fundus and Cervix by the Bimanual Method.

The size of the uterus can be judged after a little practice, as one soon learns the impression that the normal uterus conveys.

Any irregularity on the surface of the fundus uteri, such as might be caused by fibroids or malignant growths, may be determined by the external hand.

The various positions that the uterus may assume must be diagnosed by comparing the relation that the cervix bears to the vaginal axis, and the position that the fundus occupies as determined by the external hand.

If the cervix is at right angles to the vagina, and the external hand discovers the fundus about midway between the umbilicus and the symphysis, the position of the uterus is normal.

Should the uterus be anteverted or anteflexed, it would be necessary to explore with the external hand right up to and behind the symphysis, until the fundus had been located. The position of the cervix would indicate whether the uterus was anteverted or anteflexed, and this could be further confirmed by slipping the vaginal fingers in front of the cervix, when with the external hand on the fundus any sulcus or bend in the organ could be easily appreciated.

Three varieties of anteflexion may be recognized. The body of the uterus may be in its normal relation with the pelvis, while the cervix is bent so as to lie in the axis of the vagina, instead of at right angles to it. This is spoken of as anteflexion of the cervix. The opposite of this condition may exist, the cervix being in its proper position, while the body is bent forward upon the cervix. This variety is designated as anteflexion of the body, in contradistinction to the above. Then again the third variety may occur, in which both cervix and body are out of their normal positions, the flexion being very acute, and the cervix and body closely approaching each other.

When the uterus is displaced or flexed backward, the search for the fundus is made toward the sacral promontory. It is apparent that if the fundus is at or below the level of the promontory, it will be found extremely difficult—unless there is unusual relaxation of the abdominal muscles, or unless we employ a general anæsthetic—to get the uterus between the hands; indeed, in some cases, it is simply impossible to accomplish this.

The fact that the fundus could not be found, and that the cervix was pointing in the axis of the vagina, would be strong presumptive evidence that there was a backward displacement of the organ beyond the sacral promontory.

Retroversion is classified by most authors into three degrees: When the fundus points toward the sacral promontory, it is a retroversion of the first degree. If it points into the hollow of the sacrum, being practically continuous with the vaginal axis, it is the second degree. When the fundus is still lower in the pelvis, and the cervix begins to point upward toward the symphysis, it is classified as the third degree. (See Fig. 2421.) In the second and third degrees of retroversion, it is often impossible to reach the fundus with the external hand by the ordinary method of examining. In such cases the difficulty may be overcome if the uterus be drawn down by a tenaculum, until the cervix is nearly at the site of the hymen. If the index finger be inserted into the rectum while the uterus is drawn down it is frequently possible to palpate the body and fundus with great facility. Kelly's corrugated tenaculum is designed especially for this purpose, as it enables the examiner firmly to hold the tenaculum with the external fingers of the lower hand, while the counter-pressure is made as usual with the upper hand on the abdomen (see Fig. 2423). This method enables the examiner to reach the fundus with both hands.

Retroflexion of the uterus can be differentiated from retroversion by the presence of a distinct sulcus or angle being felt at the junction of the cervix with the body. When a sulcus cannot be felt, and the fundus is out of reach of the finger in the posterior vaginal fornix, it is to be inferred that the uterus is not retroflexed. The afore-mentioned method of drawing down the uterus will permit this point to be accurately determined, unless adhesions prevent, in which case the diagnosis must be left until it can be settled by the uterine sound or probe.

It is wise always to confirm a diagnosis of flexion by the sound, as a subperitoneal fibroid on either the anterior or the posterior uterine wall will frequently be a cause of deception.

Lateral displacement of the uterus to the right or left of the median line should be carefully noted. A uterus in such a position has either been drawn over to one side by the contraction of adhesions, or it is pushed over by the presence of a cyst or growth filling the opposite side of the pelvis.

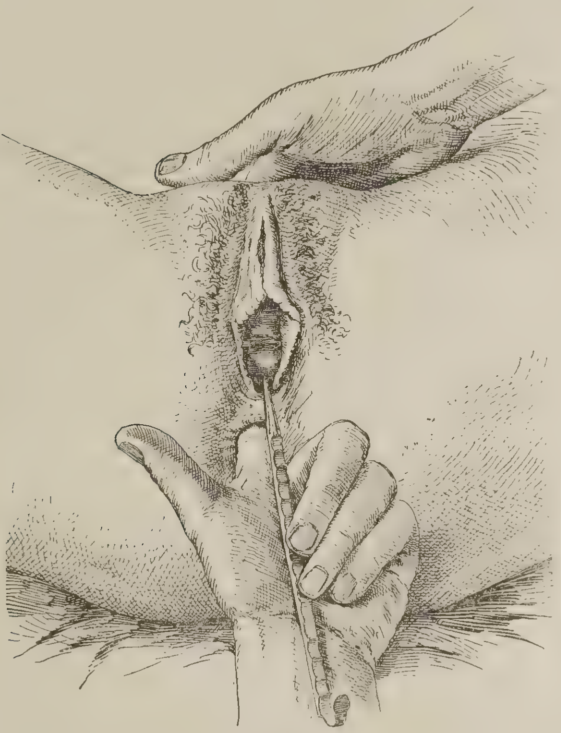

FIG. 2423.—Recto-Abdominal Palpation while Drawing Down a Retrodisplaced Uterus with Kelly's Corrugated Tenaculum.

Normally the pelvic organs, with the exception of the ovaries, are not sensitive to ordinary palpation. Deep pressure upon these organs will cause a nauseating pain, accompanied with faintness, similar to that produced by pressure upon the testicles. Tenderness of the uterus will generally indicate disease of that organ, as endometritis or metritis, although there is a certain class of patients whose organs, even when not appreciably diseased, manifest an abnormal degree of hyperæsthesia. Pelvic sensitiveness is one of the prominent symptoms of an hysterical patient.

One of the most important items of information to be derived from the examination is the consistency of the uterus and the surrounding structures, as determined by the sense of touch. Each structure has its own standard, and the examiner must first become thoroughly familiar with the normal consistency before he can appreciate deviations which indicate pathological changes. The soft, friable condition of a carcinomatous cervix, the boggy impression conveyed by a subinvoluted or œdematous uterus, the hard plaster-of-Paris-like feel of the vaginal vault in pelvic peritonitis, the fluctuating sensation of a fluid tumor or abscess, are but a few of the conditions which must depend upon a comparison with the normal for their diagnosis.

After the examination of the uterus has been completed, the attention should next be directed to the ligaments which aid in its support. These ligaments are prone to inflammatory thickening, which may give rise to pain, and which frequently interferes with the normal mobility of the organs.

The anterior, posterior, and lateral fornices of the vagina are to be palpated to ascertain the condition of the utero-vesical, utero-sacral, and broad ligaments. Normally the vaginal vault is elastic to the touch, and should induration and thickening of the ligaments be present, these conditions can usually be made out by palpation.

The vaginal fornices must be carefully explored by bimanual touch, for the presence of cysts, growths, prolapsed ovaries, collections of fluid, etc., which may occupy the cul-de-sac of Douglas or the utero-vesical space.

By comparing one lateral fornix with the other, as regards the ease with which the examining fingers may be moved in different directions, and also by comparing the two sides as regards the degree of pain elicited by pressure, one may obtain considerable information in regard to the pathological conditions that may be present.

It is not possible in a limited article like the present one to do more than hint at the diagnosis of the many complicated conditions which will be found in examinations of the vaginal fornices. It is hardly necessary to say that years of experience may be required before it is possible for one to acquire the *tactus eruditus* necessary to ascertain, by digital exploration, the pathological conditions that are present in the pelvic cavity in any given case. The most expert gynæcologists not infrequently see, on opening the abdomen, that their diagnosis was at fault. A thorough appreciation of the normal condition of the parts will enable the novice more readily to recognize pathological deviations, and especially is this true of the uterine appendages. It is a frequent occurrence, in the writer's experience, to come across men, in active general practice, who state that the palpation of the uterine appendages is a closed book to them. Diagnosis of diseases of these important organs is entirely beyond their reach for the reason that they cannot feel the adnexa, although they repeatedly examine cases in their practice. They can often make a diagnosis as to the position of the uterus, the condition of the cervix, or the pelvic floor, but the condition of the ovary and tube is like the "will-o'-the-wisp;" it easily evades the simpler methods of examination.

In examining for the ovaries and tubes, the novice will frequently attribute his failures to the shortness of his phalanges, and he will endeavor by pure physical force to gain further entrance into the pelvis, with the result that he causes needless pain to the suffering patient. As she is frightened by fears of worse pain to come, she sets to the utmost her abdominal and pelvic-floor muscles, in order to resist the rude invasion with which she is threatened, and thereby makes it impossible for the examiner to get within reach of the adnexa with his examining fingers. The novice usually has no definite plan of procedure in his mind, and his one idea as to the position of the ovary is, that it lies on one side of the uterus at or near the plane of the fundus, just as he has seen it pictured so often in his text-books.

A careful observance of the preliminaries to the examination—such as loosening the corsets and clothing, emptying the bladder, etc.—is essential to success. It is well to remember that it is easier to reach the left appendage with the left hand in the vagina, and the right appendage with the right hand.

The first step necessary to the palpation of the adnexa is to locate the fundus of the uterus, as with the fundus as a guide the location of the appendages is made easier. This is done after the manner previously described and shown in Fig. 2422. After the cervix and the fundus of the uterus have been located, the next step is to remember that the tube and ovary, unless bound down by adhesions, are *movable*, as can well be brought to the examiner's mind when he remembers how often he has seen the operator bring up the appendages out of the pelvis upon the abdomen of a patient through an abdominal incision, and how loosely they have appeared to him to be attached to the horn of the uterus.

To this fact is to be attributed the failure, in many cases, to reach these organs. The novice examines in *one* place for them, and as they are slippery bodies, they are as difficult for him to get hold of with his external and internal examining fingers, as the proverbial eel. Therefore he must endeavor to *catch* these organs, and as they may lie or be pushed into any part of the space between the middle line of the body and the lateral pelvic wall, he must systematically search each half of the pelvis.

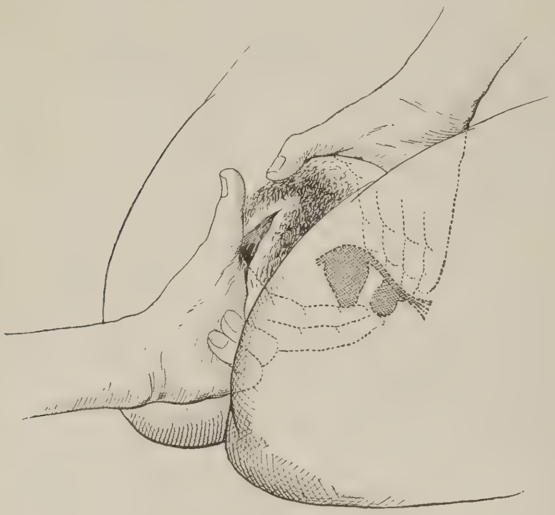

FIG. 2424.—Palpating the Adnexa by the Bimanual Method. Catching the appendage between the tips of the opposing fingers.

It is better that one hand do the searching, the other remaining stationary for the time being, to act as a counterpoint. After locating the cervix and fundus uteri, the examiner should slip the vaginal finger or fingers to one side of the cervix into the lateral fornix, and should make pressure with them in a direction upward and backward, at a point midway between the cervix and the pelvic walls. These fingers should then remain stationary, while the four fingers of the external hand, curved in the shape of a scoop, are employed in systematically exploring the area from the fundus to the side of the pelvis, in lines radiating to the examining fingers in the vagina. It may frequently be necessary to go over the ground repeatedly before the ovary can be caught. The position of the vaginal fingers is to be varied from time to time, antero-posteriorly and laterally, so as to cover new planes. As soon as the ovary and tube are imprisoned between the scoop formed by the external hand above, and the fingers in the vagina below, their character, size, sensibility, and consistency can be made out as they slip between the opposing finger tips (see Fig. 2424). The normal tube can be traced from the horn of the uterus; it feels like a cord of about the diameter of a slate pencil, and it is not painful to moderate pressure.

The normal ovary feels as large as a walnut, and when it is subjected to pressure the patient experiences the same sickening sensation and pain as does the male when his testicle is similarly pressed upon. The opposite side of the pelvis is to be explored in a similar manner for the other appendage, the right hand being used in the vagina for the right adnexa and *vice versa.*

In cases in which this method does not succeed, the examiner should resort to recto-abdominal palpation. In this method the index finger is introduced into the rectum instead of into the vagina, and the palpation is made with the opposing hand, as in the bimanual examination just described.

When the uterus is retroverted or retroflexed, recto-abdominal palpation is usually preferable, and is a great gain, especially if the uterus is drawn down to the vaginal outlet by a tenaculum or volsellum, which permits the fundus to be reached posteriorly, and brings the adnexa within the radius of the examining finger (see Fig. 2423). In commencing the practice of bimanual palpation it is wise to select a patient who has borne children, who is thin, and who has relaxed abdominal walls. In women who are fat, and who have rigid abdominal muscles, even the expert must, in many cases, necessarily resort to complete anæsthesia before he can make a positive diagnosis. The beginner must not feel discouraged if he fails satisfactorily to feel the adnexa in his first attempts, but by exercising patience and persistence, avoiding haste, paying careful attention to all the minor details, and having a definite plan of procedure in his mind, he will surely attain ultimate success.

The differential diagnosis of the various pathological conditions that may be found about the uterus is such an extensive subject that it can only be touched upon here. In general, fluid accumulations or cystic growths that can be felt through the vaginal vault are diagnosed by the sense of fluctuation and elasticity.

If a mass is diffuse, boggy, ill-defined, immovable, and tender, one would suspect an inflammatory exudate. If a mass gives evidence of fluctuation, of increased heat, and of being very painful when pressed upon, while the patient at the same time gives a history of exposure to infection, of fever, and possibly of chills, the presence of an abscess would be indicated. In inflammatory affections of the tubes and ovaries, these organs frequently are displaced into the cul-de-sac and fixed by adhesions. Generally a hydro- or pyo-salpinx is of a sausage shape, and can be traced to the uterine cornua.

Whenever the bimanual examination discovers the presence of a large growth, or it is self-evident that the patient has an enlargement of the abdomen, abdominal palpation must be practised. Special works will have to be consulted for the details of the technique necessary. Gentleness of touch is here as essential to success as in the vaginal examination. The novice will do well to avoid giving a positive opinion as to the nature of an abdominal enlargement. Pregnancy, ascites, fat, gas, fæcal accumulations, a distended bladder, are but a few of the conditions that must be differentiated from tumors.

When the presence of a growth is certain, not only its character, but also its relations to the pelvic organs, must be carefully studied. The presence of adhesions is judged by the amount of fixation that exists. It is a good plan to examine all abdominal enlargements in various postures. Percussion is of value in mapping out the relations of the intestines.

It should be borne in mind that in acute inflammatory affections of the pelvic contents, appendicitis and ectopic gestation should be carefully differentiated. Likewise, at the present time, a gynæcological examination can scarcely be considered complete without an investigation of the mobility of the kidneys.

Examination with Instruments.—After the bimanual examination has been completed, the instrumental examination is in order.

The instruments necessary are few, and comprise a Sims speculum, a bivalve speculum, a depressor, dressing forceps, single tenaculum, double tenaculum or bullet forceps, probe, sound, and a small flexible spoon curette. Cystoscopic tubes, a urethral endoscope, and an aspirating syringe would render the armamentarium complete. Suitable basins for cleansing solutions, etc., should be at hand, and also an abundance of absorbent cotton. The absorbent cotton should be made into cotton balls, as they are convenient and greatly facilitate the cleansing of the vulva, vagina, etc.

The Speculum.—Of all the many varieties of specula that have been devised, there is none better than the original Sims instrument, a description of which can scarcely be necessary. The bivalve or trivalve specula are but substitutes for the Sims and should be resorted to only from necessity and not from choice. When an attendant or nurse is not available, the examiner may have no option but to use the bivalve speculum; otherwise, the Sims should be used, because by no other method can such a satisfactory examination of the vagina and the uterus be made.

The Sims speculum alone does only a small part of the exposing of the vagina. It is in the Sims posture that the great virtue of this method lies. In the correct Sims position, the pelvis is tilted over at an angle of forty-five degrees, so that the intestines, etc., gravitate out of the pelvic brim, as if out of a basin. This produces a vacuum in the pelvis, and when the speculum retracts the perineum and opens the labia, the air rushes in and balloons the vagina, so that its folds are obliterated, permitting an unobstructed view of the vaginal vault and the cervix. In this position the uterus, unless fixed, can be drawn down nearly to the orifice of the vagina, so that treatment or examination is greatly facilitated.

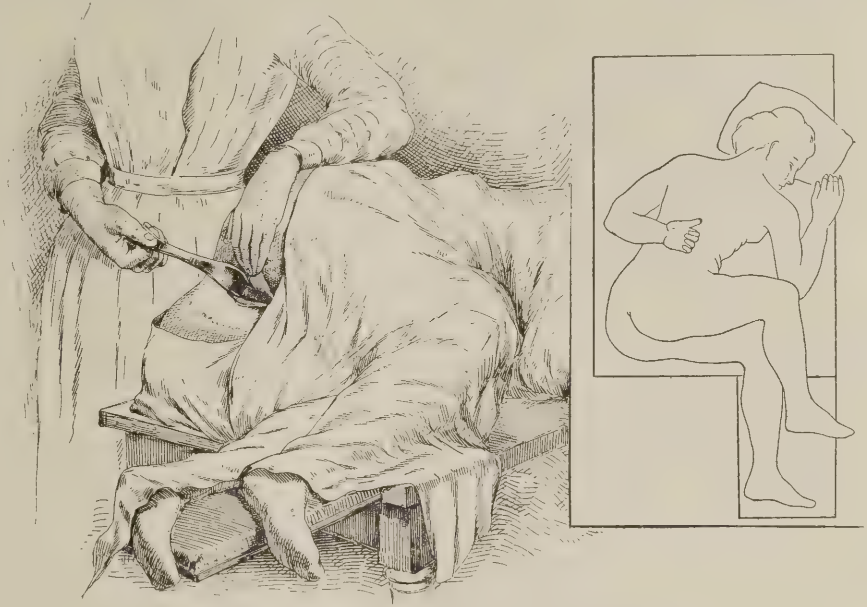

FIG. 2426.—Correct Posture of Patient and Nurse in the Sims Position.

The bivalve speculum gives but a limited view of the cervix, and affords only a small amount of space in which instrumental manipulations can be carried out. Furthermore, if the uterus is in the normal or in an anteverted position it is sometimes extremely difficult, through this pattern of speculum, to pass a sound or to make intrauterine applications.

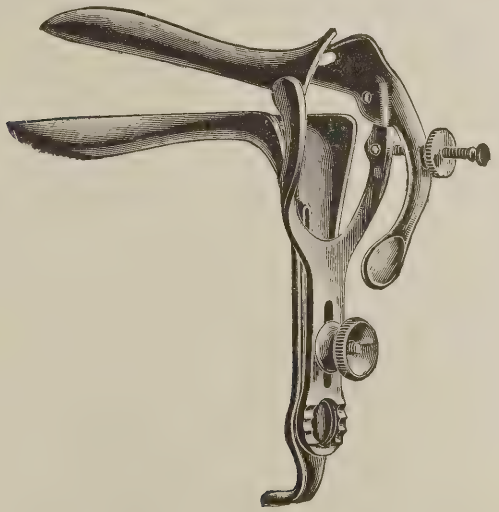

FIG. 2425.—Graves' Bivalve Vaginal Speculum.

A good example of a bivalve speculum is that of Graves (Fig. 2425). It has the advantage of being adjustable at the vaginal orifice, and it can be converted into a Sims speculum. In selecting a bivalve speculum, care should be taken to see that the anterior blade is from a half an inch to an inch shorter than the posterior blade.

Various self-retaining Sims specula have been devised, and while none of them is as good as the instrument held by an assistant, the examiner will be able to get along fairly well with one of these instruments. Perhaps one of the simplest and best is Cleveland's. Ehrich's modification is also very serviceable.

The first requisite to a successful examination with the Sims speculum is a proper Sims posture. The nurse, or the physician, will direct the patient to sit up on the table and then to lie on her left side with the left arm flexed behind her back. Both knees are then to be drawn up in the direction of the chin, the uppermost knee lying above the under one. In this position the sole of the right foot will lie above the left ankle. The left hand of the nurse should then be passed under the lower buttock until the crest of the ilium can be grasped. Traction should then be made on the crest of the ilium until the lower buttock shall have been drawn to the edge of the table, while at the same time the right hand pushes the upper buttock in the opposite direction. This manœuvre will tilt the pelvis so that the brim will lie at an angle of about forty-five degrees with the table. To prove that the pelvis is properly tilted, all that is necessary is to hold a straight rod at right angles to the table and against the lower buttock, when it will be seen that the upper buttock is four or five inches beyond its neighbor. If the clothing has been previously loosened about the lower abdomen and waist, the intestines will gravitate out of the pelvis. The legs and feet should lie on an extension leaf at the right-hand corner of the table. Finally, the patient is covered with a sheet so that only the vulva is exposed (see Fig. 2426).

The physician sits at the foot of the table, and at his right hand there should be a stand upon which the instruments, basins, etc., are arranged within convenient reach. A warm carbolized solution should be used for immersing the instruments. Care should be taken to warm them properly before they are used. The nurse stands on the physician's left, facing him and close to the side of the table. With her left hand the nurse raises the upper buttock and labium, keeping her fingers separated and extended, and taking care not to use the tips at all, but to roll up the buttock with the palmar surfaces of the fingers only. If the points of the fingers are used like a claw, it is decidedly unpleasant to the patient. The physician draws down the lower buttock and labium with his left hand in a precisely similar manner, while he grasps one end of the speculum with his right hand, being careful to have the index finger project beyond the bill of the speculum for an inch or more (see Fig. 2427). The speculum and finger should have previously been well lubricated. The idea of the projecting finger is, that it is to enter the vagina in advance of the speculum as a pilot, so as to guide the tip of the instrument behind the cervix.

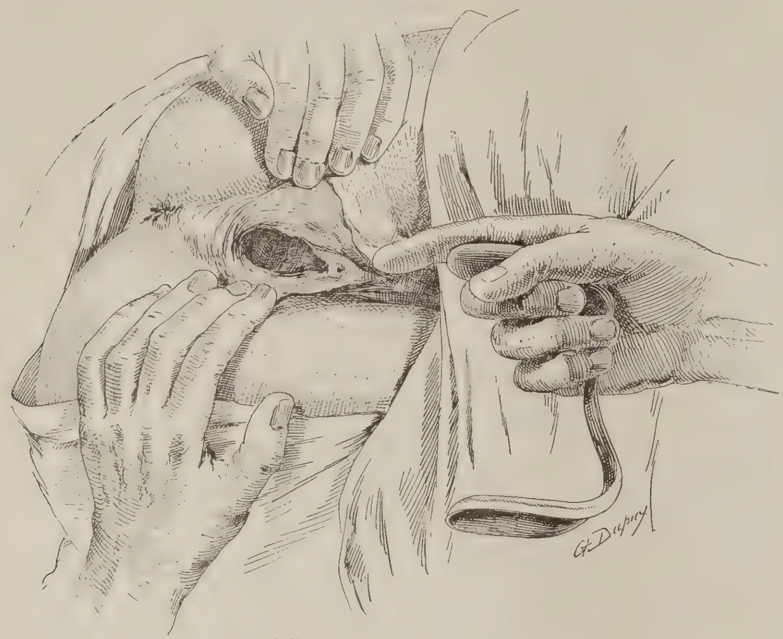

FIG. 2427.—Introducing Sims' Speculum.

The direction of the vagina must be borne in mind. As the patient lies in this position, the vagina will run in a direction toward the centre of the sacrum. As the finger enters the vagina, the speculum follows after, entering laterally; that is, the flat of the blade corresponds to the direction of the cleft between the labia. As soon as the index finger feels the cervix, the speculum can be easily guided behind it into the posterior vaginal fornix. The speculum is then rotated to its final position so that it will retract the perineum. The external end of the instrument is given to the nurse, who should grasp it firmly, the fingers surrounding the external blade while the thumb lies in the groove.

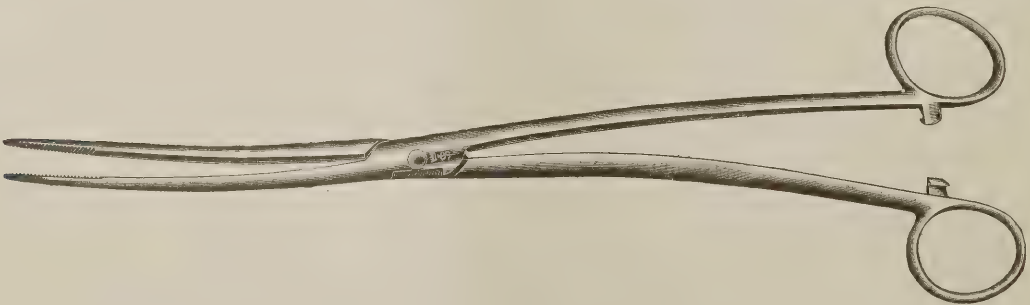

FIG. 2429.—Bozeman's Uterine Dressing Forceps.

The nurse's duties are to hold the speculum exactly as it is given her, and to keep the upper buttock retracted. She can best do this with comfort to herself and satisfaction to the examiner, if she stands straight up, facing slightly away from the physician, so that the arm holding the speculum is wrapped about her body. Her arm is thus steadied, and there is no occasion for any strain on the muscles of the hand or forearm (see Fig. 2426). If she is directed to increase the traction on the instrument, she simply rotates her whole body and does not bring into play the muscles of her arm. By this method a nurse can hold a speculum for a long period without becoming tired, and it is far more satisfactory than stooping over the patient, grasping the speculum by the shank, and keeping up all the tension with the arm muscles which soon tire and cause unsteadiness.

The Depressor.—As the perineum is retracted and the vaginal walls are exposed to view, the cervix will usually be hidden behind the anterior wall of the vagina, which bulges somewhat in front of it. We should therefore next use an instrument called a depressor, to depress the anterior vaginal wall. The depressor is practically a spatula or spoon (see Fig. 2428), which should be held between the thumb and fingers of the left hand and gently used to push aside the bulging anterior wall so that the cervix may be brought into view. Care should be taken while using this instrument that the wrist of the hand is dropped below the line of vision.

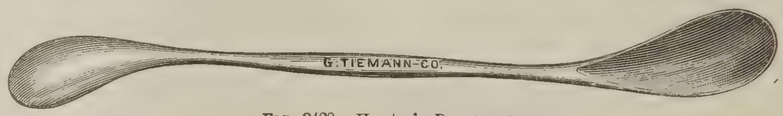

FIG. 2428.—Hunter's Depressor.

The Dressing Forceps.—As soon as the cervix is brought into view a dressing forceps, holding a cotton ball, is used to cleanse the cervix and vagina of any secretion that may be present, after which a cotton ball saturated with carbolic or other solution is used to bathe the parts. Of the different forms of dressing forceps there is a sufficient variety to suit the taste of the examiner. One having a curve is of advantage as it enables the right hand to keep out of the line of vision. Bozeman's forceps is a good illustration of this instrument (see Fig. 2429).

By the inspection of the cervix and the vagina, we are enabled to verify the diagnosis made by vaginal touch. The condition of the vaginal mucous membrane, the presence of fistulæ or of cicatrices, the extent of cervical lacerations, hyperplasia of the cervix, and erosions are all brought into view.

FIG. 2430.—Tenaculum.

The Tenaculum.—The next step is to seize the cervix by the anterior lip, so that it may be drawn down for closer inspection and also for the purpose of steadying the organ while a sound or other instrument is being passed into the uterus. The single-hook tenaculum, as shown in Fig. 2430, is the style of instrument usually employed. It should be hooked into the cervix through the os.

For the purposes of examination and of making intra-uterine applications, the double tenaculum has many advantages over the single instrument.

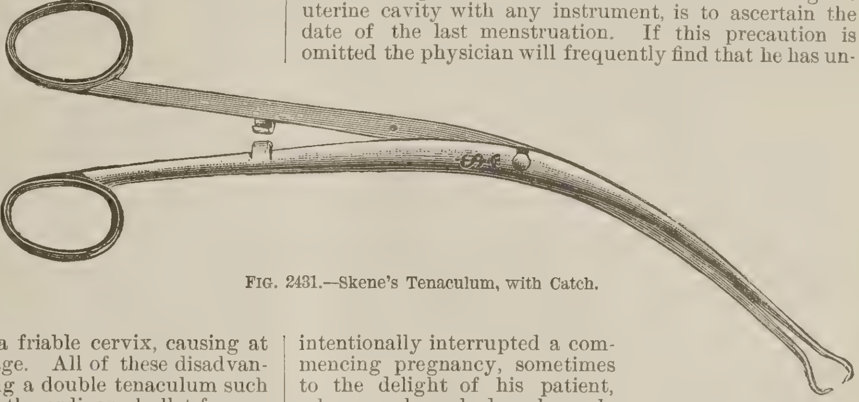

FIG. 2431.—Skene's Tenaculum, with Catch.

No matter how expert the examiner may be, he cannot help making a number of punctures with the single instrument during the course of his examination and treatment. The instrument cannot be left on the cervix, but must be held by one hand, so that if both hands are needed during the preparation of an applicator, etc., the instrument must be removed and then afterward reapplied. It frequently tears through a friable cervix, causing at times a bothersome hemorrhage. All of these disadvantages can be avoided by using a double tenaculum such as Skene's (see Fig. 2431), or the ordinary bullet forceps will answer. With the double tenaculum two punctures only are made in the anterior lip of the cervix, instead of half a dozen. The instrument is clamped on by means of the catch, so that no hand is required to hold it. It will of itself act as a depressor to keep back the bulging anterior wall. So long as it remains fastened to the cervix, the uterus will be under perfect control. A retroverted uterus can be replaced with great ease with this instrument. This is accomplished by drawing on the cervix and making it describe a circle backward into the posterior fornix. It is of course to be understood that ordinary care will be exercised, and that the instrument is at all times to be used with the same gentleness and delicacy as the single tenaculum. Great care should be used in drawing down the cervix, as this is a procedure that may do much harm and cause considerable pain, if adhesions or inflammatory conditions exist. The bimanual examination should have previously disclosed any condition of immobility of the organ, or any lack of elasticity of the ligaments. Unless the uterus can be drawn down easily without force, the procedure should not be attempted.

The Probe and the Sound.—After the cervix and its surroundings have been inspected, the next procedure will be to examine the cavity of the uterus by means of the probe or the sound.

The probe is a very flexible piece of copper or silver wire, with an olive-shaped tip, and is designed to bend on meeting the slightest obstruction. It is therefore a safe instrument with which to make an exploration of the uterine cavity (see Fig. 2432).

The sound is of a larger diameter, and is much stiffer than the probe, but is capable of being bent into any shape that may be required. Simpson's sound is the instrument usually employed (see Fig. 2433). It has a bulbous tip and at a point two and a half inches from the end there is an enlargement which denotes the normal length of the uterine canal. The shaft is marked in inches for purposes of measurement.

The sound is an instrument capable of inflicting much damage, and requires great care in its use. Great harm may be done by employing it recklessly and unskilfully. The novice had better by far use the probe only, for his investigations, until he has acquired a sufficient knowledge of the technique, and some skill in his manipulations.

The probe will reveal nearly as much as the sound, and there is no especial advantage, in the majority of instances, in employing the more dangerous instrument.

The first precaution to be taken before invading the uterine cavity with any instrument, is to ascertain the date of the last menstruation. If this precaution is omitted the physician will frequently find that he has unintentionally interrupted a commencing pregnancy, sometimes to the delight of his patient, who may have had such an object in view in requesting an examination for other trouble. The technique of using the sound is practically the same as that for introducing the probe.

The instrument should never be introduced without having the cervix clearly in view, so that it may be passed directly into the canal of the cervix without coming in contact with the surrounding parts. The method of introducing the instrument by sense of touch should be condemned just as strongly as the old method of catheterizing a patient, when it was considered desirable for the physician to be able to introduce a catheter into the bladder under a sheet.

FIG. 2432.—Uterine Probe.

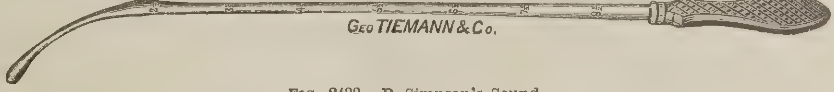

FIG. 2433.—R. Simpson's Sound.

Any instrument that is to enter the uterus in the course of an examination should be sterilized as if for an operation. Boiling is perhaps the safest plan, but when the conveniences are not at hand, the instrument can be immersed in ninety-five-per-cent. carbolic acid for a few moments, and then in alcohol to neutralize the acid. The bimanual examination will have given the physician a fairly accurate idea as to the shape of the uterus, and he should shape his probe or sound accordingly. The instrument is to be held lightly between the thumb and forefinger and the cervix steadied by the tenaculum. The tip is then passed into the external os and allowed to find its way along the canal. It will frequently become obstructed at the internal os by a shoulder or pocket in the mucous membrane, in which case a gentle twisting motion or withdrawal will enable the sound to pass the obstacle. The probe will pass a constriction at the internal os, while the sound may be arrested. Sometimes, in anteflexion, the constriction may be spasmodic in character; if such is the case, the stricture will relax if the sound is held firmly against it for a few moments. When the instrument reaches the fundus, the forefinger is slid along the shaft until it comes in contact with the cervix. The probe or sound is then withdrawn and the depth of the uterine canal can readily be noted.

FIG. 2434.—Skene's Curette.

The sound should not be used to determine the mobility of the uterus. It is such a powerful lever that the uterine mucosa will be unnecessarily injured even if worse damage is not done. The degree of mobility of the uterus can be determined better and more safely by the bimanual examination. In the healthy uterus the sound, if skilfully passed, should not cause either pain or hemorrhage. The occurrence of one or both of these symptoms denotes a diseased condition of the endometrium. The patency of the external and internal os, irregularities on the uterine mucosa, and the presence of growths in the canal are ascertained by means of the sound. The sense of touch, as communicated through the sound, is here brought into play, and this necessitates that the instrument must be held very lightly between the thumb and fingers in order to appreciate any delicate variation.

The use of the sound as a repositor is to be condemned. Any evidence of acute inflammation of the uterus or its appendages prohibits any intra-uterine manipulations.

The Curette.—The curette is a valuable instrument for diagnostic purposes. The curette for this purpose should be small, so as to pass the internal os without difficulty. It should be dull and very flexible, so that no damage can be done with it. The spoon-shaped curette, as shown in Fig. 2434, is especially adapted for diagnosis, although a dull wire curette may be used. The spoon curette enables one to scrape off shreds of tissue and epithelium from the endometrium, which should be examined under water to disclose their gross appearance, while they are to be submitted to microscopic examination for more accurate diagnosis. All that has been said in regard to employing the sound applies equally to the curette. The instrument must be properly sterilized, and given the shape of the canal which has been accurately ascertained by means of the sound or probe. It is to be used with all gentleness. The curette is not to be used in the office to curette the uterus as for an operation; it should serve simply as a means of procuring a small amount of tissue or débris from the uterine canal for diagnosis only.

Dilatation of the Cervix.—This is a procedure which is sometimes necessary in order to admit the passage of the examiner's finger into the uterine canal for purposes of diagnosis. As it is of such a nature as to require an anæsthetic for its proper performance, as well as the usual preparations for a surgical operation, its description does not belong in this article.

Examination of the Urethra and Bladder.—This subject is fully treated in Volume II. of this work.

The Aspirating Syringe.—The ordinary aspirating syringe used in exploring the chest for pleuritic effusions is all that is necessary. It is desirable to have a long curved needle, as the curve greatly facilitates its introduction through the vaginal vault. Cystic or inflammatory masses which are situated low down in the pelvis, and which can be palpated by the examining finger through the vaginal vault, can be safely punctured with the needle and the contents withdrawn by the syringe for examination.

The Microscope.—The aid of the microscope for differential diagnosis is of especial value in gynæcological examinations. The recognition of the gonococcus by the microscope is of prime importance in investigating the character of vaginal or other discharges. In fact it is impossible to be sure of the character of a discharge without its aid. As the important position that the gonococcus holds as an etiological factor in diseases of women becomes better known, the necessity for the use of the microscope by the gynæcologist appears in a clearer light. Commencing epithelioma and carcinoma are to be detected with positiveness only by submitting uterine scrapings or small pieces of cervical tissue to microscopical examination. It must also be resorted to, in many cases, in differentiating malignant from non-malignant growths.

George Gray Ward, Jr.

HÆMATEMESIS. See *Stomach, Diseases of.*

HÆMATIDROSIS is a functional disturbance of the sweat apparatus whereby blood, through diapedesis into the coils and ducts from their surrounding vascular plexus, becomes mingled with the sweat and appears with it upon the normal skin, producing the phenomenon of so-called "*bloody sweat.*" It is an exceedingly rare occurrence, and when observed the subject has been generally a highly neurotic person undergoing some strong emotional disturbance. In some instances it has seemed to be a form of vicarious menstruation. It has been observed in the newborn. The points where it has been observed to occur are the face, ears, umbilicus, feet and hands in limited areas, giving rise to the term "bleeding stigmata" and other names. Treatment is that of the patient.

Charles Townshend Dade.

HÆMATOCELE, RETRO-UTERINE OR PELVIC. See *Extra-Uterine Pregnancy.*

HÆMOGALLOL, HÆMOL.—Two patented compounds prepared from the coloring matter in the blood and thought to be more readily absorbed than other preparations of iron. The first is obtained by the action of pyrogallol, the latter by the action of zinc dust.

Hæmogallol is a brownish-red powder, very soluble in water. The dose is from gr. v. to x. three times a day. Hæmol is a black powder, also very soluble and administered in the same dose. They have been recommended for the treatment of chlorosis and anæmia.

Beaumont Small.

HÆMOLYMPH GLANDS. (HISTOLOGY AND PATHOLOGY.)—The hæmolymph glands are lymphadenoid structures occupying a position intermediate between the spleen and ordinary lymphatic glands. In structure they closely resemble the latter, the essential difference between the two being that they possess blood sinuses in place of lymph sinuses. Transition forms between the two, however, exist; a gland may contain both lymph and blood sinuses; but the presence of the latter, however small, is sufficient warrant for its classification as a hæmolymph gland. There are also transition forms between the hæmolymph glands and spleen, many of the former, particularly in the lower animals, possessing a spleen-like pulp. The spleen itself may be regarded as a hæmolymph gland; and undoubtedly many of the so-called accessory spleens fall into the class of hæmolymph glands.

OCCURRENCE.—The existence of hæmolymph glands was first noticed in the lower animals, particularly those used for food purposes. In the steer, pig, and sheep these structures are very numerous in the prevertebral fat, and conspicuous because of their deep blood color. From their number and size in these animals it is reasonable to suppose that their function is of importance. Butchers and meat dealers have long been acquainted with their gross appearances, but have usually regarded them as blood clots. From the scientific side they have been strangely neglected, though as early as 1857 Leydig pointed out the close resemblance between these glands and the spleen. More recently they have become objects of scientific investigation, and have been found to be present also in the goat, horse, dog, rat, guinea-pig, common fowl, and turkey.

Their presence in man has only lately become a matter of careful study, though lymph glands with blood-containing sinuses have been many times observed. Such findings were, however, interpreted as ordinary lymph glands into whose lymph sinuses there had been a hemorrhage or backward flow of blood. H. Gibbes, in 1884, was the first observer to consider such glands to be permanent and independent structures. A similar view was taken by Robertson in 1890, and to this observer we owe the designation hæmolymph gland, this name having been suggested to him by Dr. Russell. The constant presence of these glands in the human body was confirmed later by Gibbes and Vincent, and more recently by the present writer. According to the investigations of the latter, lymph glands containing blood sinuses are found constantly in the human body, at all ages, and in both normal and pathological individuals. That these glands are organs *sui generis* and not hemorrhagic lymphatic glands is evident from the following facts:

First. Lymph glands containing blood sinuses are constantly present in the human body in all conditions and at all ages.

Second. The structure of such glands differs in many respects from that of ordinary lymphatic glands; and the appearance presented by hemorrhagic lymphatic glands is wholly unlike that of a hæmolymph gland.

Third. These glands in the human body show many points of similarity to the hæmolymph glands found in the steer and sheep, and the latter from their number, size, constant occurrence, and individual structure must be regarded as organs *sui generis* without question.

LOCATION.—In the lower animals the hæmolymph glands are found chiefly in the prevertebral fat, along the course of the aorta, renal and adrenal vessels, brim of the pelvis, and in the root of the mesentery. They rarely extend far out into the latter, but are occasionally found in the omentum and epiploica. They are also of rare occurrence in the mediastinal region. In man they are found in greatest numbers in the prevertebral, retroperitoneal, and cervical regions, in the neighborhood of the adrenal vessels, along the brim of the pelvis, in the root of the mesentery, but rarely extending far out into it, and are of very rare occurrence in the epiploica and omentum. They are also rare in the mediastinal tissues and along the thoracic aorta, except under conditions in which there is a general enlargement of all the hæmolymph glands of the body, as in certain forms of anæmia and leukæmia. This fact suggests the possibility of new formation of these structures in these diseases or their existence as resting glands too small to be found under normal conditions.

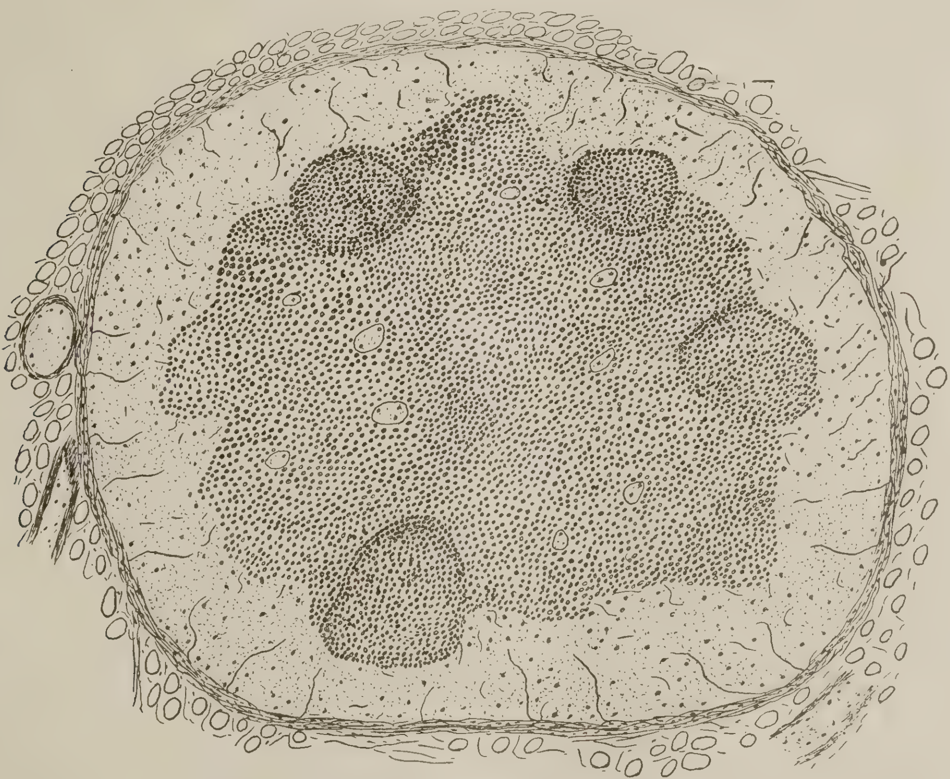

FIG. 2435.—Common Type of Hæmolymph Gland from Steer. Peripheral blood-sinus. Camera lucida drawing. Leitz objective 3; eyepiece No. II. Reduced one-third.

HISTOLOGY.—*Bullock.*—Hæmolymph glands are found in the prevertebral fat of this animal to the number of several hundred. Their deep red color contrasted with the white fat in which they lie embedded makes them very conspicuous. They vary in size from a pinpoint to that of a large cherry or almond. In many the blood sinuses occupy so large a part of the gland that they resemble blood clots. Their gross appearance varies greatly owing to the different proportions between the amount of lymphoid tissue and the size of the blood sinuses in different glands. On microscopical examination they show a great variation of structure in regard to the amount and arrangement of the lymphoid tissues and the number, size, and course of the blood sinuses. The capsule of the gland is usually very thin and contains yellow elastic tissue and unstriped muscle. The lymphoid tissue is often very scanty, consisting of small islands lying in the large blood sinuses, or, on the other hand, the greater part of the gland may be composed of lymphoid cells while the sinuses are small. In the large glands trabeculæ of connective tissue pass from the capsule toward the centre of the gland. The sinuses are usually large and prominent, and in the majority of cases make up the greater part of the organ. They are both peripheral and central, with communicating branches, and are traversed by a coarse reticulum, which may be very scanty or so close and mesh-like as to give an appearance resembling spleen pulp. The reticulum is lined throughout with flattened endothelium. The lymphoid portion shows usually a division into cortical and medullary zones. Germinal centres may be present in the cortical portion, and in these numerous mitotic figures may be found. In the medullary portion the lymphoid tissue is usually arranged in columns between the blood sinuses. The cells of the lymphoid areas are chiefly lymphocytes, but large mononuclear cells, mononuclear eosinophiles, transitional and polynuclear forms are numerous. Many of the cells of the reticulum and also of the endothelial cells lining the blood sinuses show a mast-cell granulation. In the central sinuses large mononuclear phagocytes are found in great numbers in the meshes of the reticulum, and these usually contain disintegrating red cells and blood pigment. The glands are supplied by numerous large arteries which on entering the organ quickly break up into small vessels feeding the sinuses.

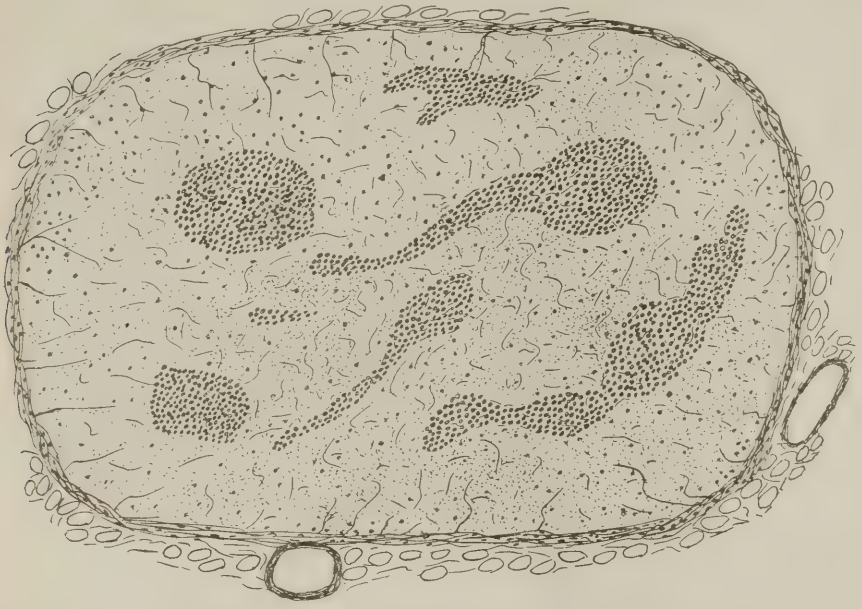

FIG. 2436.—One of the varieties of Hæmolymph Gland from Sheep. The blood-sinuses form the greater part of the gland; the small, irreguar islands of lymphadenoid tissue are surrounded on all sides by blood-sinus. Camera lucida drawing. Leitz objective 3; eye-piece No. II. Reduced one-third.

Sheep.—The hæmolymph glands are as large and prominent in this animal as in the steer, and in structure closely resemble those found in that animal. As a rule, they contain more lymphoid tissue, and the sinuses are relatively smaller. Their capsule is also more delicate.

The type with central lymphoid tissue and peripheral sinus is more common than in the ox. Phagocytes containing red cells and pigment are also less common, and the degree of hæmolysis is evidently less. Giant cells resembling those of the bone marrow are not infrequently found in the reticulum. A very remarkable feature is the large number of mast cells present; in many glands nearly all of the cells in the central lymphoid area may show this granulation. Germinal centres are not so numerous as in the glands of the steer. Red blood cells are found throughout the reticulum of the lymphoid areas.

Horse.—The hæmolymph glands of the horse have received but slight attention. They have been found chiefly in the neighborhood of the kidneys, no thorough study of the prevertebral region having been made. They appear as dark-red bodies of varying size and shape, the largest about 2.5 cm. in diameter, the average diameter being about 1.5 cm. On section they resemble very closely the glands of the sheep; but usually contain a larger amount of lymphoid tissue which is grouped in regular nodes, each of which is surrounded by a well-defined blood sinus, usually of uniform width. Cells containing disintegrating red cells and blood pigment are numerous, more so than in the case of the steer and sheep.

Goat.—Hæmolymph glands similar to those in the steer and sheep are stated to have been found in this animal, but no detailed description has been given of them.

Pig.—The first observations of hæmolymph glands were those made by Leydig in 1857, on the gross appearances of glands lying along the thoracic aorta in the pig, which bore a close resemblance to splenic tissue, and were regarded by him as intermediate structures between lymphatic glands and the spleen. Hæmolymph glands are also mentioned by Clarkson as occurring in this animal, but no description of their microscopical appearance has ever been published.

Dog.—Hæmolymph glands occur constantly in the prevertebral peritoneal fat, along the brim of the pelvis, and near the renal vessels. They may be of large size. In puppies they resemble closely those of the sheep; but in older dogs they are not very easily distinguished by the naked eye from ordinary lymphatic glands, in this respect being similar to those of the human body. They may often be recognized by a reddish peripheral zone or by red streaks corresponding to the blood sinuses. Phagocytes are numerous, and hæmolysis may occur to a great degree as shown by the large amounts of blood pigment present.

Rat.—Small oval or lenticular hæmolymph glands can almost always be found at the lower border of the pancreas, near the kidneys, and in the gastrosplenic omentum. The sinuses are both peripheral and central; and are of large size. They are usually filled with red cells; but may be partly or wholly empty. Phagocytes are numerous, and the evidences of hæmolysis are usually marked. The lymphoid tissue consists of both cortical and medullary zones, the former very dense but showing no germinal centres.

Guinea-Pig.—Hæmolymph glands have been observed in this animal by workers in the writer's laboratory. They occur in the prevertebral tissues as minute points usually too small to be recognized by the naked eye. Their microscopical appearance is very similar to that of many of the hæmolymph glands in man. The sinuses are small and are usually partly collapsed, the lymphoid areas are dense and only rarely show germinal centres.

Chicken.—Dark red glands resembling hæmolymph glands to the naked eye have been found in the abdominal fat, near the stomach, and below the rectum. On microscopical examination the greater part of the gland is found to be composed of blood sinus filled with nucleated red cells. There are numerous communicating branches between the central and peripheral sinuses. Pigment and phagocytes containing red cells are abundant. Red cells are numerous throughout the reticulum of the lymphoid areas.

Turkey.—Glands similar to those in the chicken are found also in the turkey.

Fishes.—The head kidney of certain Teleostean fishes is analogous in structure to the hæmolymph glands of the higher vertebrates, being composed of irregular masses of lymphoid tissue separated from each other by blood sinuses. The peripheral sinus is of large size.

Hæmolymph glands have also been sought in the *monkey, rabbit, cat, squirrel, mouse, hedgehog, mole, pigeon, parrot, duck, frog, toad,* and many fishes without success. As these investigations were based almost wholly upon naked-eye appearances, it is highly probable that careful microscopical investigation of the tissues of these animals will show them to be present.

Man.—Lymphoid structures containing sinuses filled with red blood cells are constantly present in the human body. To the naked eye they are not nearly so prominent as the glands of the sheep and steer because of the fact that their blood sinuses under ordinary conditions are more or less collapsed after death. Those possessing large sinuses are dark red in color; those with small or collapsed sinuses are recognized by their dark peripheral zone and red streaks corresponding to the blood sinuses. The search for these glands may be greatly facilitated by fixing the prevertebral tissues in four-per-cent. formalin, which bleaches other tissues, but darkens the blood-containing areas. In this way the blood sinuses are brought out very much more distinctly.

The human hæmolymph glands vary greatly in location, number, and size, seldom occurring in exactly similar manner. They are larger and consequently more easily found in early adult life than in old age, becoming atrophic in late years. They are present in the newborn. No difference has been observed in their occurrence in the sexes. They lie for the greater part deeply embedded in fat tissue, and possess a very rich vascular supply. The average size is that of a small pea; their relative proportion to ordinary lymphatic glands is 1 to 20–1 to 50, but in some cases they are found in such large numbers as to suggest the possibility of new formation or of resting glands taking on an active state.

On microscopical examination the human hæmolymph glands show an exceedingly great variation in structure. It would seem inadvisable to attempt to classify these variations, inasmuch as confusion would result from the numerous transition forms found. Broadly, two distinct types may, however, be distinguished, and to these I have applied the terms *splenolymph glands* and *marrow-lymph glands* as indicating their structure and probable function. It must be understood that there are no hard-and-fast lines between these types, all possible transition forms existing between them, as also between them and ordinary lymphatic glands.

The splenolymph gland is the more common form and is found chiefly in the neighborhood of the solar plexus, adrenal and renal vessels, and in the deep tissues of the cervical region, and occasionally in the mediastinal region, omentum, and mesentery. These glands are usually round, possessing a distinct hilum into which a large plexus of vessels passes. The capsule of connective tissue contains unstriped muscle and yellow elastic tissue. It may be very thick in proportion to the size of the gland, but not infrequently is very thin and delicate. From the capsule trabeculæ of varying size run into the organ cutting it up into irregular lobules; in small glands no distinct trabeculæ may be present. Immediately beneath the capsule there is a blood sinus of varying width which usually runs entirely around the periphery of the gland, but very often only for a portion of the way, being frequently interrupted by masses of lymphoid tissue reaching to the external capsule. Branches of the peripheral sinus run toward the centre of the gland accompanying the trabeculæ. In the central portion they often become very large and prominent. The lumen of the sinuses is traversed by a coarse reticulum through the meshes of which the blood circulates. In

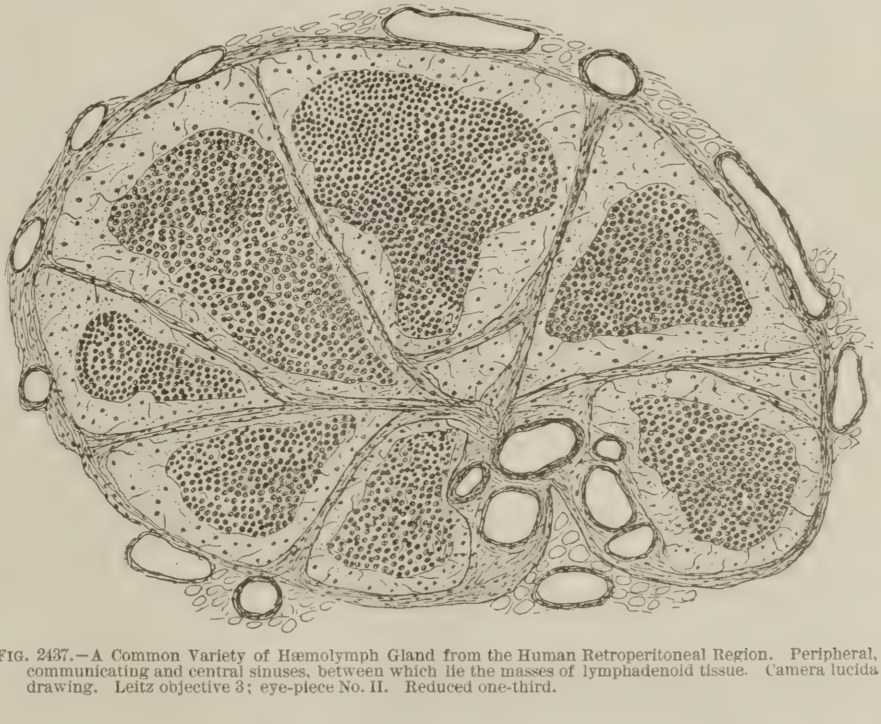

FIG. 2437.—A Common Variety of Hæmolymph Gland from the Human Retroperitoneal Region. Peripheral, communicating and central sinuses, between which lie the masses of lymphadenoid tissue. Camera lucida drawing. Leitz objective 3; eye-piece No. II. Reduced one-third.

the large central sinuses the reticular meshwork may at times be very scanty.

The reticulum of the sinus appears, in part at least, to be lined with endothelial cells, but these are with great difficulty made out, and in many places the blood seems to be in direct contact with the reticular surfaces. The circulation is therefore of the type described as sinusoidal. The nuclei of the cells of the reticulum stain much more lightly than those of the neighboring lymphoid tissue. There is apparently a direct continuation of the sinus reticulum with the reticulum of the lymphoid areas; and the latter may be regarded as the same structure enclosing in its meshes masses of lymphocytes. The number and size, as well as the general arrangement of the blood sinuses, vary greatly, so that scarcely any two glands resemble each other in these respects.

The lymphoid tissue lying between the blood sinuses resembles that of the spleen or ordinary lymphatic gland. It varies very much in amount, sometimes forming a mere network between the sinuses, while in other cases it may form the chief part of the gland. Usually the greater mass of lymphoid tissue is toward the periphery, forming the inner border of the peripheral sinus; but frequently extending to the capsule, breaking up the peripheral sinus into small sections that run for a short distance only. Small round collections of lymphoid cells resembling splenic follicles are often seen. These occur more frequently at or near the periphery, but they may occasionally be found near the central portion of the gland. They may be partly or wholly surrounded by the blood sinus. The cells in the central portion of the follicle stain more lightly than those at its periphery. Serial sections show that these nodes are almost perfectly round in the majority of cases. Usually they possess no arterial relations, but occasionally a small capillary is found in them which under certain pathological conditions may become gradually converted into a small arteriole with thickened walls. The resemblance in this case to the splenic follicle is very complete.

The cells of the lymphoid area are for the greater part small lymphocytes. These vary greatly with respect to the relative size and staining power of the nucleus and the relative amount of protoplasm. Next to the small lymphocytes the large mononuclear leucocytes are the most common form present. These also vary much in size, form, and staining power. Transitional and polynuclear leucocytes are also present in varying numbers. A small number of basophile and mononuclear eosinophiles is also usually present; mast cells are rare in the majority of cases, but occasionally a gland may be found in which the majority of the cells of the central portion are mast cells, as is so frequently the case in the hæmolymph glands of the steer and sheep.

The reticulum of the lymphoid areas resembles that of the blood sinuses, and is directly continuous with it. In its meshes lie the cells of the lymphoid tissue and also numerous red blood cells. The latter fact suggests the presence in the lymphoid tissue of very fine blood spaces similar to those in the spleen pulp, but differing from the latter in that the blood spaces are smaller and the reticulum is more dense. The reticulum of the large sinuses is much more abundant and of a coarser mesh than that of the lymph sinuses of the lymphatic glands. Small fibrillæ of elastic tissue and unstriped muscle may be scattered through it. In its meshes there are constantly present large mononuclear phagocytes containing disintegrating red cells and blood pigment. These cells are also found in the reticulum of the lymphoid tissue in connection with free pigment; but they are always more numerous in the reticulum of the medullary sinuses than elsewhere. Under normal conditions their number in individual glands varies greatly, the appearances suggesting a possible cyclical function of hæmolysis. Glands containing many of these cells may be found side by side with others whose reticular spaces contain but few. The same appearances are found in the hæmolymph glands of the lower animals, particularly in those of the dog and rat. Multinuclear giant cells, eosinophile, basophile, and mast cells may at times be found in the reticular meshes. The origin of the phagocytes has not yet been definitely determined; they may arise either from leucocytes or from the endothelial cells lining the reticulum.

Scattered masses and droplets of a fuchsinophile hyaline substance are often found throughout the lymphoid tissue; they are usually most numerous toward the periphery of the gland. They are frequently seen as highly refractile spherules lying in the meshes of the reticulum or enclosed in phagocytes. They are evidently the product of the destruction of red cells, as all stages of their formation can be found. In some cases the spherules are seen partly extruded from the phagocyte. They frequently give an iron reaction, especially those found in phagocytic cells.

MARROW-LYMPH GLANDS.—This type of hæmolymph gland is of very much less frequent occurrence in the normal body; but is much more prominent in certain pathological conditions, suggesting the possibility of resting glands or new formations. In some cases they appear to arise directly out of adipose tissue. They have been found only in the retroperitoneal region, along the vertebræ and brim of pelvis, and always in close proximity to the large vessels, abdominal aorta, vena cava, common iliacs, adrenal and renal vessels. They are present most frequently behind the aorta or between it and the vena cava. These glands are usually flattened and elongated, their greatest dimension lying parallel to the axis of the neighboring vessel. They may possess a distinct hilum, but the number of vessels entering is not so great as in the case of the splenolymph gland. Lymph vessels are also found in connection with these glands. Not rarely the marrow-lymph gland is found as a slender cylinder several centimetres in length embedded in fat. On section these glands are white or pinkish in color with fine red streaks corresponding to the course of the blood sinuses. Their consistence is very soft, and on section they present an almost homogeneous surface.

The capsule is thin and contains but little unstriped muscle and yellow elastic tissue. Delicate trabeculæ run from it toward the centre of the gland. Beneath the capsule there is a peripheral blood sinus of small size which usually runs entirely around the gland, and from this there are narrow branching sinuses accompanying the trabeculæ toward the centre of the gland. All of the sinuses are filled with a coarse reticulum through the meshes of which the blood circulates. Dilated sinuses as in the splenolymph glands are not present. The course of the sinuses is distinctly shown by the lighter staining nuclei of the reticulum and the presence of red cells. Lymph sinuses may also be present. Between the sinuses lies the lymphoid tissue arranged in irregular lobules. It is in much greater amount than in the case of the splenolymph glands. Throughout the lymphoid tissue, near the central portion of the gland, fat cells are present, either singly or in small groups. This may be regarded as one of the most striking characteristics of this type. Collections of cells resembling follicles are not present. The reticulum of the lymphoid areas is more delicate and scanty, and contains but little elastic tissue. The cells of the lymphoid areas present a much more striking variety of form and staining properties than in the splenolymph glands. Mononuclear eosinophiles and mast cells are more numerous; and multinuclear as well as large mononuclear forms with deeply staining knobbed nuclei may be present. Giant cells resembling those of the bone marrow are occasionally found, and in certain pathological states of the blood may be very numerous. No nucleated red cells have been found under normal conditions. Phagocytes containing red cells, pigment, fuchsinophile, hyaline bodies, and leucocytes occur to a less extent than in the splenolymph glands. Numerous red cells are found scattered throughout the reticulum of the lymphoid tissue suggesting the presence of smaller blood spaces.

Transition forms between spleno- and marrow-lymph glands are found, and also between the latter and ordinary lymphatic glands. The various forms found are such as to suggest the idea that hæmolymph glands are not permanent structures in any one form, but possibly show a certain amount of fluctuation. Thus the blood sinuses may become increased in size by a decrease of the lymphoid portion, while, on the other hand, an increase of lymphocytes may occur at the expense of the blood sinuses.

Circulation. — The exact mode of circulation in the hæmolymph glands has not yet been worked out. It is probable that the arteries entering the hilum quickly divide into smaller branches which, passing toward the periphery, empty into the blood sinuses from which the blood is again gathered into veins which pass out at the hilum or obliquely through the capsule. The circulation in the sinuses is of the type known as sinusoidal, only the endothelium separating the blood from the cells in the reticular meshes. The current in these spaces must be very slow, and a long period of time must be required for the complete circulation through the intricate meshes of the reticulum crossing the sinuses. The relations of the lymphatic and blood systems in these glands are also unknown. It is possible that, in the human body at least, a mixture of blood and lymph, the so-called hæmolymph, may be present in the sinuses, and that direct communication between the two systems occurs in these glands.

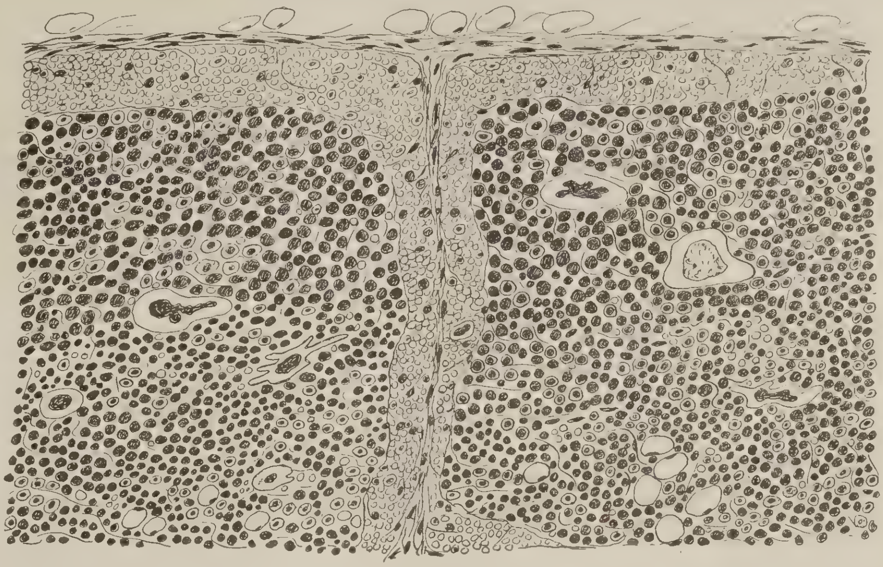

Fig. 2438.—Portion of Human Hæmolymph Gland (Marrow-lymph Gland) from Retroperitoneal Region of an Individual who had Died of Hemorrhage from the Nose. In the lymphadenoid tissue are giant cells resembling those of the marrow, nucleated red cells, mononuclear eosinophiles, etc. A number of fat cells are also seen scattered through the lymphadenoid tissue. Leitz objective No. 7; eye-piece No. IV. Reduced one-third.

Development.—No work has yet been done upon the development of these structures. They are found as fully developed organs in the new-born child, and have been found at an early period in the fœtal calf. They are without doubt to be regarded as individual organs whose early stage of development runs parallel with those of the lymphatic glands. Under certain pathological conditions it is possible that they may be developed from ordinary lymphatic glands or from adipose tissue in compensation for the spleen or bone marrow.

Function.—The hæmolymph glands are so numerous in the steer and sheep that their function is obviously of importance. In other animals and in man, while constantly present, they do not under ordinary circumstances attract attention through either their numbers or their size. The constant presence of phagocytes containing disintegrating red cells and pigment would indicate that extensive hæmolysis is one function carried on in these structures. As before mentioned, the presence of glands containing many phagocytes in their sinuses side by side with those whose sinuses contain only red cells would indicate a cyclical function; and there are many other appearances to suggest this. Under normal conditions no evidence of the formation of red cells has been observed, unless the occasional presence of bone-marrow giant cells may be taken as an indication of this process. The presence of these in the sinuses may, however, be explained on the assumption of giant-cell embolism. Under pathological conditions, such as anæmia and leukæmia, the hæmolymph glands, particularly those described as marrow glands, show evidences of increased functional activity in the hyperplasia of all the glandular elements and the increased number of mitoses in the lymphoid cells. In addition large numbers of giant cells may be found in the reticulum of the sinuses and in the lymphoid areas, evidently formed in the gland; also nucleated red cells, myelocytes, etc., may be present, so that the gland may come to resemble lymphoid marrow. These changes are not shared by the other lymph glands of the body. The hæmolymph glands are also to be regarded as important centres of leucocyte formation. After splenectomy or in certain pathological conditions of the spleen the splenolymph glands may compensate for this organ through hyperplasia and increased hæmolytic activity. In short, the hæmolymph glands normally possess a hæmolytic function and give rise to leucocytes; under pathological conditions they may also become centres of red-cell formation.

Pathology.—The more common pathological processes, such as congestion, inflammation, tuberculosis, metastases of malignant tumors, etc., have been found affecting these glands in common with the ordinary lymphatic glands. In a limited group of conditions such striking changes occur that they must be regarded as specific in character. These changes are confined entirely to cases showing more or less marked pathological alterations of the blood.

Anæmia.—In all of the cases of anæmia examined either the splenolymph or the marrow-lymph glands showed changes of greater or less extent. These changes varied with the nature and degree of the anæmia.

Post-hemorrhagic Anæmia.—In a case of fatal anæmia following repeated and prolonged attacks of epistaxis the only lymph glands showing change were those of the retroperitoneal region, particularly those in the neighborhood of the solar plexus. These were moderately enlarged, of a pink color and soft consistence. On microscopical examination they presented a structure resembling in the most striking way the lymphoid marrow. Throughout the reticulum of the sinuses and lymphoid areas were numerous giant cells in all respects resembling those of the marrow. The findings admitted of but one interpretation: these giant cells must have been formed within the gland, most probably from the reticulum or the endothelium lining it. Large numbers of mononuclear eosinophiles, nucleated red cells of large and small size, large mononuclear leucocytes corresponding to myelocytes, and all possible varieties of transitional forms were also present. The bone marrow of this case showed scattered areas of lymphoid marrow, and in both the liver and spleen changes were found suggesting a return to a fœtal mode of blood formation. Numerous nucleated red cells were present in the blood. The remaining lymph glands showed only a fibroid hyperplasia.

Secondary Cachectic Anæmia.—In a large number of cases examined showing a more or less severe cachectic anæmia both marrow- and splenolymph glands showed increased hæmolysis, but no evidences of the formation of red blood cells were present.

Splenic Anæmia.—In a case of splenomegaly with severe anæmia, the patient dying after splenectomy, numerous minute nodes of lymphoid tissue were found scattered throughout the adipose tissue of the mesentery and retroperitoneal region. The majority of these possessed a small arteriole showing a much thickened wall; in some cases the lumen was completely obliterated by the proliferation of the intima. The new tissue blocking the vessel in many cases showed a hyaline change, and the concentric arrangement in some instances bore a strong resemblance to the thymus corpuscles. In some cases the hyaline tissue had undergone calcification. This new formation of lymphoid tissue resembles very much the changes found in the omentum of animals whose spleens had been experimentally removed, and is probably to be interpreted as compensation for the diseased spleen. The splenolymph glands in this case showed also such changes that they resembled splenic tissue, both to the naked eye and on microscopical examination, being regarded at the autopsy as accessory spleens.

Pernicious Anæmia.—In five cases of pernicious anæmia examined the changes in the hæmolymph glands were so constant and so marked that the writer regards them as specific in nature. In the more rapidly progressing forms the number of splenolymph glands is so great that they must be regarded either as new formations or as resting glands become active. In one case over sixty of these glands were removed from the cervical, thoracic, and retroperitoneal regions; and in another over thirty from the retroperitoneal region alone. The glands are enlarged and darker in color, often a chocolate brown. On microscopical examination the central and communicating sinuses are found almost filled with large phagocytes containing red cells and pigment. The processes of hæmolysis are increased to an extraordinary degree, particularly in the rapidly progressing forms. The spleens in these cases showed but little evidences of hæmolysis, while liver and kidneys showed marked hæmosiderosis. No evidences of increased activity on the part of the bone marrow were found; on the contrary, in all of the cases there was marked atrophy of the red marrow associated with osteoporosis and the formation of cystoid cavities filled with liquid fat.

In one case of progressive anæmia extending over three years, characterized by repeated severe attacks of epistaxis, hæmatemesis, and bloody stools, the only pathological changes of importance found on autopsy were in the retroperitoneal lymph glands. These were enormously enlarged, forming an almost continuous double row on each side of the abdominal aorta and diverging below along the brim of the pelvis. Each gland was 3 to 4 cm. in length and 1 to 2 cm. in thickness. They were almost cylindrical, somewhat flattened, and were dark red in color, almost black. On section the blood flowed freely from the greatly dilated veins. On microscopical examination a great hyperplasia of the lymphoid tissue was found, extending beyond the original capsule of the gland into the surrounding fat tissue. The appearances suggested strongly the possibility of a direct conversion of fat into lymphoid tissue. Numerous mononuclear eosinophiles, nucleated red cells, and occasional giant cells were present throughout the reticulum of the lymphoid areas. Mitotic figures were numerous. The presence of blood sinuses proved these glands to be hæmolymph glands of the marrow-lymph type, and the process was interpreted as a compensatory hyperplasia for the bone marrow which was atrophic and cystoid.

Leukæmia.—In a case of mixed leukæmia an enormous hyperplasia of the marrow-lymph glands similar to the above was found. On microscopical examination the blood sinuses were found filled with giant cells which were also scattered throughout the lymphoid areas. Mononuclear eosinophile cells, nucleated red cells, myelocytes, and an almost infinite variety of leucocytes, especially well shown in specimens stained with the tri-acid stain, made up the lymphoid portions. The resemblance to lymphoid marrow was very close, as in the case of fatal anæmia following epistaxis. The other lymph glands showed but slight enlargement due to the increased number of leucocytes present. The bone marrow showed but little lymphoid increase; the spleen was greatly enlarged. The changes in the marrow-lymph glands are to be interpreted in this case also as being evidence of the ability on the part of these glands to take up the blood-forming function of the bone marrow.

Leucocytosis.—In cases of pyæmia showing marked leucocyte increase the hæmolymph glands exhibit evidences of increased activity in the cells of the lymphoid areas, as shown by numerous mitoses. The mononuclear eosinophiles are also increased in number, and nucleated red cells and giant cells may also be found.

Experimental Pathology. — In animals whose spleens have been removed the hæmolymph glands show hyperplasia and evidences of increased hæmolysis. In poisoning with hæmolytic agents such as pyrogallic acid, muscarin, toluylendiamin, etc., these glands show greatly increased hæmolysis, the sinuses being packed with phagocytes containing red cells and pigment.

Summary.—By the above cases it is shown that under pathological conditions of either the spleen or bone marrow, the hæmolymph glands may assume either a hæmolytic or a hæmatopoietic function; and that in all conditions characterized by increased hæmolysis the chief seat of the blood destruction appears to be located in the sinuses of these organs. *Aldred Scott Warthin.*

HÆMOPERICARDIUM.—Blood in the pericardium is a rare condition and of small clinical interest.

Etiology.—In tuberculous and malignant diseases of the pericardium, just as in similar diseases of the peritoneum, the exudate is usually bloody. By hæmopericardium is meant a hemorrhage into the pericardium. This accident occurs under the following conditions:

(1) As a result of traumatic injury from without, or by foreign bodies penetrating the œsophagus from within.

(2) Such hemorrhages have been found associated with scurvy, purpura, leukæmia, and allied conditions.

(3) From rupture of the heart or a cardiac aneurism.

(4) From rupture of an aneurism of the aorta or pulmonary artery. The first part of the aorta is usually involved and it may be by only a pinhole rupture.

(5) From rupture of smaller vessels, namely, one of the coronary arteries, or of vessels in a new growth.

Anatomical Characters.—The quantity of blood varies much. It is greater when the opening in the aorta is small. When an aneurism bursts into the pericardium the average amount of blood usually found is said to be about seven ounces. When the hemorrhage takes place through a small hole, it may reach twenty-four ounces. A traumatic case has been reported in which over six pints of thin, dark, fluid blood were removed from the pericardium in the course of three hours. The patient recovered. The blood may appear as a soft, red, jelly-like clot. A variable amount of serum may have separated from it.

Clinical History.—The condition may occur suddenly. The associated disease, such as aneurism, may have been previously demonstrated. When the hemorrhage takes place through a large rent, immediate or very rapid death usually occurs, either from the effects of the hemorrhage, or from paralysis of the heart. The fatal event may be preceded by grave cardiac symptoms. When the accumulation takes place gradually the patient may live for some time, complaining of cardiac oppression or pain, dyspnœa, and faintness.

Physical Signs.—These are not likely to be noted in the sudden cases. When the progress is slower there is a more or less rapid increase in the area of cardiac dulness; the apex beat disappears and the heart sounds become weak.

Treatment.—In the majority of cases treatment is limited to the relief of symptoms. Hæmostatics are useless. In the protracted cases cardiac stimulants may prolong life. A few patients recover as a result of aspiration of the pericardial sac. *James Rae Arneill.*

HÆMOPHILIA.—(Synonyms: Hemorrhagic Diathesis or Idiosyncrasy, Hæmorrhaphilia, Hæmatophilia, Heredity Hemorrhage; Ger., *Hämophilie, Bluterkrankheit, Blutsucht, Blutungssucht;* Fr., *Hémophilie.* Otto, an American physician, gave the name Bleeder [Ger., *Bluter;* Fr., *Homme saignant*] to an individual patient.)

Definition.—An hereditary and congenital disease, characterized by a tendency to frequent, obstinate, and prolonged hemorrhages, external or interstitial, spontaneous or traumatic, associated with swelling of the joints.

History.—Our knowledge of this disease is modern. Its historians have been able to find the records of but few probable cases or families prior to the present century, and even these, with the exception of the cases reported by Hochstetter and Sir W. Fordyce, may all be considered doubtful examples, and Legg cannot admit Banyer's case to be beyond doubt. It was left for American physicians accurately to fix the characteristics of the disease. Otto, E.H. Smith, Hay, the Buel brothers, and Coates, in the early part of the last century, and Hughes, Gould, Harris, Hutchinson, Holton, and Dunn, in the past thirty years, have been the chief contributors to its literature. The early writers first demonstrated its hereditary nature. In the second and third quarters of the last century the Germans were prolific workers. Nasse, Rieken, Schönlein, and others, were of the earlier writers. Wachsmuth's monograph, Lange's statistics, Virchow's complete description in his "Handbuch," the monograph of Grandidier, the most complete published, and the article in "Ziemssen's Handbuch," by Immermann, familiarized modern German physicians with the affection. The exhaustive monograph of Legg is the principal contribution made by any English physician.

Etiology.—Sex and heredity are the most important factors in the etiology of hæmophilia. It occurs with greatest frequency in the male, the ratio having been put as high as eleven males to one female. Females do not usually present typical cases, and danger to life is less in the latter sex.

Hereditary disposition is so essential that its absence in a supposed case is sufficient to negative the diagnosis, although, it is true, it is difficult, often impossible, to trace genealogy among the lower classes. Legg believes all or nearly all cases may be traced to an hereditary origin. It has been suggested that this hereditary tendency is the result of the intermarriage of near relations. The fact that it occurs largely among Germans and Jews favors this argument, for in both classes such marriages are common. A common ancestry for all bleeders has been assumed by some authors.

While the females are not the bleeders of a hæmophilic family, the disposition is transmitted through them. The mother, not a bleeder, will transmit the tendency to her sons. They in turn are not likely to conduct the disease to their children, but the tendency passes through the daughters to the grandson. The females that transmit the tendency are usually in perfect health, although cases have been reported, in rare instances, in which the mother, a bleeder, transmitted it to the children of both sexes. The cases are still more rare in which the father, a bleeder, will pass down the tendency to either the sons or the daughters, respectively. A male non-bleeder, in a hæmophilic family, seldom transmits the disease to his descendants. Transmission through the female line is the rule. It is said that the first-born of a family are less liable to become bleeders. This tendency to bleeding may continue for many generations. The Clitherow family, reported by Legg, have exhibited the tendency for two hundred years. The families of Tenna, Switzerland, trace the disposition through five generations.

One peculiarity of bleeder families that has been noted is the marked intellectual power of the individuals; another, the great fertility of the families. Although they have many children, few reach adult age, as the number is much lessened by death from hemorrhages in early life, the mortality at that period being very great.

The disposition to bleed, Grandidier believes, may gradually be lost in a family. He has himself seen one such example, and another has been reported by Legg.

It was noted above that among Germans hæmophilia is common. In fact, some think it a disease peculiar to the Anglo-Germanic races. Dunn's analysis of 219 families shows its distribution about as follows: Germany, 94; Great Britain, 52; North America, 23; France, 22; Prussia and Poland, 10; Switzerland, 9; and the remainder in other European countries. The condition is rarely found in the negro, as has been pointed out recently by Steiner (Johns Hopkins Hosp. Reports, 1900) who reports one case and refers to one other decribed by Hadlock.

Hæmophilia spares no social class, though cases are reported more frequently from the middle and lower classes. Its presence or absence is not influenced by geographical position, and the nature of the food is also without effect on it.

While it has been asserted of many cases of hæmophilia that they arose spontaneously, yet nothing is known of the circumstances contributing to their origin. Legg rightly criticises the case of Mutzenbecher, in which the disease was reported to have arisen *de novo.* A mother, suckling her child, received a great fright, after which the child nursed. Shortly afterward symptoms of hæmophilia developed. Two other sons, also bleeders, were subsequently born, a fact which renders very probable the hereditary transmission in this case.

The circumstances, aside from traumatism, influencing the occurrence of hemorrhage, or which may be the predisposing or exciting causes of the accident, in a person belonging to a hæmophilic family, are the age, the constitution, and the temperament of the individual; the time of day, the season of the year, and the climate. Hemorrhages have not appeared for the first time after the twenty-second year; it is rare for them to appear after the twelfth year, and in the larger number of instances the first attack occurred before the fifth year. Its most usual appearance is about the end of the first year. Hemorrhage from the umbilicus, after sloughing of the cord, is very rare.

Bleeders are always in good health except that they suffer from anæmia. They often have blue eyes, light hair, a thin skin, and prominent veins.

Instances are recorded in which the hemorrhages occurred most frequently at night. The winter season and a cold, damp climate favor attacks of hemorrhage.

Those who consider the disease to be an infectious condition have scanty evidence to support their view. Bacteriological examinations have been entirely negative, and the manifestations of the disease cannot be explained by the theory of infection.

SYMPTOMS.—The occurrence of frequent, obstinate, and prolonged hemorrhages, spontaneous or traumatic, with their sequelæ, and the joint manifestations, are the essential symptoms.

Legg makes three degrees of hæmophilia: in the first form, the most typical and severe, there is a tendency to every kind of hemorrhage, spontaneous or traumatic, interstitial or superficial. The joint swellings are also marked. In the second form, spontaneous hemorrhages only are present, with rheumatic pains. In the third degree spontaneous ecchymoses alone are observed. The first degree is most often seen in men, the second in women, and the third in members of bleeders' families.

External Hemorrhages.—These are usually capillary. Even a traumatic hemorrhage is of that nature. In one case (Blagden's) a vessel which had been ligated soon gave way on account of the thinness of its coats. One of the cases reported by Dunn had an ulcer in the nostril, from which the spontaneous hemorrhages would spring.

Spontaneous hemorrhages are often preceded by prodromal manifestations. These are usually the symptoms of plethora or nervous symptoms. In children great cheerfulness and liveliness, attacks of crying, morbid fears, and even convulsions, have been noticed. In adults, a good temper, with great restlessness and sensitive emotions, are seen. Pain is often complained of in the locality in which the hemorrhage is about to occur. These prodromal symptoms disappear after the hemorrhage sets in.

The seat of the hemorrhage in the spontaneous form varies with the age—in childhood, the nose and mouth are the most frequent localities; in adult life, in addition to these situations, the stomach, the bowels, the urethra, the lungs, the female generative organs, etc.*

Of interest, in regard to local origin, is the case observed by D. Hayes Agnew (quoted by Osler), in which hemorrhage occurred from cuts and bruises above the neck, but never from those below.

The frequency of occurrence of spontaneous hemorrhages varies. They may occur daily, or at intervals of days or weeks. Resal (Legg) points out two forms of spontaneous hemorrhages. In one they are small in quantity, but frequently repeated, occur without prodromal signs, and always from the same mucous surface. In the other form there are prodromes, the hemorrhage is excessive, and does not usually cease spontaneously. Just as it is impossible to estimate the usual frequency of occurrence, so it is difficult to calculate the length of time the hemorrhages may continue. It is variable, from a moment to weeks, the latter with varying intermissions. Epistaxis is the most fatal of all forms of spontaneous hemorrhages; it has proved fatal in twenty-four hours.

Traumatic hemorrhages are due to blows, cuts, scratches, etc. Even after the most trivial operation the hemorrhage may be fatal. The amount of bleeding from a wound varies in bleeders from time to time—at one time scarcely any hemorrhage will be observed; at another, with the same wound, the bleeding can scarcely be checked. So, too, families appear to differ as to the extent of injury they can suffer with impunity. In one family venesection can be performed; in another the application of blisters would be dangerous (Legg). A superficial lacerated wound is thought to be more serious than a deep, clean-cut one. The healing of a wound may occur with or without suppuration; a profuse bleeding, when it occurs, will prevent healing by first intention.

The amount of blood lost by either form of hemorrhage is sometimes enormous. The famous case of Coates lost half a gallon in twenty-four hours, and three gallons in ten days. Thore's case (Legg), that of a boy aged five, lost nearly a pound from a small wound.

The result of these repeated hemorrhages is a profound, and often fatal, anæmia. Digestive troubles also often develop afterward, and in some cases a depraved appetite has been observed (Buel's).

Severe palpitations, dyspnœa, vertigo, syncope, and other evidences of anæmia may be observed. Enlargement of the heart and systolic murmurs at the base and in the vessels of the neck may be detected. The urine after a hemorrhage frequently contains albumin. Fever has been observed, but is not constant.

Ecchymoses and Petechiæ, Interstitial Hemorrhages.—They may be spontaneous or traumatic. The spontaneous varieties may occur without external bleedings, or may precede a hemorrhage. They are seen in early childhood. They are similar in appearance to purpura, and are seated chiefly on the trunk and limbs. They vary from a pin's head to a quarter of a dollar in size, are tender on pressure, and on disappearing pass through the same changes that an ordinary traumatic ecchymosis does, and exhibit the same play of colors. The traumatic ecchymoses are larger than the spontaneous; they may cause death by hemorrhage into the connective tissue. Blood tumors—hæmatomas—may follow the slightest blow. They may become as large as a child's head and are of a bluish-black color. By some authors it is thought they may arise spontaneously.

Joint Affections.—Legg believes that the joint affections are sometimes due to traumatism. In other instances the origin is not understood, the exciting causes being exposure to cold or dampness, and variations in temperature, particularly in the spring and autumn. The larger joints, chiefly the knee-joint, are the ones affected. They become painful, hot, much swollen, soft, and boggy. Often the affection develops suddenly. Marked constitutional symptoms, as fever, anorexia, and general pains, attend the attack. The pain is increased by motion. The duration of the affection varies from a few days to many months. It may change from joint to joint, or the swelling may alternate with a hemorrhage. Once affected, the patient is liable on the slightest provocation to have a recurrence of the disease. Repeated attacks may lead to destructive lesions in the joints, with crippling and deformity.

Persons affected with hæmophilia often suffer from general rheumatic pains, which vary in degree with atmospheric changes.

It is said that some bleeder families are very sensitive to cold and dampness, and that bleeders are very susceptible to the action of mercury. They are not differently affected by various diseases than are non-bleeders. "They appear more liable to acute affections within the chest" (Legg). Rheumatism and scrofula are said to occur frequently; gout is very rare. Gangrene is especially liable to occur after traumatic hemorrhage.

MORBID ANATOMY.—The *blood* is usually normal. After a profuse hemorrhage or a series of small ones, it partakes of the nature of the blood of anæmia. Under these circumstances the white corpuscles have been found in excess, the red in smaller numbers, and the hæmoglobin reduced, *i.e.*, the natural result of hemorrhage. The fibrin is apparently not greatly diminished. The salts are said to be increased. Recent studies indicate an actually decreased coagulability of the blood.

There are no characteristic anatomical changes. Blagden called attention to the thinness and transparency of the vessels. One observer found the large vessels smaller than normal; another, an increase in the size of the superficial, in proportion to the central vessels (Immermann). Wilson thought that the arteries resembled the veins. Fatty degeneration of the heart has been found. Kidd observed proliferation of the endothelial cells in small arteries and veins, and "hydropic degeneration" of the muscular fibres. Klein, Ackland, and other observers fail to confirm these studies. The joints, when involved, are the seat of blood extravasation; not only the cavity but the tissues around are infiltrated. Bowlby has shown that the changes in the articular structures cannot be attributed to the mere effusion of blood. As in arthritis deformans, the cartilaginous covering of the articular ends becomes fibrillated, and in the parts most exposed to friction may be eroded and inflamed. There is also the same tendency to the formation of ecchondroses which in time may become osteophytes. Unlike arthritis deformans, fibrous adhesions may form, resulting in limitation of motion.

---

* The following statistics are interesting, mainly from Grandidier, also quoted by Legg, and by Osler. Spontaneous Hemorrhages—localities and frequency: From the nose, 169 times; the mouth, 43; stomach, 15; bowels, 36; urethra, 16; lungs, 17; cerebral hemorrhage, 2; swollen place on scalp, 4; tongue, 4; finger-tips, 4; ear, 5; eyelids, 2; tear papilla, 3; female generative organs, 10; ulcer of skin, 2; navel (long healed), 2. Fatal hemorrhages have occurred from the following wounds: Blow on head, 11 times; slight scratches on skin or abrasion of dermis; laceration of frænum of the lip; slight cut in a duel wound, bite of the tongue (7 cases); fall on the mouth; blow on the nose; blow of a stone on the finger; cut in paring the nails; fall on the head with meningeal hemorrhage (2 cases, brothers); and rupture of the hymen on the wedding night.

Deaths after operations: Cutting of frænum linguæ, 1; leeching, 5; venesection, 4; blister, 2; extraction of tooth, 12; circumcision, 8; cutting umbilical cord, 4; vaccination, 2; fistula, stone, ligature of carotid, of radial, of ulnar, of femoral arteries, amputation of arm and of thigh, 1 each; phimosis, 2.

PATHOLOGY.—This is obscure. While a congenital fragility of the vessels is said to exist, it has never been proven. It has been observed that bleeders always suffer from prodromic symptoms, which are due to an increase in the volume of the blood. Hence, variability in the volume has been invoked as causal. Disturbed innervation, diminishing from time to time vascular tone, is thought by many to be the pathological factor. It is merely an hypothesis, as have been all suggestions thus far put forward regarding the pathology of hæmophilia. As suggested by Eichhorst, it may be possible that the changes in the blood are of a chemical nature, not to be discovered by our present methods.

DIAGNOSIS.—Many cases of a hemorrhagic diathesis occur, the exact nature of which it is difficult to determine. Especially is it so with this diathesis in women. If, however, there is no history of heredity, if the hemorrhages did not occur in early life, prior to twelve years, and if she should not transmit it to her sons, it is not likely to be a case of hæmophilia. The hereditary predisposition, the spontaneous and traumatic hemorrhages setting in early in life, and the joint symptoms, are conclusive evidence of the nature of a case. Cases arise, no doubt, in which heredity cannot be determined, and which may yet be the founders of a stock of bleeders. One of the writer's cases is possibly of this class. Since the age of five months spontaneous bleedings, often to syncope, have occurred; since puberty (the patient is now twenty-two years of age) plethoric prodromes have preceded the attacks. The patient undertook to learn carpentering, but had to give it up on account of traumatic hemorrhages. Extractions of teeth have caused serious hemorrhages. Annually the patient is afflicted with severe joint symptoms, rheumatic in character.

Umbilical hemorrhage in the new-born is not due, or but rarely, to hæmophilia, but is usually the result of liver disease or syphilis. The hemorrhagic conditions of the new-born, probably infectious in character, referred to as *transitory hæmophilia, spontaneous hemorrhage, or infectious hæmophilia of the new-born*, can be distinguished from true hæmophilia by their transitory character, the occurrence of spontaneous hemorrhages in different parts of the body, their acute course, their self-limited character, the early appearance of symptoms, and the frequency of umbilical hemorrhage, jaundice, and high fever. Purpura, simplex and hæmorrhagica, scurvy, peliosis rheumatica, toxic and septic purpura, must be excluded.

PROGNOSIS.—The first bleeding is rarely fatal. The younger the patient, the more grave the prognosis. Hæmophilia is more serious in boys than in girls, and more so in the delicate than in the strong. With advancing years the prognosis improves. Often, especially if the patient suffer from joint complication, the tendency to hemorrhage may disappear for a number of years. Long-continued oozing is a serious form of hemorrhage. The bleeding after the extraction of a tooth is very serious, as is also the hemorrhage from lacerated and contused wounds. Face injuries are also serious.

TREATMENT.—If a person suffering from hæmophilia present the symptoms indicative of an attack of hemorrhage, an active purgative should be administered and the patient put on low diet without stimulants. Often an attack is averted thereby. Otto advised the sulphate of soda; Fordyce, the sulphate of magnesia. Venesection has been resorted to under similar circumstances. If a spontaneous hemorrhage occur, opinions differ, whether to check it or not is advisable. Wachsmuth, Legg, Frish, and others claim that apoplectic symptoms or grave dyspnœa may arise if it is checked. The latter author advocates venesection. It is certain, if the hemorrhage is not too profuse, a bleeder always feels better after it. When it is decided to check the hemorrhage the method of treatment depends largely on the seat of the bleeding, and is similar to the plan adopted in the traumatic varieties if it arise from external parts. Internal remedies are more frequently required in the spontaneous form, but are used in both. Ergot or ergotin, the latter by mouth or hypodermatically, hamamelis, gallic acid, opium, alum, turpentine, and preparations of iron, have been used with benefit. Legg recommends the tincture of the perchloride of iron, thirty to forty minim doses every two hours, together with a purge if there is no intestinal hemorrhage. Transfusion may be resorted to when external and internal remedies are used without avail.

The principles that govern the treatment of any traumatic hemorrhage apply in a case of hæmophilia. A few of the usual methods must be modified as follows: Ligation of the artery should never be performed; the actual cautery should be used as a last resort only; care in exercising pressure should be used on account of the possibility of ecchymoses and sloughing taking place; plugging of the nares should only follow failures to control bleeding by other means. The wound should be cleansed, rest secured, compression used, the artery pressed upon if possible, cold, and especially ice, or very hot water applied to the bleeding parts, and finally, styptics, as the astringent salts of iron, preferably Monsel's solution, the nitrate of silver, alum, and other well-known astringents should be tried. The famous styptic of Pancoast is a clean and most efficient application. Gelatin in five-per-cent. solution may be used. A hemorrhage from the extraction of teeth may be controlled by means indicated above, by replacing the tooth in its socket, by taking a plaster-of-Paris cast of the jaw, by retaining the jaw in position by a roller bandage, or finally by the cautery.

Recently the physiological principles of coagulation have been applied to the treatment of hemorrhage. A. E. Wright recommends the local use of a solution of fibrin ferment in an aqueous calcium-chloride solution. Schmidt and von Manteuffel have controlled a hemorrhage after tooth extraction by application of Schmidt's zymoplastic substance after cocainization. For the epistaxis Wright also recommends the inhalation of carbon dioxide through the nostrils.

Traumatic hemorrhage must be prevented by avoiding all surgical operations on a person affected with hæmophilia, unless life is in peril, and by preventing him from engaging in any occupation in which he is liable to receive an injury. A tooth should not be extracted under any circumstance.

In the interval between the hemorrhages the patient should use a generous but non-stimulating regimen, should live in the fresh air, should avoid exposure to cold and dampness, and should be free from all excitement. Iron and cod-liver oil should be used, unless plethora should ensue. The prolonged use of the Rock Bridge alum water, of Virginia, has been of service in some cases, in reducing the frequency of hemorrhages.

Surgical principles must be invoked in the treatment of the joint affections. Residence in a damp locality, or exposure to cold and dampness is particularly likely to cause and aggravate these complications. If they are obstinate, a warm, dry climate must be sought.

The marriage of the daughters of a family of bleeders should be prohibited. In this way only can the advance of the disease be checked. If the brothers are marked subjects of the disease their marriage should be prevented.

J. H. Musser.
R. M. Pearce.

HÆMOPTYSIS.—Etymologically considered, the word hæmoptysis signifies the expectoration of blood, without regard to its source or quantity. Practically, however, the term has come to indicate the expectoration of pure, or of almost pure blood, emanating from the respiratory organs, viz., from the larynx, trachea, bronchi, or lungs. The expectoration of rusty, prune juice, or greenish sputa, in pneumonia; of blood-streaked sputa in bronchitis; of jelly-like masses, as in cancer; or of chocolate-colored material in hepatic abscess, does not, therefore, properly constitute an example of hæmoptysis in the ordinary acceptation of the word. The term is, however, applied by some authors to the expectoration of blood in sufficient quantities to be microscopically discovered, even if the sputa containing it be largely composed of other constituents.[1] The spitting of blood which, having been extravasated at points more or less remote from the respiratory organs, and having reached the pharynx, has gravitated into the air passages (as in hæmatemesis, and in buccal, œsophageal, or nasal hemorrhages), may be designated as pseudo-hæmoptysis or spurious hæmoptysis. The expectoration of blood follows bronchorrhagia and pneumorrhagia in so large a proportion of cases that only hæmoptysis due to these causes will be considered in this place, the reader being referred, for information regarding laryngeal and tracheal hemorrhages, which are comparatively rare, to the articles in this HANDBOOK treating of diseases of the larynx and trachea. An absolute discrimination between bronchial and pulmonary hemorrhage being very difficult, and of slight importance from a therapeutical standpoint, will not be insisted on in the present article. Furthermore, as the etiology and pathology of hæmoptysis are fully discussed under other headings (the various diseases of the heart, lungs, bronchi, larynx, etc.), it seems best to omit, in the present article, all discussion of this part of our subject.

SYMPTOMATOLOGY.—The clinical history of hæmoptysis embraces: I. Prodromal Symptoms; II. Actual Symptoms, or those of the attack, and III. Consecutive Symptoms, or sequelæ.

I. *Prodromal Symptoms.*—Premonitory symptoms are often absent in hæmoptysis, particularly if it be due to traumatic causes, to the rupture of an aneurism, or to incipient phthisis.[2] Under these circumstances the hemorrhage occurs either without an evident exciting cause, while the patient is quiescent, or it is precipitated by some physical effort, such as lifting, riding, running, or dancing. Subjective precursory phenomena generally precede hæmoptysis from active or passive congestion, and in cases of recurrent hæmoptysis. The most noteworthy premonitory symptoms are cold extremities, accelerated pulse, vertigo, cephalalgia, epistaxis, thoracic oppression, constriction, distention or warmth, a dry hacking cough, vague general discomfort, slight dyspnœa, and cardiac palpitation. An objective prodromal symptom is cerebral congestion, accompanied by flushing of the face, throbbing of the carotids, and augmented rapidity and force of the pulse. Important suggestions relative to the possible occurrence of hæmoptysis may be derived from the previous history, particularly if this includes evidences of phthisis, of cardiac disease, or of one of the dyscrasiæ. Prodromes may be observed several days before a pulmonary hemorrhage, recurring at irregular intervals before the attack, or they may directly precede the hæmoptysis.

II. *Actual Symptoms, or those of the Attack.*—In an ordinary case of hæmoptysis, whether inaugurated by premonitory symptoms or not, the patient experiences a sensation such as might be referred to the trickling of a warm liquid beneath the sternum, perceives a saline, sweetish taste, and, on clearing his throat, expectorates blood without effort. Cough, attended by characteristic large, moist, tracheal and bronchial râles, now begins, or may have preceded the first bloody expectoration, and each paroxysm of coughing leads to the expulsion of a variable quantity of blood, which is generally fluid, arterial in color, of alkaline reaction, frothy from the admixture of air, and often mingled with mucus or muco-pus. If the quantity of blood be small, and its expulsion gradual, it is often venous, or even black in color, and more or less completely coagulated. Coagula emanating from the lung are usually of low specific gravity, on account of the air bubbles which they contain. Blood casts of the bronchi may be expectorated. The quantity of blood rejected varies within wide limits. In some cases only a few drachms are expectorated; in others, particularly in hæmoptysis from ruptured aneurisms, from phthisical or other cavities and in pneumorrhagia, several pounds may be rejected. If the blood is so abundant that it fails to find a ready exit through the buccal cavity, which rarely happens, it flows in an almost uninterrupted current from both nose and mouth, quickly producing syncope, or even convulsions and death. A certain quantity of blood is often swallowed, giving rise to hæmatemesis or to melæna. The uninterrupted duration of hæmoptysis is very variable, ranging from a few minutes to several days. A single attack sometimes occurs, but hæmoptysis is generally recurrent. The intervals between successive attacks vary from a few hours or days to months or years. Eichhorst affirms that malarial hæmoptysis recurs periodically at the time when a febrile paroxysm should be expected. A similar periodicity may obtain in amenorrhœal hæmoptysis. Hæmoptysis manifests a strong tendency to self-limitation, but it may, in exceptional cases, especially when dependent upon phthisis or on hæmophilia, recur so often as to cause death by exhaustion. Only in rare instances does the spitting of blood prove immediately fatal from rapid asthenia, or from asphyxia due to obstruction of the air passages.

The first sight of blood, especially in an initial hæmoptysis, engenders characteristic excitement and terror on the patient's part; but when a few safely surmounted paroxysms have demonstrated their comparative innocuousness, his mental equilibrium is often little disturbed by the onset of a new hemorrhage. In cases of moderate hæmoptysis the constitutional symptoms, aside from mental perturbation, betrayed by an anxious expression and by gentle tremor, are at first those of slight shock, *i.e.*, pallor, faintness or nausea, chilliness, and enfeeblement of the pulse. These symptoms are succeeded by congestion of the face and by augmented force and frequency of the heart's action, which phenomena gradually disappear after the cessation of the hemorrhage. In cases of more copious hæmoptysis the facial congestion gives place to returning pallor, the pulse becomes irregular and compressible, the respiration suspirious, the surface clammy, and the mind apathetic. Restlessness, tinnitus aurium, urgent thirst, falling temperature, nausea, muscæ volitantes, dimness of vision, increasing asthenia, transient syncope, and convulsive twitchings are symptoms which complete the clinical picture. In the worst cases of hæmoptysis the phenomena just enumerated appear in rapid succession, and death results either from syncope or from suffocation, due to obstruction of the air passages by fluid and coagulated blood. Hæmoptysis from hemorrhagic infarction generally ensues forty-eight hours, or even later, after the occurrence of pulmonary embolism, which, if the embolus be of septic character, is frequently announced by a chill. For the symptoms peculiar to hemorrhagic infarction, *vide* the article on *Lung, Infarction of the.* Hæmoptysis from the other predisposing and exciting causes described under the caption *Etiology,* as cancer, aneurisms, abscess, and gangrene, will, of course, be accompanied by the symptoms peculiar to these diseases. That pulmonary or bronchial hemorrhage and hæmoptysis are not convertible terms is shown by the fact that hemorrhages from the lungs sometimes occur without giving rise either to the prodromal or to the actual symptoms of hæmoptysis. These symptoms may be absent either if the quantity of extravasated blood be insignificant and undergo reabsorption, or if it be so large as to preclude the possibility of its expectoration by causing sudden death.

The *physical signs*, aside from those due to the diseases causing hæmoptysis, are usually unimportant. If the attack be slight, there may be no physical signs, or moist râles may show the presence of blood in the alveoli, bronchioles, and bronchi. No additional signs will be discovered, unless considerable consolidation has been produced by the accumulation of blood in the air passages and the interstitial pulmonary tissues, when dulness, and, provided that the bronchi be unobstructed, broncho-vesicular or bronchial respiration and increased vocal fremitus may be found. If the bronchi are completely or considerably obstructed, there will be diminution or absence of respiratory and of vocal signs.

TREATMENT.—The indications for the treatment of hæmoptysis are: first, the arrest of an actual attack; second, the prevention of its recurrence by treatment of the causative affections; and finally, the relief of its consecutive symptoms.

Energetic therapeutical measures are not indicated in mild attacks of hæmoptysis. Inasmuch as local depletion exerts a beneficial effect upon pulmonary congestion, which is the cause of most slight hemorrhages, it is advisable not to interfere with nature's efforts for the relief of excessive intravascular tension, but to second them by measures tending to the accomplishment of the same end. Whether, therefore, the congestion be active or passive, perfect quiescence, in a semi-recumbent position, should be strictly enjoined upon the patient. The statement that hæmoptysis is useful in relieving pulmonary congestion, and that its occurrence, given the usual pre-existing congestion, is desirable, should be confidently made, and is usually effective in quieting the patient's apprehensions. The sick-room must be kept cool, well ventilated, and free from all persons whose demeanor would tend to excite misgivings in the patient's mind. The bed-coverings are to be so light as not to compress the chest. The patient should be frequently reminded persistently to restrain his desire to cough. Mild revulsive measures, such as the application of mustard leaves, or of dry cups, to the exposed parts of the chest, and of stimulating pediluvia, are in order, as is derivation by means of a gentle saline purgative. If the pulmonary hyperæmia be active, cardiac sedatives may be employed, one of the best being the tincture of aconite, in two-drop doses, every twenty minutes, until a reduction in the force and frequency of the pulse, or tingling in the throat and finger-tips is observed. Should the hyperæmia be passive, as in uncompensated heart lesions, the tincture of digitalis, in ten-drop doses, should be administered, every hour, for the purpose of strengthening the heart's action. In cases of more profuse or protracted hæmoptysis the same rules regarding the patient's position and surroundings should be rigidly enforced, and more potent therapeutical measures adopted. If the hemorrhage be occasioned by excessive active hyperæmia, the patient being strong and plethoric, or by so great passive congestion as to threaten cardiac paralysis, venesection, to eight or ten ounces, affords prompt relief. This treatment is particularly adapted to the initial hæmoptysis of tuberculosis, and to pulmonary hemorrhage from rarefaction of the atmosphere, from the inhalation of irritating substances, and from violent physical exertions.

If the patient will not submit to the operation of phlebotomy, active congestion may be measurably controlled by a brisk saline purgative, by emetic doses of ipecac, as recommended by Trousseau and Graves, and recently advocated by Massina and Peter, but which must be avoided in hæmoptysis from cavities because of its tendency to prevent closure of bleeding vessels, or by the following therapeutic agents, which are useful in all varieties of profuse pulmonary hemorrhage. The most potent of these is cold, which is best applied by means of an ice-bag, of moderate weight, placed over the primary bronchi, or on that part of the chest to which the detection of râles points as the probable seat of hemorrhage. Small pieces of ice should be constantly dissolved in the mouth and swallowed. The best form of nourishment is cold milk, taken in quantities of eight ounces, at intervals of two or three hours. Physical examinations should be studiously avoided, as calculated to increase and to excite hæmoptysis, and as affording no important results. Ligation of the extremities, which is sometimes a very efficient hæmostatic measure, acts by retaining the venous blood in the limbs, while the arterial current is not arrested; but it must be cautiously employed, lest syncope or venous thrombosis be induced. These untoward results may be prevented by the simultaneous ligation of only two members, by leaving the ligatures in place for only a few minutes, consecutively, and by removing them so soon as hæmoptysis ceases. Ligation must, naturally, be undertaken only under the physician's immediate direction and supervision. Ergot is probably the most efficient hæmostatic remedy. It may be exhibited in the form of the fluid extract, in doses of one or two drachms, diluted with an ounce of water, every half-hour or hour, until the hemorrhage ceases or a decided diminution in the force and frequency of the pulse is observed. Should the stomach prove rebellious, half an ounce of the fluid extract, diluted with an equal quantity of lukewarm water, may be given by rectum, and repeated every hour until the physiological effects are produced. If it is desirable that the action of the drug be very speedily exerted, half a drachm of the fluid extract, or three grains of ergotin, dissolved in equal parts glycerin and water, should be subcutaneously administered, every half-hour, until the desired result is obtained. One grain of opium, or one-fourth grain of the sulphate of morphine, preferably in fluid form, must be immediately administered for the purpose of checking cough, and of inducing mental and physical quietude. The opiate should be repeated in doses of half the size mentioned, every two hours, until hemorrhage ceases or the physiological effects of the medicine are obtained. The most speedy and satisfactory method of administering the narcotic is by hypodermatic injection of the sulphate of morphine, particularly if simple emesis or hæmatemesis coexist with the hæmoptysis. Opiates are contraindicated when fatal accumulation of blood in the air passages is threatened. At such times expectoration should be encouraged and facilitated. Many authorities recommend that several teaspoonfuls of dry common salt be administered, if no other remedy be at hand, largely for the desirable moral effect resulting from medication in general, and partly on account of the unexplained but well-attested restraining effect of salt upon hæmoptysis. Inhalations of astringents, preferably of Monsel's solution, or of the *liquor ferri sesquichloridi*, diluted twenty-five times with water, and administered in the form of spray generated by an atomizer, are sometimes useful. The acetate of lead in two-grain doses, or gallic acid in twenty-grain doses, every three hours, is often administered internally, although the question of their value is still debatable. Bartholow extols the virtues of turpentine in hæmoptysis dependent upon hæmophilia and purpura.[3] It may be exhibited by mouth, in twenty-drop doses, in emulsion, or on sugar, or its vapor may be inhaled, for one-quarter hour, at intervals of two hours.

After-Treatment.—The objects of the after-treatment are the prevention of a recurrence of hæmoptysis, and the relief of its consecutive symptoms. The former indication is best fulfilled by the removal of predisposing morbid conditions, and by the avoidance of exciting causes. Many of the diseases predisposing to hæmoptysis, although, unfortunately, not amenable to curative measures, may be favorably influenced by judicious treatment. Pernicious malarial fever, of the hemorrhagic type, may be controlled by quinine and by other antiperiodics. Vicarious amenorrhœal hæmoptysis is to be combated by means tending to excite the normal menstrual flow, and scorbutic pulmonary hemorrhage by good food and vegetable acids. In cases of puerperal or marantic venous thrombosis, the utmost quietude should be enjoined, in order that pulmonary embolism, resulting in infarction and hæmoptysis, may be averted. Acute and chronic pulmonary inflammations must be subjected to appropriate treatment, and earnest efforts made to establish a compensation for existing organic cardiac diseases.

The exciting causes of hæmoptysis most easily avoided are those producing active pulmonary congestion, such as violent physical efforts, mental excitement, great rarefaction of the atmosphere and the inhalation of irritating vapors and gases. The chief direct sequelæ of hæmoptysis are bronchitis, bronchopneumonia, anæmia, and asthenia. The first and second are to be treated in accordance with generally recognized methods. The anæmia and asthenia are to be combated with tonics, preparations of iron, nourishing food, moderate and regular out-of-door exercise in pleasant weather, and, if extreme, by alcoholics rationally administered. If no other cause for a given attack of hæmoptysis can be discovered, it should be regarded as a probable initial symptom of pulmonary tuberculosis, and appropriate prophylactic measures should be immediately inaugurated.

HÆMOSTATICS.—Hæmostatic drugs are such as are employed to control hemorrhage. When the hemorrhage occurs upon an exposed surface or from some accessible cavity, ordinary surgical measures are usually resorted to; but if the bleeding is not amenable to surgical treatment or if it occurs in some deeply seated organ, it becomes necessary to make use of astringent and styptic drugs. These may be made to act directly upon the part by applying them to the bleeding point, or their hæmostatic effect may be obtained by internal administration.

Whenever bleeding occurs the efforts of nature are directed toward a spontaneous cure. There is at once a contraction of the injured vessel, the torn coats of the artery retract, and the escaping blood is coagulated by contact with the surrounding tissues and upon exposure to the air. Should the loss of blood be severe, there is a weakening of the heart's action and a lessening of the blood pressure which greatly aid nature's efforts. These changes afford us an indication for treatment, and it is upon these principles that we select our remedies and endeavor to overcome the trouble.

The local application of extremes of heat and cold is a very common and a very effective means of controlling hemorrhage. Ice almost immediately contracts the vessels and blanches the part, and the employment of very hot water produces in a similar manner a spasmodic contraction of the vessels, and exercises a more marked effect in coagulating the blood. The custom of applying cold to the thorax with the object of checking hemorrhage in the lungs, or to the abdomen when the intestines are the seat of the trouble, is of doubtful value, unless the bleeding vessels are close to the surface. Many hold that it may do more harm than good by driving the blood from the surface to the organs beneath. The application of heat to the spine, although less common, is probably a more rational mode of treatment, the heat being applied over the ganglia which control the nerve supply of the part. Both heat and cold are most effective when brought in direct contact with the bleeding surface. Lumps of ice may be swallowed in hæmatemesis, or inserted into the rectum or vagina if the intestinal canal or the uterus is the part affected. In the same way the application of hot water to the open wound, or a hot injection in uterine hemorrhage is always of service and much more desirable than a cold application if there is much depression.

The local actions of hæmostatics differ somewhat. Some cause a firm clotting of the blood and are termed *styptics*, while others produce their effect by acting more directly upon the vessels. Of the styptics, the best known are the salts of iron, especially the subsulphate and persulphate, alum, acetate of lead, and tannic acid, all of which, although they exercise a constringing effect upon the vessels, act almost entirely by causing firm, adherent coagulation, not only of the blood but also of the adjacent albuminous tissues. By the time when this mass becomes detached the bleeding points are obliterated and a healthy surface remains. The hæmostatics which act more directly upon the vessels are alcohol, oil of turpentine, a weak solution of acetate of lead, antipyrin, and suprarenal extract. Suprarenal extract, as well as its derivative adrenalin, is the most typical of this class, and is probably the most valuable local hæmostatic that we possess. It produces a most powerful contraction of the vessels, and this persists for a long time. A solution of adrenalin, 1 in 10,000, renders the conjunctiva or any of the mucous membranes almost devoid of blood. It has been much employed to secure bloodless operations upon the nose and throat, as well as to check hemorrhage from any mucous surface.

The effect of the internal administration of hæmostatics is not so definite, nor is it readily explained, but clinical experience has taught us that several drugs may be depended upon for their hæmostatic action. Ergot, hydrastis, oil of turpentine, and aromatic sulphuric acid have all proved of service. They act upon the muscular elements of the arterial coats, causing a marked diminution in the calibre of the vessels; their effect is particularly marked on unstriped muscular tissue.

Tannic acid and vegetable preparations the astringency of which is due to tannin, are much employed in this way and have been thought to be decidedly beneficial. Tannin, however, is never absorbed into the blood except as gallic acid, which does not coagulate albumen and possesses very slight astringent properties. Except in hemorrhages from the stomach and bowels, tannic acid probably exerts no true hæmostatic effect. In such cases the drug probably produces an astringent effect because it is brought into direct contact with the affected parts. The same argument applies to the use of the mineral astringents, as alum and acetate of lead, for they both actively coagulate albumen and are thought not to pass beyond the mucous membrane of the intestines. Lead, however, enters the circulation as an albuminate and has a decided action in causing muscular contractions. Its effect upon renal hemorrhage is marked, but upon other organs its value is not so certain. The action of alum is less certain; it is absorbed as an albuminate and exercises an astringent effect when excreted by the kidneys and skin Its beneficial action in hemorrhage from other organs is doubtful.

In addition to the help obtainable from astringent remedies, it is possible to derive considerable assistance, in our efforts to control hemorrhage, from the use of sedatives and revulsants, which secure rest and lessen congestive states. Formerly these ends were attained by such drugs as tartar emetic, aconite, lobelia, and tobacco, and from a resort to venesection. Excepting in cerebral hemorrhage these remedies are now never resorted to. Instead, we place the patient in the most favorable position to secure bodily ease and functional rest of the implicated organ. If the lungs are affected, talking is forbidden; if the bleeding is from the digestive organs, food is restricted and rectal feeding substituted. Opium is always of the greatest service. In all forms of hemorrhage there are much restlessness and mental anguish, which interfere with all our efforts to effect a cure. Opium overcomes this disturbance by putting the muscles at rest and by calming the mental irritability. It also favors functional rest, not only of the organ affected, but also of the heart and circulation. It should be given freely (opium, from one to three grains; or morphine, half a grain). The only contraindications to its employment are cerebral hemorrhage, or those conditions which are characterized by extreme prostration and by the fact that the respiratory function is markedly weakened. Active purgation must not be neglected unless the bleeding is from the stomach or intestines. Such remedies as calomel, compound jalap powder, elaterium, and croton oil produce free evacuations, lessen all congestive states of the abdominal and thoracic organs, and reduce the general blood pressure. *Beaumont Small.*

HAIR DYES, INJURIOUS EFFECTS OF.—Although it is unquestionably true that the injurious effects of hair dyes have been grossly exaggerated, physicians should bear in mind the widespread habit of dyeing the hair, when called upon to treat certain obscure nervous symptoms and atypical lesions of the skin. This habit is not new, nor is it one of the passing fads of the day. It has been handed down to us from the most remote antiquity, and its votaries are to be found not only among the peoples of the East, but also among those of the western hemisphere. Thus, for example, we find that even the primitive American Indian found it expedient to dye his hair. Therefore, in view of the prevalence of the custom and when we consider the very few cases that are thereby injured, we are justified in coming to the conclusion that the evil effects have been grossly exaggerated.

The animal, vegetable, and mineral kingdoms have all been drawn upon to furnish their quota of substances for dyeing the hair and beard, until finally modern chemistry has been called upon to perfect the art.

It would be beyond the scope of this article to enter into a full description of the several hair dyes and the substances that have been employed for this purpose; it will suffice us to make a short summary of the ones most commonly used, such as pyrogallic acid, walnut hulls, indigo, henna, curcuma, hydrogen peroxide, potassium bichromate, silver nitrate, salts of lead, copper and iron, and last, but not least, chloride of paraphenylendiamin.

The injurious effects of hair dyes may be divided into three classes: First, injury to the hair; second, injury to the general system; third, local injury other than to the hair.

In the first class we would place hydrogen peroxide, which at the same time that it destroys the pigment extracts the fatty matter from the hair and thus destroys its vitality.

As an example of the second class the most common, most talked about is, of course, chronic saturnine intoxication with its attendant train of symptoms, wrist-drop, colics, etc.; this being due to the absorption of the salts of lead by the hairy scalp. At the present time we see little of this condition, but years ago it was relatively common.

In the third group we must place a number of trivial accidents, such as staining of the skin with the salts of such metals as iron, copper, manganese, silver, cadmium, etc.

The stains of iron, manganese, and cadmium may be removed by weak solutions of acids, while the brown stains of copper and the black stains of silver will be made to disappear by the application of cyanide of potassium and iodide of potassium.

Chromic acid or acid chromate of potassium will dye the hair yellow, but they are both caustic and poisonous.

The accidents brought about by pyrogallic acid and paraphenylendiamin chloride are more serious in character. Pyrogallic acid will sometimes produce, when used in sufficient strength anywhere about the face, a severe dermatitis with œdema, while if employed about the eyes it is apt to be followed by œdema of the eyelids, by conjunctivitis, and by extensive inflammation of the mucous lining of the nasal cavity.

Ever since the introduction of paraphenylendiamin chloride as a constituent of hair dyes many more instances of injuries due to hair dyes have been brought before the profession. The injuries that have sometimes followed the use of the drug include, among others, dermatitis of the hairy scalp, of the back of the neck, of the face, etc.—in fact, a dermatitis of that part of the skin that was brought in contact with the drug. In some cases the inflammation has extended to the neighboring parts, while Cathelmeau records a case in which the whole body was affected.

The character of the eruption varies from a slight erythema to a vesicular, papular, or pustular lesion; it may also be urticarial in character; œdema may be well marked, while pruritus may be intense. The eruption is sometimes accompanied by an elevation of temperature.

The *diagnosis* is sometimes attended with difficulty. Fournier gives as diagnostic points the suddenness of onset of symptoms, the rapidity of extension of the eruption, the enormous swelling of the eyelids. Sometimes the patients will aid us by connecting cause and effect. On the other hand, as in other conditions, too much reliance should not be placed on their statements, as they are apt to mislead us voluntarily or otherwise.

There is nothing special to offer in the way of *treatment;* these injuries should be treated exactly in the same manner as one would treat similar lesions in other conditions, provided that before the institution of any line of treatment the original cause be removed.

The *prognosis* is, as a rule, very good, although Brocq claims that in rare instances the condition proves rebellious to treatment. *N. J. Ponce de Léon.*

HAND.—Cresollius calls the hand "the minister of reason and wisdom." As the active servant of the brain, adjusted for the most delicate and varied uses, it has always been held in peculiar honor. The coat-of-arms of the surgeons' guild of the Middle Ages was a hand, with outspread fingers and an eye in their midst, typifying thus the noble art of chirurgie, which name was itself derived from *χείρ*, the hand, and *ἔργον*, work. Respect for this important member has even been carried so far that it has been supposed to contain a force within itself capable not only of intelligent action, but of transmission beyond the body. When we regard the high degree of muscular coördination which it possesses we readily see whence originates the first of these popular fancies, for the hand of the skilled musician, artist, or handicraftsman is a very different organ from that of the untrained and inexpert novice. The very word "handy" expresses this idea.

As to the second notion, it appears to be founded upon the extraordinary degree of tactile sensibility which the hand possesses. The laying on of hands has been a favorite method of healing from the very earliest historical period, and is still prevalent, not only where the royal touch is believed to be a sovereign remedy for "king's evil," but also among the so-called healing mediums.

The mesmeric passes were believed to be efficacious only when performed with the ends of the fingers, in order that the "force" might be drawn off into the patient's body. Von Reichenbach's patients saw flames of "od" force issuing from the ends of the fingers; many worthy people have no doubt that a nervous headache can be cured by some transfer of this force by means of passes over the brow of the sufferer; and we have lately had a revival of the old astrological theory of an "astral fluid" which is more transmissible from those with pointed fingers. Obscure nervous sensations felt in the fingers and along the nerve tracts are believed to be caused by this force or fluid. Owing probably to this superstitious reverence, we find that the physicians of the Middle Ages used the detached hand of a corpse for the scattering of tumors and the reduction of swellings.

The use of this strange remedy still survives. The author has recently found several authentic cases of such application. In one it was used for the cure of a white swelling, and in another for a protracted intermittent fever, a female homœopathic physician vouching for its efficacy. She explained this to the writer by stating that the "morbid processes going on in the dead hand attracted the disease and removed it" (!). Sometimes the virtue of the deceased is believed to have a marked influence. This was shown in the case of a well-known Catholic priest who died recently in Washington, and in that of a Carmelite nun in Baltimore. Many applications of the dead hand were made in both cases for the cure of the sick and afflicted, showing that the old belief is still active.

Another superstition which had a prominent place in the black art of the Middle Ages was that of the "hand of glory." This was a dead right hand of a murderer prepared with appropriate conjurations, in which was placed a magic candle made of murderer's fat and the hair of the dead. This was believed to prevent sleepers from awakening and to open locks and bars. As late as 1831, such a hand was left by thieves in a house in Loughcrew, Ireland. Thieves in Mexico use for a similar purpose the left hand and arm of a woman dying in her first childbed, and in 1875 a Mobile negro carried around with him the hand of his murdered victim to insure himself against detection.

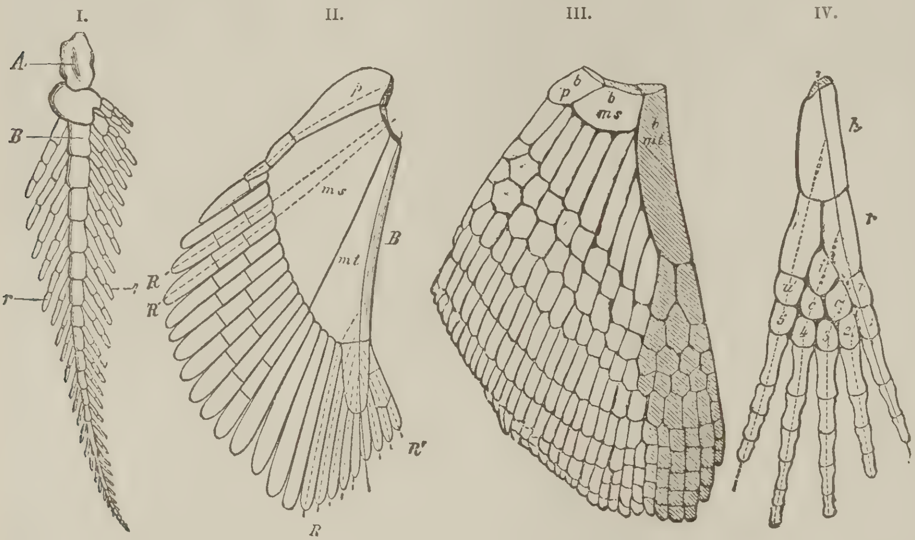

FIG. 2439.—Skeletons of the Thoracic Limb of Lower Vertebrates, showing the Gradual Development of the Hand.

Sir Charles Bell, the author of the celebrated "Bridgewater Treatise on the Hand,"[1] says: "We ought to define the hand as belonging exclusively to man, corresponding in sensibility and motion with that intelligence which converts the being who is weakest in natural defence, to a ruler over animate and inanimate nature." However flattering to our pride this statement of the great physiologist may be, modern investigation has shown that it is not anatomically correct, as there is nothing in the structure of the human hand that distinguishes it, except in degree, from that of anthropoid apes. Even Huxley's statement, that the apes do not possess an extensor of the metacarpal bone of the thumb, is open to question. Comparative anatomy shows us in fact that a general typical form for the thoracic limb and hand pervades the entire vertebrate series. This is especially marked in the mammalia, and in many cases the student of human anatomy has no difficulty in determining at once the different bones of the forefeet of an animal which he has never before seen. In one case within the author's experience, a professor of obstetrics who was not an anatomist, was obliged to examine a class in anatomy, and procured from the cabinet the skeleton of a bear's forepaw, which he passed around as belonging to the human skeleton. As the functions of the member vary, the different parts become reduced or increased either in size or in number, but a general plan pervades the whole, and the fin of a fish, the wing of a bird or a bat, the paw of an animal, are all constructed on a single type.

While the differences between the human hand and that of the higher apes are not essential, being only those of degree, yet the relative proportions of the different parts distinguish it markedly. The following table from Humphry shows the size of the hand and the foot relative to the stature taken as 100:

	Hand.	Foot.		Hand.	Foot.
Man	11.82	16.96	Chimpanzee	18.00	21.00
Gorilla	14.54	20.69	Orang	20.83	25.00

This superior length is due mainly to the metacarpal bones and phalanges.

With regard to the primitive origin of limbs two distinct views have been advanced by anatomists. According to the first the proximal part of the limb, which we are accustomed to call the shoulder or pelvic girdle (scapula and clavicle for the arm, innominate bone for the leg), arises from visceral arches of the vertebræ, and upon these radial bars of cartilage are set for the support of the fins. The pelvic girdle is thought to have become shifted backward in a marked degree. A complete homology, therefore, is believed to exist between the thoracic and the pelvic limbs.

The opposing view, which has recently been rapidly gaining ground, is that the shoulder and pelvic girdles are formed from coalesced vertebral elements. It is held that the most primitive form of limb is simply a lateral skin fold extending along the whole body, and that into this certain cartilaginous processes, or rays (actinophores of Ryder, pterygophores of Parker), extend. Each of these may bear several others extending radially through the fin. When necessary for more special forms of locomotion, the actinophores become united into solid bars constituting the shoulder and pelvic girdles, and the other skeletal elements are distally situated rays. Fig. 2439 shows various forms of fins found in primitive fishes; and it will be seen that there is a certain general resemblance to a hand with a large number of digits. According to this view there is no absolute homology between the thoracic and pelvic limbs, but only a homodynamy. Between fishes with fins and amphibia with feet there is a gap which has not yet been filled up by the discovery of intermediate forms, but it appears probable that the limb in its reduced state is the result of adaptation to walking instead of swimming.

In swimming it is necessary only to propel the body forward, in walking it must be also supported and raised; hence the necessity of the strong proximal bones and the bending at the shoulder, elbow, and wrist, and at the hip, knee, and ankle.

Fig. 2439, IV., shows how closely the plan of the hand and arm of an amphibian corresponds with that of man. From this point up through mammals there are many modifications, produced by the peculiar functions which the limbs are called upon to perform. When of use for prehension, digging, etc., the five-fingered type remains, and it is in fact the most persistent of all; but occasionally the occurrence of extra digits in the human species reminds us of a far-off ancestry, in whom the rays were more numerous. When the anterior limbs are used more for locomotion they become variously modified by stress and impact, and lose unnecessary digits. The reduction always takes place laterally. First the thumb becomes rudimentary or disappears, then the little finger, next the second finger, then the fourth, and so on. The discussion of the various causes for this is of extreme interest, but would exceed the proper limits of this article. The principal typical forms are shown in Fig. 2440.

Embryological evidence as to the development of the hand agrees, as far as it can at present be understood, with the facts observed in the animal series.

The first rudiment appears as a thickening and crescentic protuberance (see Fig. 2441, *A*), which grows laterally from the body wall. Further outgrowth may be arrested at this point, and in that case we have a child born with a hand springing directly from the shoulder, a species of monstrosity reminding one of the flipper of a seal, and hence called phocomelus. Normally, however, other segments are developed between the first bud and the body wall (Fig. 2441, *B*), and in these the bones of the arm develop. The formation of the fingers is first indicated by notches along the edge of the distal bud from which converging grooves run, indicating the future interdigital spaces (Fig. 2441, *C*). The first groove that appears is that between the thumb and the forefinger. The terminal phalanges soon become free, but the remaining portions of the fingers are united until the third month. If development is arrested here, we have the fingers remaining with a web between them, as in the amphibian paddle and in some quadrupeds. The thumbs become free first.

The varied structures of connective tissue, cartilage, bone, muscles, nerves, and vessels all develop gradually within this rudimentary bud, as they do in other parts of the body, by a differentiation of mesoblastic cells.

Some interesting problems are connected with the time and order of ossification of the various parts. The typical plan of the hand is shown in Fig. 2439, IV. In the wrist there are originally nine bones, which are arranged in two rows; those of the first are named systematically, the intermedium, between ulna and radius, ulnare, radiale, and correspond to the scaphoid, semilunar, and cuneiform bones of man. There is then a centrale (sometimes two, as shown in the figure) found in many apes and rodents, represented in the second month of fœtal life by a small independent cartilage; and then, in a second row, carpales I., II., III., IV., and V., each bearing a metacarpal bone. The first three of these correspond to the trapezium, trapezoid, and os magnum, the fourth and fifth uniting to form the unciform. The pisiform bone is generally held not to be an essential carpal element, but a sesamoid developed in the tendon of the extensor carpi ulnaris. A radial sesamoid occurs in some apes, and is occasionally found in man.

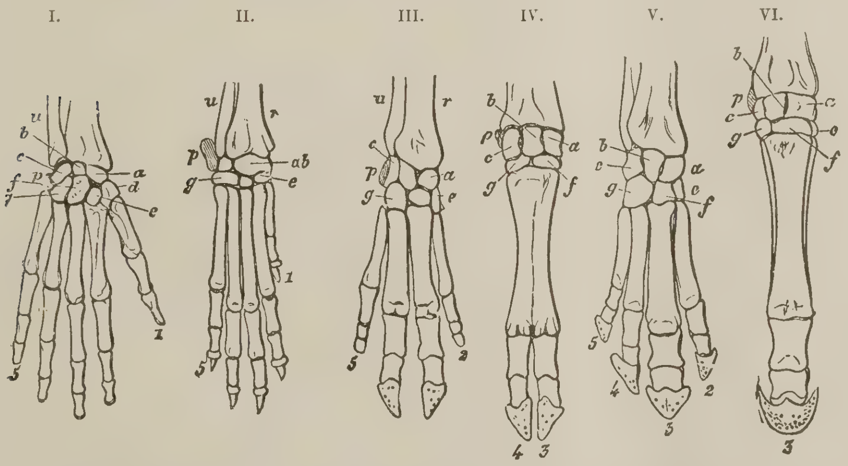

FIG. 2440.—Skeleton of Hand or Forefoot of Six Mammals. I., Man; II., dog; III., pig; IV., ox; V., tapir; VI., horse. *r*, Radius; *u*, ulna; *a*, scaphoid; *b*, semilunar; *c*, cuneiform; *d*, trapezium; *e*, trapezoid; *f*, os magnum; *g*, unciform; *p*, pisiform; 1, thumb; 2, index finger; 3, middle finger; 4, ring finger; 5, little finger. (Gegenbaur.)

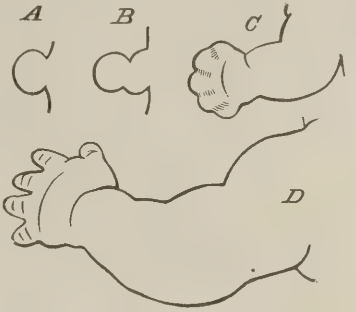

FIG. 2441.—Outlines of the Anterior Extremities of Human Embryos at Different Ages. (Allen Thompson, after His.) *A*, At four weeks; *B*, at five weeks; *C*, at seven week; *D*, at nine or ten weeks.

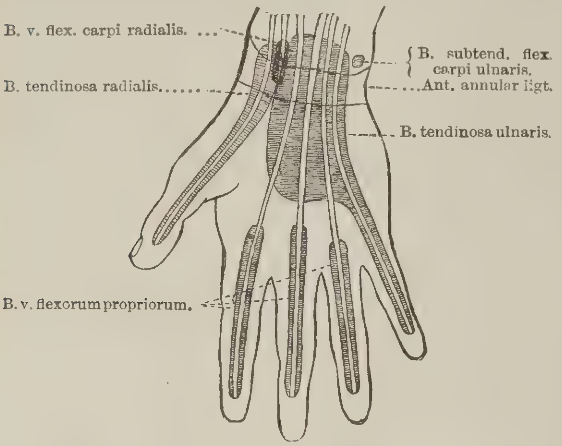
At birth all the carpal bones are cartilaginous. Ossification begins in the os magnum (first year), then follow the unciform, cuneiform, semilunar, scaphoid, trapezoid, and trapezium in about that order, and at intervals of from nine months to a year, so that the carpus proper is complete during the eighth year. The pisiform is somewhat later, not ossifying until from the tenth to the twelfth year.

The metacarpals follow the rule of long bones and ossify much earlier, commencing in the shaft at about the ninth week of fœtal life, an epiphysis remaining cartilaginous. In the metacarpal bone of the thumb this epiphysis is at the proximal end, but in the others it is distal. The epiphysis begins to ossify about the third year. The phalanges ossify in a similar manner, but the epiphyses in them are always at the proximal end. The agreement in ossification between the first metacarpal and the phalanges has given rise to much speculation. It has been supposed to indicate that the missing bone of the thumb is not a phalanx, but a true metacarpal. Sappey [2] believes the metacarpal epiphysis to be the metacarpal proper, the remaining part being a phalanx, which would make the thumb agree with the other digits as to the number of segments, as is the case with some other mammals, the sloth, for example. The metacarpal bone proper has, he supposes, atrophied so as to allow the thumb to be set farther back and obtain more perfect opposability. It appears doubtful whether we ought to accept this interpretation, as a proximal epiphysis occasionally appears in the second metacarpal, and some animals have both proximal and distal. It is suggested that too much weight should not be given by osteologists to epiphysial ossifications, as it appears probable that their presence or absence depends very much upon the activities of the animal in producing strains upon the skeletal elements.

The hand is regarded as divided topographically into three regions: the wrist, middle hand, and fingers—corresponding to the skeletal divisions of carpus, metacarpus, and phalanges.

REGION OF THE WRIST.—Externally this region is not very precisely defined. Its upper limits are generally regarded as marked in front by the upper transverse crease which runs across the forearm, always quite well marked even in extreme extension. Its lower limits are marked by another furrow, which curves around the base of the thumb. Behind, the marks of limitation are by no means as clear. Upon strongly extending the hand (dorsal flexion) there appear three or more furrows which correspond in a general way to the joints of the wrist, viz., the radio-carpal, medio-carpal, and carpo-metacarpal. Although described as such by Malgaigne, they are not practically good guides to the joints in question.

The muscles of the arm as they reach the wrist all become reduced to comparatively small tendons, which pass down over this region to be inserted below, the flexors lying on the anterior surface, and the extensors on the posterior and external. The wrist is, therefore, the narrowest part of the limb, and this affords an increased facility of motion to the hand as a whole. The bony parts are so arranged as to form an arch with the concavity forward, filled with the descending flexor tendons, and the great vessels and nerves. Under the skin of the anterior surface, which is smooth and without hairs, can easily be felt the prominent points of this arch, viz., on the radial side the tubercle of the scaphoid, on the ulnar the pisiform. These vary in prominence in different individuals. It is not uncommon for uninstructed persons to suppose that they have "a bone out," and unscrupulous quacks take advantage of this notion to work supposed cures.



B. v. flex. carpi radialis.

B. tendinosa radialis
Ant. annular ligt.
B. tendinosa ulnaris.
B. v. flexorum propriorum.

FIG. 2442.—Synovial Sheaths of the Palmar Surface of the Hand.

Upon flexing the hand a tendon starts up. This belongs to the palmaris longus, and in a lean wrist it can be plainly seen to spread out and become continuous with the palmar fascia. On the radial side of the palmaris tendon, and close to it, can be easily felt the tendon of the flexor carpi radialis. Behind and between these two lies the median nerve. When the superficialis volæ artery is large, it may be seen to pulsate where it lies alongside of the tubercle of the scaphoid. The radial artery usually does not appear here, having already passed outward under the extensor tendons of the thumb to reach the back of the hand. The point where the pulse is usually felt is not, strictly speaking, within the anatomical region of the wrist, but upon the lower end of the radius. It is admirably adapted for the purpose, as the artery here lies upon a bony bed, may be easily compressed, and is about to make a sudden and abrupt curve. Hence a careful palpation shows at once the amount of tension of the arterial wall. By extending the wrist, the artery may be slightly stretched and the structures above it rendered tense, so that it may be still more easily felt. Occasionally the superficialis volæ is given off higher than usual, and makes a secondary pulsation, the "*pulsus duplex*" of old authors (not the pulsus dicrotus). In this case it is easy to control it by pressing it against the scaphoid. On the ulnar side, the flexor carpi ulnaris tendon shows prominently in flexion of the wrist, as it passes down to its insertion in the pisiform bone, and externally to this the pulsation of the ulnar artery may be felt. The tendons of the flexors of the fingers lie deeper.

The skin upon the front of the wrist is firmly bound to the deeper structures by a very thin layer of subcutaneous tissue, and it is therefore difficult to make a flap from it in amputating the forearm. Flexion has produced a number of transverse markings. These are the *rasceta* of the chiromants, a word derived from the Arabic, signifying wrist. There are usually three of these, and they are not only prominent in all states of the hand, but are found in fœtal life. An attempt has therefore been made to give them significance as characteristic signs, but when we reflect that the hand of the fœtus is also movable and actively used, and that its condition is one of pronounced flexion of all the joints, it is not surprising, in view of the peculiar relations of the skin and subdermal tissue, that these as well as the lines of the palms should be formed.

Across the front of the wrist passes a thick band of fascia, called the anterior annular ligament. This being attached to the bony prominences on either side, confines the tendons in the deep carpal furrow or canal. The continual friction of the tendons along this furrow has caused extensive synovial sacs or sheaths to be formed. Occasionally but a single one occurs, enclosing all the tendons. The usual arrangement is, however, for two sheaths (Fig. 2442), one (*bursa tendinosa ulnaris*) surrounding the tendons of both superficial and deep flexors, the other (*bursa tendinosa radialis*) surrounding the tendon of the flexor longus pollicis. The ulnar sheath is almost always continuous with the sheath of the little finger, and amputation of that digit is therefore more apt to be followed by extensive suppuration than that of the index, middle, or ring fingers. These extensive synovial sacs are very troublesome when inflamed, as they may lead to extensive suppuration of the forearm, and, indeed, death has been known to follow. An amputation of the hand is much less serious.

Upon the dorsal surface of the wrist the skin is much more movable, somewhat hairy, and without prominent furrows. Under it may be seen two prominent, bony eminences—first, the round head of the ulna, second, the more obscure, pointed styloid process of the radius. From this latter, running toward the thumb, the tendon of the extensor of the metacarpal bone of the thumb appears on extension, and a short distance from it the extensor of the first phalanx. The triangular space between these has been called *la tabatière anatomique*, or anatomist's snuff-box, because it was formerly the custom, when snuff-taking was fashionable, to carry snuff to the nose in this little hollow (Hyrtl). By pressing deeply on this space, the beating of the radial artery may be felt as it passes under the tendons to reach the first metacarpal interspace, where it passes into the palm. It here rests on the scaphoid and trapezium. Over the back of the

wrist and hand the tendons which come down from above, and are at first closely pressed together, begin to spread out to go to their respective insertions. These tendons are, from within outward, those of the extensor carpi ulnaris, extensor minimi digiti, extensor communis digitorum, extensor indicis, and the extensors of the thumb. These tendons are also confined by an annular ligament, and are furnished with synovial sheaths, as shown in Fig. 2443. The affection popularly known as weeping sinew (ganglion) is rather common in connection with these sheaths.

The small bones of the skeleton of the wrist are undoubtedly of considerable value in breaking and dispersing the shocks transmitted from the lower hand. The general plan of its construction has been already alluded to. We may consider the radius as bearing, first, the scaphoid (radiale), which in turn bears the trapezium and trapezoid (carpales I. and II.), the supporters of the first and second metacarpals; second, the semilunar (intermedium), which bears the os magnum (carpale III.) and the third metacarpal. The ulna does not directly join with the wrist, its carpal bone, the cuneiform (ulnare), being separated from it by the triangular fibrocartilage. This bears the unciform (carpales IV. and V. united) and the fourth and fifth metacarpals. The joints and ligaments of the wrist will be treated in a separate article.

Region of the Middle Hand.—The muscles which belong to the hand proper are arranged in two groups, one upon the radial side, making an elevation called the thenar eminence; another on the ulnar side, called by correspondence the hypothenar eminence. The upper part, where these two join, is called the ball of the hand, or by French anatomists *le talon de la main*. The central portion between the eminences is the hollow of the hand, and it can be contracted and deepened by the action of the muscles on either side. Because of this, it was called by the old anatomists *poculum Diogenis*, or Diogenes' cup, in allusion to the story that the cynic philosopher, on seeing a shepherd drink from his hand, vowed to henceforth use this, as the simplest possible utensil, instead of the rude wooden cup which he had heretofore deemed the acme of simplicity. Around this hollow are set the so-called "mounts" of chiromancy, governed, as is asserted, by the seven planets. The thenar eminence is styled the mount of Venus, and we may see a survival of the old notion in the fact that among the vulgar a titillation of this surface is believed to excite amatory passion.* It is possible that there may be an anatomical basis for this belief. An inspection of Fig. 2451 will show that the region in question lies in the boundary between the distribution of the ulnar and the median nerves, and is somewhat less fully supplied than are other parts of the hand. It is therefore, like other regions with the same character of nerve distribution, susceptible to that obscure form of nervous excitement called "tickling," which is known to cause a variety of reflex acts. We are as yet hardly sufficiently versed in the laws of transmission of impulses to decide absolutely that this may not have a reflex effect connected with the genital apparatus, especially if aided by an association of ideas

The lower part of the hypothenar eminence is called by palmisters the mount of the Moon, its upper the mount of Mars. At the root of the four fingers are the other mounts, which anatomical peculiarities are caused by the insertion into the roots of the fingers of the strong palmar fascia, by slips between which the tissues bulge. The mount of Jupiter belongs to the index, Saturn to the mediums, the Sun to the ring finger, and Mercury to the little finger. That this absurd farrago is not entirely obsolete the author has had ample evidence, as several intelligent people have assured him that they believe that these eminences have power to attract the seven different qualities of "astral fluid," and the doctrine has been fully set forth in more than one serious treatise within the last ten years.[3],[4],[5],[6],[7],[8]. Indeed, it would seem as if the advances of science within the present century, instead of extinguishing ignorant pretension, had caused pseudo-sciences to spring up by the score. Dazzled and bewildered by the evidences seen on every hand of the power of science, those untrained in the exact methods of scientific research are unable to distinguish between the true and the false, and a vast field is left open for charlatans and visionaries. The old astrologists believed not only that the hand was governed by the influence of the stars, but that certain signs were fixed upon it before birth, and became a basis from which to interpret the individual's character and constitution. Since this character and constitution have their limitations, signs for these also were found in the hand; and they further assumed that future events, such as sickness, death, and other matters of fortune or misfortune, could be foretold. There were many who went much farther than this into all the excesses of charlatanry.

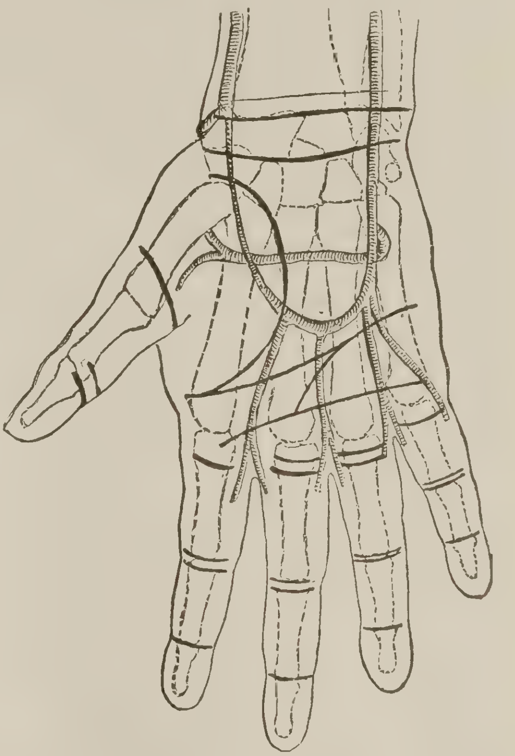

Fig. 2444.—Surface Markings on the Palm of the Hand. The thick black lines represent the chief creases on the skin. (Altered from Treves.)

The hand, being the servant of the mind, is modified and changed according to the use to which it is put; hence, say the palmisters, this organ is the appropriate index of character, and the lines of the hand, caused by the nervous influences actuating different muscles, and the tension and stress exerted on the skin, must be, if truly interpreted, a most significant guide. A little reflection will show that the modern disciples of palmistry have fallen into the same error as have the physiognomists and phrenologists, in that they expect to obtain exact and detailed particulars by examining physical characters which are highly generalized, being the result of a great number of separate physiological processes and acts.

Certain general notions as to bodily constitution, use, and adaptability can undoubtedly be made out upon the inspection of the hand; but there appears to be no warrant for any exact details. The principal lines are shown upon Fig. 2444.

---

* Iago says of Desdemona: "Didst thou not see her paddle with the palm of his hand? Lechery by this hand, an index and obscure prologue to the history of lust and foul thoughts."

It will be seen that they form, rudely, the letter *M*. The one running around the ball of the thumb and marking off the thenar eminence was known to the old chiromants as the linea vitalis, or line of life. Measurements along this, made by describing arcs of circles from the several mounts, were believed to represent different periods of life, and any break in the line at the points where these crossed was said to indicate sickness or death at that period. This, gravely set forth in all recent works on palmistry, also appears in books of the sixteenth century, and probably farther back.[9] This fold, with another which occasionally occurs running from the wrist toward the finger, centrally through the palm, and called the saturnine line, or linea fortunæ, indicates to an anatomist only the action of the adductor pollicis in drawing the thumb over, and is deep or almost entirely absent as the thumb has great or little flexion. The statement is made by Langer,[10] that the saturnine line is not found in any but those of pure Caucasian race. As it is well marked in the chimpanzee, this seemed open to doubt, and the author has examined the hands of several negroes to ascertain if the statement had any foundation. In all those examined it showed with great clearness, even better than in whites.

From the radial border of the hand, near the upper end of the linea vitalis, arises the linea cephalica, or head line, which passes obliquely across the palm, disappearing near the ulnar edge. The value of this line to a surgeon is considerable, as, where it crosses the fourth metacarpal bone, it marks the superficial palmar arch (see Fig. 2444).

The arch may in some individuals be seen to pulsate strongly at this point. The commencement of the line indicates the metacarpo-phalangeal joint of the index finger. It appears to be caused by the flexion of the four fingers, and corresponds rather closely to the origin of the lumbricales from the flexor tendons.

Another line, not so extensive, is the linea mensalis, or heart line, which extends across under the mounts at the bases of the third, fourth, and fifth fingers. It is a little behind the metacarpo-phalangeal joints, and expresses flexion there of the three outer fingers, which usually act together. The name mensalis was given it because the names of the mounts were also names of months.

Besides the lines described, a number of others are mentioned by the chiromants, and in some hands there is a complete network. These might be of value for the purpose of proving personal identity in medico-legal cases. The occupation of the individual may occasion marks, callosities, and discolorations of the skin, alterations of the nails and hairs, formation of special bursæ, and even changes in the articulations, muscles, and bones, which are of importance in determining identity. The limits of this article will not permit of a full treatment of this subject, which has been very carefully examined by Vernois.[11] The shape of the hand may be permanently altered by the use of tools. The epidermis of the horny hand of a laborer may be so thick as to prevent the eruption of an abscess. The subcutaneous connective tissue of the palm is composed of short and thickly set fibrous bands, which firmly unite the skin with the deep fascia, forming partition walls of little chambers which contain fat. When the tissue is cut through, these little adipose masses, released from their confinement, extend beyond the edges of the wound. This arrangement secures a considerable degree of elasticity and protection. Abscesses do not usually point under thicker parts of the subcutaneous tissue, but seek the ball of the thumb and the hypothenar eminence.

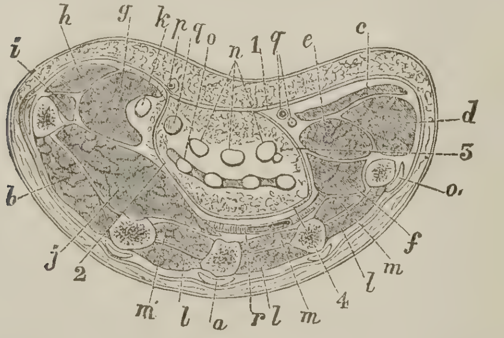

FIG. 2445.—Horizontal Section of the Hand through the Middle of the Thenar and Hypothenar Eminences. (Tillaux.) *a*, Metacarpal bone; *b*, first dorsal interosseus; *c*, palmaris brevis; *d*, abductor min. digiti; *e*, flexor brevis min. dig.; *f*, opponens min. dig.; *g*, flexor brevis poll.; *h*, abductor poll.; *i*, opponens poll.; *j*, adductor poll.; *k*, flexor long. poll.: *l*, dorsal interossei; *m*, palmar interossei; *n*, flexor sublimis: *o*, flexor profundus; *p*, superfic. volæ; *q*, median nerve, and (on inner side) ulnar artery and nerve; *r*, deep palmar arch; 1, palmar fascia; 2, outer septum; 3, inner septum: 4, deep fascia of palm.

The deep fascia is a strong and firm sheet, triangular in shape, the palmaris longus, its tensor, being inserted at the point of the triangle. Indeed, so continuously are the two united, that we may properly consider the fascia to be an expansion of the tendon. It occurs, however, when the muscle is wanting. Opposite the fingers it splits into four processes, which are inserted by these slips at the bases of the fingers and into the sheath of the flexor tendons and the first finger-joint. Acting through these slips, the palmaris acts therefore as a flexor of the fingers. A chronic shortening of this sheet is known as Dupuytren's contraction, and is always accompanied by a permanent bending of fingers. The little finger and ring finger are most affected; the thumb never, as it receives only a very insignificant slip of the palmar fascia.

A band of fascial fibres stretches across the roots of the fingers, and is known as the superficial transverse ligament. A thin fascia also separates the interosseous muscles from the rest of the palm. The metacarpal bones of all the fingers except the thumb are bound together at their lower ends by a strong strip called the transverse metacarpal ligament, and processes extend between this and the palmar fascia, making thus distinct chambers through which pass the flexor tendons as they go down to the fingers. It is through this passage that suppuration extends from the fingers into the palm.

Another series of orifices at the sides of the fingers permits the collateral vessels and nerves and the tendons of the lumbricales to reach the fingers.

The structures beneath the palmar fascia are contained in three compartments, which are separated by intermuscular septa; one (see Fig. 2445), external, separates the muscles of the thenar eminence and becomes continuous below with the sheath of the adductor pollicis, passing with it to be inserted into the third metacarpal; the other, internal, is attached to the anterior border of the fifth metacarpal, separating off the muscles of the hypothenar eminence. The middle compartment is the most important, as it contains, besides the flexor tendons and their accessory muscles, the vessels and nerves of the palm. The following table (on page 485) gives the principal facts regarding the muscles of the palm, as stated by the best authorities.

It should be noted that between the two heads of the flexor brevis pollicis the tendon of the long flexor of the thumb passes, lying in the groove of the trapezium. The deep head of this muscle (supplied by the ulnar nerve), as usually described, should rather be called a portion of the adductor pollicis, with which it is somewhat closely allied. The palmaris brevis probably, by its contraction, assists to protect the ulnar artery and nerve, which pass directly under it. When the fist is firmly clenched, this muscle assists in tightening the palmar aponeurosis, and its situation is marked by a little hollow on the ulnar side of the hand. It is not usually capable of independent action, but the author has found some persons who had the power to move it at will, thus wrinkling the skin. It appears to be a muscle derived from the panniculus carnosus, like the small muscles of the face.

	Origin.	Insertion.	Innervation.	Action.
THENAR MUSCLES.				
Abductor pollicis.......	Trapezium and annular ligament.	Base first phalanx of thumb.	Median...........	Abducts and rotates thumb and extends second phalanx.
Opponens pollicis......	Trapezium and annular ligament.	Metacarpale I. along whole length.	Median...........	Brings first metacarpal forward and rotates it inward.
Flexor brevis pollicis...	Trapezoid, os magnum, and metacarpales II. and III.	Base first palanx of thumb, with sesamoids.	Outer head median. Inner head ulnar.	Flexes and rotates first phalanx of thumb.
Adductor pollicis.......	Shaft of metacarpale III.	Base first phalanx of thumb.	Ulnar............	Adducts thumb.
HYPOTHENAR MUSCLES				
Abductor minimi digiti.	Pisiform and tendon flexor carpi ulnaris	Base first phalanx digit V., with slip to extensor tendon.	Ulnar............	Draws little finger away from others.
Opponens minimi digiti.	Annular ligament and unciform.	Ulnar border metacarpale V.	Ulnar............	Draws little finger forward, narrows hand, and deepens hollow.
Flexor brevis minimi digiti.	Annular ligament and unciform.	Base first phalanx digit V.	Ulnar.............	Keeps phalanx firmly down in grasping.
Palmaris brevis........	Palmar fascia and annular ligament.	Skin of inner border of palm.	Ulnar............	Draws up integument on inner side.
MEDIAN MUSCLES.				
Lumbricales...........	Radial sides of tendon of flexor profundus digitorum.	Radial sides of tendons of extensor communis digitorum and first phalanges.	First two by median, last two by ulnar.	Extensors of last two phalanges, flexors of first phalanges when these are semiflexed by the dorsal interossei. The first and second are abductors and rotators, the third and fourth adductors and rotators.
Palmar interossei......	Metacarpales II., IV., and V.	Bases of first plalanges digit. II., IV., and V.	Ulnar............	Extensors of last two phalanges, adductors and rotators, flexors of first phalanges.
Dorsal interossei........	Adjacent sides of metacarpals, more particularly upon those of the finger where insertion occurs.	Base of first phalanges digit. II., III., and IV., and to extensor tendon.	Ulnar............	Flexors and abductors of first phalanges, and in slight degree rotators. The third extends last two phalanges.

The lumbricales are so called because of their round, worm-like appearance. The old anatomists, because of their use in flexing and extending the fingers, called them fiducinales, or fiddler's muscles.

Duchenne[12] noticed that in persons who were suffering from lead paralysis, and had therefore no control over the extensor muscles supplied from the musculo-spiral nerve, there was still some power of extension in the second and third phalanges. The statement made in the table as to the action of the lumbricales is that of Adam,[13] founded upon observations made on the cadaver, and with electrical excitation with special instruments.

Fig. 2446 shows the manner of insertion of the lumbricales, as well as that of the interossei and the flexor tendons.

Besides the muscles mentioned in the table, the tendons shown in Fig. 2446 lie in the hollow of the hand. As they approach the fingers, the tendons of the superficial flexor lie immediately upon those of the deep, and in fact embrace them in a groove upon their under surface, this groove deepening until it at last becomes a slit through which the tendons of the deep flexor pass. It is therefore impossible to cut the tendons of the superficial flexor without at the same time cutting those of the deep flexor.

The back of the hand is convex, and shows plainly the metacarpal bones. When laid upon a flat surface, it is comparatively flat, but when the flexor tendons act they pull the bones together in such a way as to increase the convexity. The adaptability of this for the purpose of firmly seizing objects may be seen by reference to Fig. 2449. When the fingers are extended and spread apart, the extensor tendons shown in Fig. 2447 are well displayed.

Shallow furrows appear between the tendons, and at the lower part of the dorsum the heads of the metacarpal bones become prominent. At the base of the fingers the skin becomes thinned out into an interdigital web semilunar in shape. The web between the thumb and the index finger is thicker and more marked than elsewhere, because it contains in front the adductor of the thumb where it becomes free from the first dorsal interosseous muscle, which covers it in the upper part of the interspace. As the skin and fascia on the dorsal surface of the web are thinner than on the palmar, abscesses of the palm which reach the base of the fingers usually discharge behind.

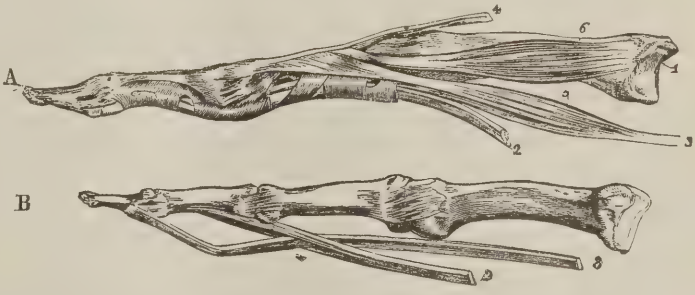

FIG. 2446.—Bones of Two Fingers, with the Insertions of the Tendons. (R. Quain.) In *A*, the tendons of the flexor muscles are bound to the bones by the fibrous sheath. In *B*, the sheath has been removed, as well as the vincula accessoria; 1, metacarpal bone; 2, tendon of the flexor sublimis: tendon of the flexor profundus; *, perforation of the sublimis by the profundus tendon; 4, tendon of the extensor communis digitorum; 5, lumbricalis muscle; 6, one of the interosseous muscles.

The skin of the dorsum is in many respects the opposite of that of the palm, being thin, easily movable, hairy, especially toward the ulnar side, and but slightly sensitive. Œdema is much more quickly shown here, the subcutaneous tissue being loose and numerous veins course through it. Some idea can be obtained of the tonicity of the vascular walls by noting their visibility through the skin. They vary much, however, in different individuals.

The deep fascia forms the sheaths of the tendons as they pass down. These tendons are arranged in two sets, which may be said to represent a superficial and a deep extensor similar to the arrangement of the flexors. To the superficial extensor belong the tendons of the extensor communis and the extensor minimi digiti, which pass down under the annular ligament almost vertically, diverging to their respective insertions after reaching the dorsum. The tendons of the communis, which go to the last three fingers, are united by oblique bands. This restricts the motion of the ring finger to a considerable degree, and it cannot be fully extended when the third or fifth digit is held firmly flexed. Subcutaneous section of these bands is sometimes resorted to for the purpose of giving pianists more independent movement of the ring finger. To the deep extensor set belong those muscles which, arising lower down upon the forearm, run somewhat obliquely across the others to be inserted into the index finger and the thumb. These are the three extensors of the thumb and the extensor indicis. Many varieties occur which confirm this view. In apes the extensor indicis also supplies the middle finger, and sometimes the ring finger as well. The extensor secundi internodii pollicis (which should be called extensor longus pollicis) also sends a tendon to the index, and sometimes to the medius. Similar variations occur in man. Koster[14] found the tendon of the indicis and the long extensor of the thumb united by a cross band like those which appear on the tendons of the common extensor.

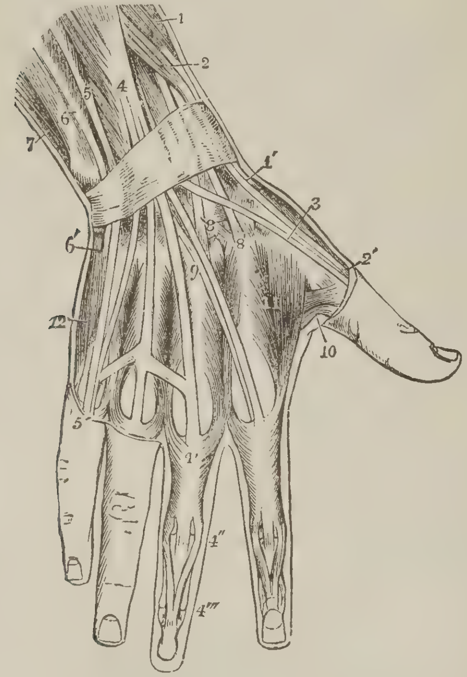

FIG. 2447.—Superficial Muscles and Tendons on the Back of the Wrist and Hand. (After Bourgery.) The posterior annular ligament of the wrist is represented. 1, Extensor ossis metacarpi pollicis; 1′, its insertion; 2, extensor primi internodii pollicis; 2′, its insertion; 3, tendon of extensor secundi internodii pollicis; 4, extensor communis digitorum; 4′, tendon of the middle finger receiving the insertion of the second and third dorsal interosseous muscles; 4″, division of the tendon into three portions, of which the median is inserted into the second phalanx, the two lateral passing on to be inserted at 4‴ into the terminal phalanx; 5, extensor minimi digiti; 5′, its junction with the slip of the common extensor; 6, placed on the lower end of the ulna, points to the extensor carpi ulnaris; 6′, insertion of this muscle into the base of the fifth metacarpal bone; 7, part of the flexor carpi ulnaris; 8, placed on the os magnum, points to the insertion of the extensor carpi radialis brevior; 8′, placed on the base of the second metacarpal bone, points to the insertion of the extensor carpi radialis longior; 9, tendon of extensor indicis; 10, small part of the adductor pollicis, and inner head of the flexor brevis pollicis; 11, first dorsal interosseous or abductor indicis; in the other three interosseous spaces are seen in succession, from the radial side inward, the insertion of the first palmar, second dorsal, third dorsal, second palmar, fourth dorsal, and third palmar interosseous muscles; 12, abductor minimi digiti.

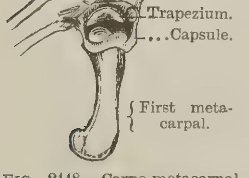

FIG. 2448.—Carpo-metacarpal Joint of the Thumb.

The bones of the middle hand are the five metacarpals, each concave toward the palm, and having a somewhat prismatic shaft with two enlarged extremities. Closely applied at the bases they spread along the shaft so that they never touch there, while again at the lower end they can be brought together. There is thus left room for the interossei muscles. The first metacarpal is an exception, as, in order to preserve the independence and opposability of the thumb, the base is set over and in front of the line of the others, and its distal end is not confined by ligaments. Since it is shaped more like a phalanx than like the others, anatomists have not failed to add this to other evidence which has been adduced to prove that the thumb has no true metacarpal. The joint by which it articulates with the trapezium is a saddle-joint, the movement being free in two planes, viz., that of flexion and extension, and that of adduction and abduction. It is not, however, limited to these, as circumduction can take place quite easily. There is no rotation. The capsule is thick and strong, and dislocation is very rare.

The situation of the joint is easily made out by running the finger upward along the shaft of the bone until it reaches the process at the base, immediately above which is the articulation. The process is made more prominent by strongly flexing and adducting the thumb, and the interarticular line can then be easily made out in most individuals. The other metacarpals are united to the wrist bones and to each other by articulations which are fixed by means of interosseous ligaments, which make their disarticulation very difficult. The fifth joint has the most movement.

The rounded lower ends of the metacarpals are of importance in forming an arch which strengthens the hand. For this reason they should be preserved in amputating the fingers, when it is possible to do so. The articular surfaces here are directed in such a manner as to have the planes of movement converge toward the middle of the hand. This greatly increases the power of grasp of the phalanges, as the tighter the fingers close the more strenuous becomes the lateral pressure. The convergence of the flexor tendons assists this. The extensor tendons pass over the most prominent part of the metacarpal heads behind. The third metacarpal, though not the longest, has its head more prominent, and is usually the one which receives injury from striking heavy blows.

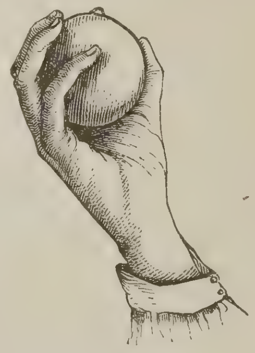

FIG. 2449.—The Length of the Fingers as Adapted in Grasping. (Humphry.)

THE FINGERS.—The anatomical names of the five digits or fingers are the pollex or thumb, indicis or index, medius or middle finger, annularis or ring finger, and auricularis or little finger, the latter presumably so called because of its use in cleaning the meatus auditorius. They are of notably different length, but somewhat nicely adjusted to the functions of grasping, as will be seen on holding a ball in the hand, as shown in Fig. 2449. The middle finger is the longest and has, therefore, the longest circumference to span, and the others are so adjusted, as to length, that they come very nearly to the same level at their tips. For this reason all tools which are to be grasped by the hand should have a swelling in the handle opposite the middle, so as to insure a good grip.

The usual arrangement as to length of the fingers is that in the extended hand the thumb does not quite reach the second phalanx of the index, the medius is longer than the annularis by half a nail, and the auricularis reaches only to the last phalanx. There is considerable variation in the length of the index. In about two-thirds of the cases (Mantegazza[15]) the index is shorter than the annularis, reaching only to the root of the nail of the medius. In others the two fingers are nearly of the same length, and rarely the index exceeds the annularis in length. Ecker[16] considers the shortness of the index to be a characteristic of apes, and thinks that when relatively longer it is an attribute of a higher form of hand. He finds it longer in women, who show in this, as in many anatomical features, signs of a purer morphological form. Carus[4] does not mention the length of the fingers, but figures what he calls, after d'Arpentigny,[3] the idealistic hand (seelische Hand, main psychique), which shows a long index. It is noticed by Hyrtl[17] that the apparent length of the ring and index fingers may be influenced by the posture of the hand. If the hand is laid flat, so that the axis of the medius corresponds with that of the entire arm, the index usually appears a little shorter than the ring, but abduct the hand, and the ring finger will appear a whole nail's length longer. Grüning[18] has recently given the results of two hundred observations very carefully taken. He finds that the ring finger is usually the longer, yet the reverse is not uncommon, and more frequent in females. In the foot the second toe is usually the longest, but a greater length of the big toe is not rare, also more frequent in females. This lends some support to the theory that the foot has no digit homologous with the thumb.

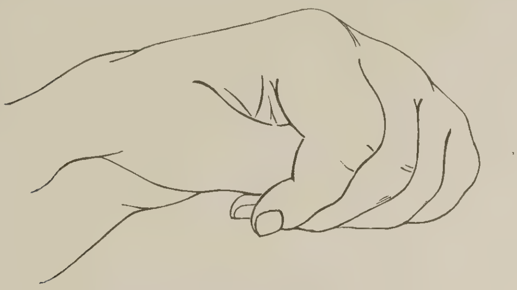

FIG. 2450.—The Convulsive Hand. (Warner.[21])

The general relation of the middle finger to the rest of the hand is expressed by Langer[10] as follows: If a measurement be taken from the os magnum to the end of the finger, the various parts, as measured from the angles at the joints made by flexion, will be in the proportion of 8 : 5 : 3 : 2, that is to say, the middle hand is as long as the three other portions, and the basal phalanx is as long as the middle and ungual together. The length of the entire hand has been used by artists as a canon of proportion for the whole body, being set at one-ninth of the whole height. The Egyptian canon seems to have been based upon the length of the index, which was reckoned as one-nineteenth of the height. Many measures used as rough estimates are taken from the hand: the length of the middle finger from knuckle to point is reckoned as one-eighth of a yard, and from the tip of the thumb nail to the second joint as about half of that, and is called one nail. The breadth of the hand is used as a measure for horses, and is reckoned at four inches. The breadth of the thumb is the pouce or inch of the old French measures. Of course all these are liable to vary because of individual peculiarity.[19]

It should be noted that the proportions of the hand to the entire height are attained very early, at least by the fifth year (Quetelet[20]). The member appears to have the same early physical development that the brain has, and the hand of the new-born child is structurally that of the adult, differing only in size.

The thumb has from very early times held the place of honor among the digits, as the loss of it deprived the hand of much of its power. It is especially by the superiority of the thumb that man's hand is distinguished from that of the higher apes. There are no less than eight muscles attached to it, and this gives a freedom and variety of motion which is not possessed by any other digit. To cut off the thumb was an old method of disabling an enemy, by preventing him from properly using his weapons, and soldiers sometimes resorted to this mutilation to exempt themselves from military duty —as those of our own time have been known to amputate the terminal phalanx of the index to unfit themselves for pulling the trigger of a gun. It is from this custom that the word poltroon is said to have arisen, being a corruption of *pollice truncus.* The palmisters exalt the thumb far above the other digits. D'Arpentigny says: "*l'Animal supérieur est dans la main, l'homme est dans le pouce.*"

The Esquimaux tradition is that woman was originally formed from the thumb of man. The thumb was used by the spectators of Roman gladiatorial combats to indicate whether the conquered party should die or live. In La Vendée a large thumb indicates a predilection for the black art, and to bite the thumb is a grave insult in Scotland and Italy.*

The unusual strength of the muscles which are attached to the thumb, making it an efficient portion of a pair of forceps when applied to the other fingers, leads also to its being affected by convulsive action. In almost all cases of this kind the thumb is firmly clenched and drawn into the palm (see Fig. 2450). This may be of service as a medico-legal sign, as it is almost always found in those who have died a violent death, and consequently suffered spasmodic contraction of the muscles during the last agony.

The index or pointing finger has been called the gynæcologist's eye. It is somewhat more sensitive to tactile impression than the others, and, being supplied with special muscles, it is particularly serviceable as the antagonist of the thumb. It is always best to preserve this finger and the thumb, if possible, in injuries to the hand, as by themselves they make quite a serviceable organ.

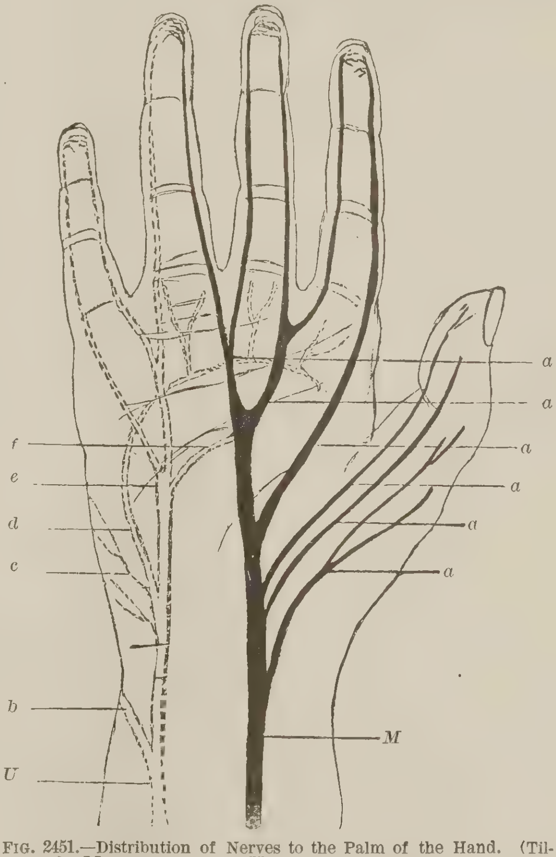

FIG. 2451.—Distribution of Nerves to the Palm of the Hand. (Tillaux.) *M*, Median nerve; *U*, ulnar nerve; *a*, *a*, *a*, *a*, *a*, *a*, collateral branches of the median nerve; *b*, dorsal branch of the ulnar nerve; *c*, muscular branches; *d*, superficial branch; *e*, deep branch; *f*, anastomotic branch.

---

* Vide Romeo and Juliet, Act I., sc. 2. "I will bite my thumb at them, which is a disgrace if they bear it."

The ring finger, or annularis, is so called from the fact that it has been customary, since the time of the Romans, to carry rings upon it. This has been said to originate in the fact that they supposed it to be especially connected with the heart, either because it is supplied by two nerves (see Fig. 2451), or more probably because the vena salvatella runs prominently from it up the arm. Owing to the connection of the tendons this finger is somewhat protected by those beside it, and consequently is less liable than the others to injury, and this affords ample reason why it, as well as the left hand, should be chosen to wear the ring. The old anatomists called it the digitus medicus, because they were accustomed to mix medicines with it.

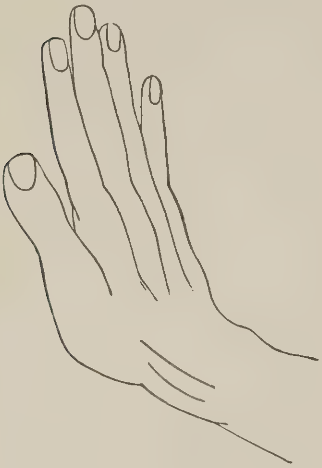

FIG. 2452. — The Hand in Fright. (Warner.)

Upon the palmar face of the fingers are seen certain transverse furrows, well marked. These are important guides to the joints and should be well noted (see Fig. 2444). They are not correctly given in any of the books on palmistry which the author has consulted, which shows that in point of accuracy their "science" leaves something to be desired. The folds nearest the palm are single for the index and little fingers, double for the others. They do not correspond exactly to the metacarpo-phalangeal joints, but are three-fourths of an inch below. The middle folds are double and exactly opposite the joints, the lower folds are all single and a trifle above the joints. Upon the thumb there are also three folds, the upper and lower folds correspond to the joints very nearly, the middle one having no topographical significance. The skin on the fingers is remarkably rich in papillæ; the number of these containing nerves increases as we proceed toward the finger tips. These papillæ, both on the fingers and palm, are arranged in lines forming characteristic curvilinear ridges. Upon the eminences formed by the pulps of the fingers and the eminences of the palm these are arranged in elliptical or spiral patterns, and it has been seriously proposed to use these as a means of identifying individuals. In certain cases they have been of service. Faulds[22] mentions that by means of finger marks upon a greasy glass it was ascertained who, among a number of servants, had been drinking some rectified spirit; and another case, in which a criminal was detected by an impression of sooty finger marks on a white wall. He considers that the Mongolian races have a special and characteristic pattern. The city authorities of San Francisco recently considered the propriety of registering all the Chinese who arrived at the port by taking an impression of the thumb. It is said that the legal expression "my hand and seal," arose from the custom of sealing papers with the thumb.

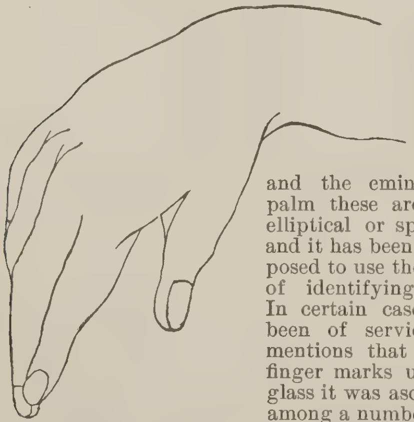

FIG. 2453.—The Feeble Hand. (Warner.)

Beneath the skin the subcutaneous tissue is like that of the palm—a series of little cushions of fat. On the last phalanx this is called the pulp of the finger. Still deeper is found the canal for the flexor tendons. The fibres of this sheath are less thick opposite the joints, so as not to impede flexion. They are continuous above with the palmar fascia. The canal contains in the thumb only the tendon of the long flexor, in the other fingers the tendons of the superficial and deep flexors. They are united to the sheath by small bands termed retinacula. Opposite the first phalanx the flexor sublimis splits and the two halves fold around the deep flexor, again uniting behind it by their margins. They then separate and are inserted into the second phalanx (see Fig. 2446, *B*). The deep flexor is inserted into the terminal phalanges. Some persons have power to use it independently.

On the dorsal surface of the fingers the skin forms elliptical folds at the articulations of the first and second phalanges, and simply a few transverse folds at the articulations of the second and third. Under the skin the extensor tendons form a broad aponeurotic sheet into which the expanded tendons of the lumbricales and interossei are inserted. This sheet terminates with the insertion of the extensor into the last phalanx.

The nails which terminate the digits are, as is well known, really epidermal elements. They are found in the embryo at about the third month of pregnancy. Their growth is always from the root, and the rate at which they grow can frequently be noted by the spots which occur upon them, and thus a general notion may be obtained of the vigor of the processes of nutrition.

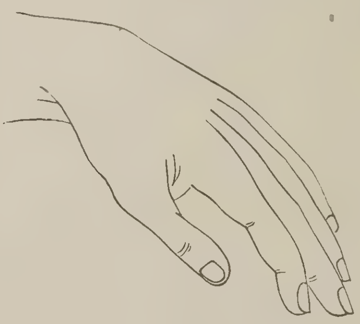

FIG. 2454.—The Tonic Hand. (Warner.)

The joints of the fingers have a general resemblance to each other, the metacarpo-phalangeal being merely a little broader. The ends of the phalanges broaden out somewhat at their extremities, and when the body becomes emaciated, as in a wasting disease, these ends become very prominent, and the disorder known as clubbed fingers results. At the metacarpo-phalangeal joint of the thumb there are two sesamoid bones, which are believed to be one of the causes of the difficulty of reducing a dislocation at that joint. Similar structures, usually cartilaginous, however, are found on the palmar surfaces of each of the phalangeal joints. In negroes, or in those laborers who use the hands much for heavy work, they may all be ossified, as they are in the forefoot of a bear. The articulations are all imperfect hinge joints, having lateral ligaments and a thickening of the capsule on the palmar surface. It should be remembered that the articular line is always found beyond the angle formed by the flexion of the phalanges.

The nerves of the hand are three in number. Their distribution to the palmar surface is shown in Fig. 2451, and the muscles they supply are mentioned in the table on page 485.

To those mentioned there should be added those which come down from above. Of these the flexors are supplied by the median and ulnar, the extensors by the radial. The ulnar supplies the flexor carpi ulnaris and the principal part of the deep flexor, leaving to the median that portion which goes to the index finger, which might, therefore, properly be classed as a separate muscle.

After section of the median nerve a considerable movement is left to the fingers, pronation being effected by the shoulder muscles acting on the arm, flexion of the wrist by the flexor carpi ulnaris, the first phalanges flexed by the interossei, the others by the deep flexor. The thumb suffers most, and we may, accordingly, say that the median nerve especially presides over the movements of that digit.

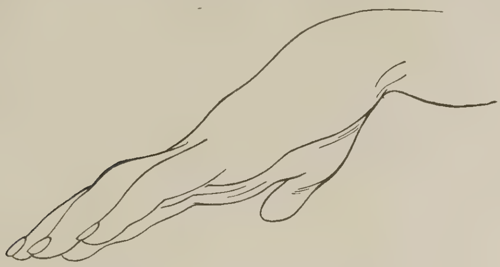

FIG. 2455.—The Nervous Hand. (Warner.)

In the same way as motility is not entirely lost, so also is sensibility retained to some extent. The anæsthesia does not correspond with the distribution of the nerve. The reason for this is believed to be found in the collateral branches which run from the ulnar to anastomose with the median. There is no doubt that the anæsthesia after section continues to grow less, and it has been suggested that when certain parts are disabled, other nerves may send out filaments from the fine plexus into which the nerves break up before going to supply the papillæ, in order to supply the need.

The correlative action of the muscles and nerves has a very marked result upon what may be called the physiognomy of the hand. Warner[21] has carefully studied this subject, and describes, among others, the following types, which relate to the expression of the emotions: The convulsive hand (Fig. 2450), in which the thumb is forcibly and violently adducted, the fingers are pressed closely together and semiflexed on the thumb, the hand assuming a conical shape. The opposite of this is the hand in fright (Fig. 2452), the phalanges and the wrist being extended. The whole attitude is that of repelling an abhorrent object. In pure horror, not accompanied by fear, the hands are thrown widely back, the arms uplifted, the fingers open. A passenger upon a train that ran over a man told me her first intimation of an accident was seeing through the window a person assume this attitude as the train shot past. The convulsive wringing of the hands is an expression of quite an opposite order, indicating intense and continued painful emotion, and instead of the hand-washing motion performed by tragic actors, is, when genuine, a passing of one hand down the other, with a convulsive twist at the ends of the fingers.

The feeble hand (Fig. 2453) is indicated by a dropping of the thumb and a bending of the phalanges.

The tonic hand in rest (Fig. 2454) is like this, but differs in the degree of the action. The nervous hand (Fig. 2455) has the wrist slightly bent, and the metacarpophalangeal joints hyperextended, and the first and third internodes slightly flexed.

The energetic hand (Fig. 2456) is the opposite of this, the wrist being extended and the small joints in flexion.

The vessels of the hand have recently been the subject of careful study by Bourceret,[24] and he has arrived at some conclusions which seem important and new. By a very ingenious process, and using a series of injections, he has been able not only to fill the entire arterial and capillary system, but the venous system as well, injecting from the heart outward, notwithstanding the valves.

The arrangement of the arteries has already been alluded to. The radial and ulnar form, as shown in Fig. 2444, two arterial arcades known as the superficial and deep palmar arches, the first of them being made by the radial and the deep branch of the ulnar. To these may be added a third arch over the back of the wrist, formed by collateral branches of the two trunks. From these arches pass branches which supply the fingers, being of considerable size throughout their length, even to the last phalanges, and not accompanied by venæ comites. The object of this excessive vascular supply is not only the nutrition of the fingers, but also to maintain the bodily warmth there. They communicate by two sets of capillaries, one small and intended for nutrition only, the other large and intended for increasing the heat. These capillaries are arranged in very complicated tortuosities, like little balls of tangled thread. They open immediately into the veins, which are also remarkable for their flexuosities. Any consideration of the hand would be incomplete without some remark concerning the separate use of the two hands. Right-handedness, or rather right-sidedness, for the matter is not by any means confined to the hand, is the rule among all races of men, and some traces of it may be seen in the animal creation. The elephant, for example, is said to use the right tusk more than the left, and this is accordingly called the servant tusk.[25] Left-handedness is the exception, occurring in about nine per cent. of individuals. Many attempts have been made to explain this, and Franklin's[26] plea for the left hand, and Charles Reade's essay[27] upon the injury mankind inflicts upon itself by the continuous use of the right, are well-known curiosities of literature. It appears, however, that there is reason to suppose that we have, in dextral preference, merely a further differentiation like that which has resulted in the development of the feet and hands from four originally similar organs. The left hemisphere of the brain appears to be assuming control of the more complicated motor functions performed by the right side of the body, while the right hemisphere attends more especially to the nutritive functions through the sympathetic system. It is noted that the senses of temperature and of weight are usually more acute in the left hand. Perhaps this is in some degree due to its less frequent use. Granting this, we have to search for the origination of the tendency. Hyrtl[17] supposes it to arise from the fact that the innominate artery carries more blood to the right side. Dwight and others[28,29,30] think it depends upon the situation of the left carotid at the top of the arch, surmising that it receives a swifter current of blood, which goes to the left brain, controlling the left side. Blumenbach supposed that it was due to a deviation of the innominate artery to the left. Breschet thought that there was an innate tendency to a predominance of nutrition on the right side in fœtal life. The right side of the spine develops first and so throws the heart to the left. Comte[31] suggests that it is due to the fact that the fœtus in utero lies usually on the left side, owing to the obliquity of the pelvis, and that this occasions a precocity of development of the right side. The percentage of left-handed persons is about that of presentations where the fœtus lies on its right side.

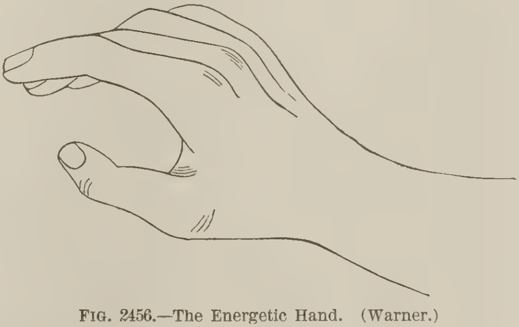

FIG. 2456.—The Energetic Hand. (Warner.)

An ingenious explanation is offered by Buchanan,[32] who holds that the centre of gravity lies on the right side owing to the weight of the liver, and that this causes a greater development of the muscles there. It is possible that several of these causes may have had an effect upon the matter. An efficient cause may be found in the situation of the heart upon the left side. A savage soon learns that his enemy is vulnerable there, and takes pains to protect himself by withdrawing the left side and using the weapon with the right. The constant persistence of this use of the right arm as the weapon-bearing member has probably resulted in organic dextral preference, and left-handedness may be considered an atavism.

HANDS AND FINGERS, DISEASES AND DEFORMITIES OF.—The hand is such an important and essential factor in the practical economy of life that the pathological conditions to which it is subject and which tend to impair its usefulness form an important field of medical science and practice. It is a topographical region so well marked off, and is subject to such special pathologic and etiologic factors, that the morbid conditions which affect it make up quite a distinctive and well-marked group of diseases. The diseases to which the hands and fingers are subject comprise a considerable variety of conditions, diverse in their nature and cause, with the only element of unity resting in their common site. A comparative consideration of all these various conditions may prove of advantage in questions of differential diagnosis; and some of the rarer affections may be pointed out which from not being often observed may prove puzzling when cases are met with.

Special Pathological and Etiological Factors.—The hand exhibits a number of characteristics that exert special influences in determining and bringing about the morbid conditions to which it is subject.

Among these special causative factors is the peculiar anatomical construction of the hand. The hand is essentially a delicate motor mechanism and arrangement of joints, ligaments, tendons, and the like, all so nicely adjusted that slight impediments (as in trigger finger) may result in material deformity or impairment of function.

Another condition that subjects the hand to certain forms of disease is its use and its exposed situation, rendering it especially liable to mechanical, traumatic, atmospheric, irritative, and other influences. The constant usage of the hand incident to various occupations produces corresponding reactions and morphological and pathological consequences, as in writer's cramp and the stiffening and hardening effects of manual labor. The hand is much exposed to injuries, mechanical, chemical, thermic, while its being habitually uncovered by clothing and thus exposed to meteorological and other irritative influences makes it subject to certain skin affections.

The situation of the hand at a distance from the circulatory centres is another factor that gives rise to various pathological conditions. The great distance of the hand from the heart causes a relative weakness of the circulation in this member, which results in the occurrence of circulatory disturbances like stasis, clubbed fingers, œdema, and Raynaud's disease in this locality.

Its distant situation also renders the hand liable to suffer consequences of injuries or lesions primarily located at points between it and the trunk or the bodily centres. The motor mechanism of the hand is located chiefly in the forearm, while the vascular and nervous trunks that supply it course along the entire upper extremity, so that diseases or injuries of any of these structures in any part of their course may result in morbid conditions seated in the hand.

Other conditions there are which affect this region exclusively or peculiarly, for physiological reasons that, though obscure or unknown to us, are yet real and operative. These may be regarded as idiopathic pathological factors and diseases of the hand, exemplified by Dupuytren's contraction.

Classification.—The affections of the hand and fingers include those that are peculiar to or affect this region exclusively; those that may occur elsewhere, but show a predilection for, or exhibit special features or modifications in, this locality; those conditions affecting the hands equally and indifferently with other parts of the body; and the manifestations, exhibited by the hand, of general disease. The conditions of most pertinence to the present subject are those more or less peculiar to the hand or those that exhibit special features in this locality.

It is not easy to formulate a completely satisfactory and logical classification of all the affections of the hand and fingers on any uniform basis. There are several grounds on which classification may be based, but no one of them alone in the present state of our knowledge is sufficient to afford a practical and adequate classification.

From one standpoint a division can be made, with reference to the manner in which the etiological factors are brought to bear, into conditions arising: from local causes, either external or internal; from extension (by continuity or contiguity) from neighboring structures that are affected; from causes (nutritive, toxic, metastatic) brought to bear through the medium of the circulation; or from impressions derived from the nervous system. The difficulty with a strictly etiological classification consists in the fact that identical pathological conditions may result from very different causes.

Another basis of classification of diseases of the hand rests upon their pathological nature, as parasitic and infectious conditions, neoplasms, traumatisms, senile conditions, etc. The adequacy of such a classification is impaired by our ignorance of the essential pathological nature of many obscure affections. Another division is to be found in the different regions, tissues, and anatomical structures involved, as the affections of the nails, the fascias, the skin, the ligaments, the joints, etc. This division applies well in many cases, but in those conditions in which more than one set of tissues or structures is involved a satisfactory arrangement would be difficult.

The considerations mentioned enable us to mark off some well-defined groups of diseases of the hand, while other morbid conditions are not easily susceptible of classification. The following arrangement of the diseases and deformities of the hand and fingers will be followed in this article:

- Congenital and developmental anomalies:
    - Acheiria.
    - Ectrodactylism.
    - Hypophalangism.
    - Polycheiria.
    - Polydactylism.
    - Polyphalangism.
- Syndactylism.
- Cleft hand.
- Congenital constrictions.
- Deflections of the hand and fingers.
    - Club-hand.
    - Congenital deflections of the fingers.
    - Lateral deflections of the fingers.
    - Backward deflections of the fingers.
- Microcheiria and microdactylism.
- Hypertrophy of hand and fingers—cheiromegaly and dactylomegaly.
- Neoplasms.
- Cysts.
- Traumatisms and injuries.
- Inflammatory conditions.
- Infectious and parasitic conditions.
    - Suppurative and allied conditions.
    - Tuberculosis.
    - Syphilis.
    - Other infections and parasites.
- Necrotic conditions.
- Ulcers.
- Cicatricial contractions.
- Acquired deformities.
- Effects of occupation on the hand.
- Affections of the nails.
- Affections of the skin.
- Affections of the bursæ.
- Affections of the bones.
- Affections of the joints.
- Affections of the tendons and tendon sheaths.
- Affections of connective-tissue structures:
    - Dupuytren's contraction of the palmar fascia.
    - Contraction of the digital fascia.
    - Hammer finger.
    - General palmar induration.
- Trigger finger.
- Circulatory disorders.
- Muscular affections.
- Nervous affections.
- Senile changes.
- Condition of the hand in general diseases.

Congenital and Developmental Anomalies.

The class of developmental anomalies in general should include all aberrations or faults of development manifesting themselves at any time during the period of development, including not only conditions arising in the prenatal period (as polydactylism), but also those that make their appearance in childhood and up to the time of maturity and complete physical development (as certain forms of hammer finger). In this section it is proposed to consider only certain congenital abnormalities of the hand which develop during the intra-uterine period of existence.

The anomalies of development under consideration embrace the following conditions:

1. Conditions in which there is a deficient degree of development, either (*a*) a deficiency in the *number* of the structural parts affected, or (*b*) a deficiency in their *size*. The congenital numerical deficiencies pertaining to the hand are: *acheiria*, in which the hand is lacking altogether; *ectrodactylism*, in which one or more fingers are missing; and *hypophalangism*, in which the number of phalanges in a digit is below the normal. The congenital deficiencies in size of the hand and fingers will be considered in connection with microcheiria and microdactylism.

2. Conditions in which there is an excessive development; either (*a*) an excess in the number of structural parts, *polycheiria*, *polydactylism*, and *polyphalangism*, or supernumerary hand, fingers, or phalanges respectively; or (*b*) a congenital excess in size, or hypertrophy, which will be considered in connection with cheiromegaly and dactylomegaly.

3. Conditions of perverted development (qualitative or morphological rather than quantitative); as syndactylism, the union of fingers; cleft hand; congenital constrictions; deflections of the hand and fingers (club hand, etc.); congenital dislocations; congenital neoplasms; and various unclassifiable deformities and conditions.

In many cases anomalies of the types mentioned exist separate and distinct; in many other cases anomalous conditions of different types are associated together and coexist in the same member, as where a supernumerary finger is of rudimentary structure, or a club-hand is ectrodactylous.

Subjects exhibiting congenital anomalies of the region under consideration, especially numerical deficiencies, often exhibit other developmental faults or abnormities in other parts of the body, as harelip or cleft palate, thus testifying to the existence of a deep-seated and general developmental vice. Such anomalies of the hand are especially associated with corresponding anomalies of the foot. In many cases hereditary transmission of the deformity is marked.

The causes of these congenital anomalies are obscure. They arise largely from deep-seated and innate tendencies to aberrant development, often hereditary. The aberrant tendency is sometimes very definite and fixed, precisely the same abnormity appearing in different generations. Some cases may perhaps be due to abnormalities of the early environment of the developing embryo.

Another class of causes that produce congenital deformities of the hand is to be found in intra-uterine traumatisms or other prenatal pathological processes. Thus, intra-uterine amputation may cause loss of the entire hand or parts of it; prenatal ulcerations may be followed by abnormal union or adhesions of parts, as in some cases of syndactylism; deformities may perhaps arise from cicatrization or from adhesions to other parts of the fœtus or afterbirth, or in other ways. Deformities caused by such prenatal morbid conditions are, of course, not real developmental aberrations; but as the results produced in the two ways are rarely distinguishable they may be considered together.

Maternal impressions during pregnancy are sometimes adduced in explanation of congenital anomalies of the hand (as elsewhere); as in the alleged case of an officer's wife, who after her husband lost his right hand gave birth to children exhibiting the same deformity. It is very doubtful if maternal impression really plays any part in the production of such deformities. Some alleged instances are coincidences; others are afterthoughts, a past incident being recalled after the birth of an affected child. Considering the difficulty that is found in demonstrating the hereditary transmission of acquired characters, it is obvious that to prove that a developing fœtus can be influenced by maternal impressions is a matter of far greater difficulty.

The use of the *x*-rays now affords means of investigating and diagnosing the precise condition of the bony parts in these deformities that were lacking to the early observers.

Acheiria, or total congenital absence of the entire hand, occurs very rarely. It might arise either as a developmental abnormity or from intra-uterine amputation. It would naturally occur in connection with a greater or less deficiency in development of the upper extremity, as when the limb is entirely wanting (ectromelia) or is partly wanting (hemimelia). When the upper extremity is only partly developed, it is more usual for a rudimentary hand, or one or more fingers rudimentary or well developed, to be present on the stump than for all trace of a hand to be absent. Typical acheiria may, however, occur, as in a case reported by James Finlayson (*Archives of Pediatrics*, Philadelphia, 1890, vol. vii., p. 674).

Fig. 2459.—Absence of Index, Middle, and Ring Fingers—"pince de homard." (Annandale.)
Fig. 2460.—Absence of Four Digits. (Annandale.)

Phocomelus is the rare condition in which the hand (or foot) is attached directly to the trunk, like the flipper of a seal, the upper (or lower) extremity uniting it to the body being absent or extremely abbreviated.

Ectrodactylism consists in the congenital absence of one or more fingers (or toes), resulting either from defective development or intra-uterine amputation. It is one of the less common forms of congenital abnormity of the hand, occurring considerably less frequently than polydactylism or syndactylism. In the cases that do occur both hands are usually affected simultaneously; less commonly either hand may be affected alone. Other deformities of the hand or upper extremity, or of the foot or other parts of the body, are apt to coexist with ectrodactyly. The finger involved may alone be wanting, the corresponding metacarpal bone being present; or the metacarpal bone may also be lacking; even the corresponding portion of the carpal bones is sometimes wanting. Owing to the association of other deformities and abnormal conditions the fingers present may be useful and functional, or not. The influence of heredity in reported cases is well marked. Some cases of apparent ectrodactylism may arise from intimate union of two digits.

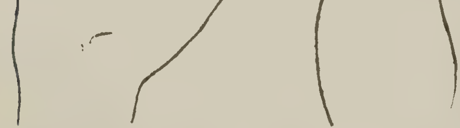

Fig. 2461. Fig. 2462.

Figs. 2461 and 2462.—Hypophalangism. (Annandale.)

Fig. 2461.—Absence of Distal Phalanges of Three Fingers.
Fig. 2462.—Absence of all the Phalanges of all the Fingers.

Any of the fingers, and from one to four in number, may be lacking. The particular fingers that may be involved, and the extent to which the metacarpus and carpus may be affected, give rise to an indefinite number of possible combinations that may occur. There are two or three particular conditions that occur with such comparative frequency, however, that they may be specially mentioned.

In a considerable proportion of cases the thumb alone is missing. This occurs especially in association with congenital absence or deficiency of the radius. Nondevelopment or partial development of the radius is in nearly all cases accompanied by absence of the thumb, its metacarpus, and one or more of the corresponding carpal bones (Figs. 2475, 2476, 2477). In the case of absence of radius illustrated in Fig. 2477, there is a rudimentary thumb present, but articulated to the head of the metacarpal bone of the index finger.

It is rare for any of the digits other than the thumb to be lacking alone, it being more common for two or three fingers to be absent than one of them only.

One of the common forms of ectrodactylism consists in the absence of the index, middle, and ring fingers. This leaves the thumb and little finger, often opposed to each other, somewhat like the jaws of pincers; the term "pince de homard" (lobster claw) has been applied to this particular condition (Fig. 2459).

Little can be done in the way of treatment to improve ectrodactylism, unless by amputation or other operation an unsightly deformity may be removed or some impediment to function obviated.

Hypophalangism is the congenital absence of one or more phalanges and the corresponding soft parts from a digit. It is an abnormity of somewhat similar character to ectrodactylism, the deficiency being less in degree. In hypophalangism either one, two, or all three phalanges may be lacking, the finger in the cases in which all three phalanges are missing (Fig. 2462) being represented simply by a rudimentary nodule of soft tissue perhaps surmounted by a nail. When all traces of the hard and soft tissues of the finger are lacking, the condition becomes one of ectrodactylism. Hypophalangism is a very rare deformity, and may occur in association with polydactylism or ectrodactylism, supernumerary fingers being often only partially developed. The condition is one form of brachydactylism or short finger.

Congenital anonychia or absence of the nails will be spoken of in connection with the affections of the nails.

POLYCHEIRIA, or *supernumerary hand* (double hand, dicheiria, also called, not very aptly, bifurcated, or bifid, hand). The development of a supernumerary hand, in addition to the normal hand, is a conceivable condition, but is exceedingly rare. A very few cases are on record which may be classified as double hand, though such cases merge into polydactylic conditions. In these cases the double hands each possessed from eight to twelve fingers in all; the two hands, which were not normally developed, were either united more or less along the adjacent sides, or the two parts were separated by a bifurcation extending to the carpus. Each hand had its own set of muscles and tendons, so that the two parts could close over and grasp each other; this feature is a distinguishing characteristic between double hand and simple polydactylism. The only treatment called for is the removal of useless or unsightly digits to improve the appearance or function of the member.

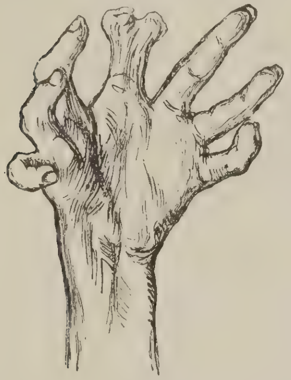

FIG. 2463. — Double Hand. (Clutton.)

POLYDACTYLISM, or *supernumerary finger* (or toe), is the presence on the hand or foot of more than the normal number of digits. The supernumerary fingers vary in the degree of their development from those that are rudimentary to those that are quite perfect and well developed. This is one of the commoner of the developmental anomalies of the hand. More often there is only one supernumerary finger, but a greater number may be present. One case is recorded in which the subject possessed thirteen fingers on each hand and twelve toes on each foot; another case had twelve fingers on each hand; several cases of ten fingers on the hand have been observed and from that number down the cases become more numerous. It is more usual for both hands to be affected together than for one hand to be involved alone, and the feet are apt to exhibit a corresponding abnormality.

Syndactylism is sometimes associated with polydactylism. Hereditary transmission has been observed in numerous cases. The cause of the anomaly evidently rests in an innate aberrant developmental tendency.

All the parts that enter into the structure of normal fingers may also be present to a greater or less degree in supernumerary digits, bones, joints, tendinous and muscular attachments, nails, etc. The most perfectly developed supernumerary fingers are as complete and mobile and useful in all respects as the ordinary fingers; from this perfectness the degree of development ranges down to rudimentary structures which are distinguishable from congenital tumors only by the presence of bony or cartilaginous tissue or a rudimentary nail. The muscular connection and the movability and functional value also range from a good degree of usefulness down to immovable and useless digits.

There is an indefinite variety in the possible forms and combinations in which the deformity may be manifested. Thomas Annandale's classification, which seems as satisfactory as any proposed, is as follows:

1. Cases in which the supernumerary digit is a rudimentary and deficient structure attached to the hand or another digit by soft tissues or a narrow pedicle and without any articulation (Fig. 2464). The most rudimentary of this class of supernumerary finger may practically amount simply to a tumor, the digital nature of which is shown only by the presence of bony tissue in its interior or a rudimentary nail. Supernumerary digits of this kind are usually situated on the ulnar side of the hand or little finger, but they occasionally occur on the radial side or any other portion of the hand. These digits usually have very little mobility or functional action.

2. Cases in which the supernumerary digit, more or less well developed and free in its distal portion, is given off from and articulates with the side or head of a metacarpal or phalangeal bone belonging to a normal digit, or common to the two digits (Fig. 2465). Some of these cases appear as if a finger were bifurcated, the two divisions being nearly equal and symmetrical: in other cases one of the digits from its less development or asymmetrical position is evidently supernumerary. Often the extra digit is not very movable or useful, but sometimes it has good functional power.

The supernumerary digit may articulate with (*a*) the side of the metacarpal or phalangeal bone common to it and the normal finger, in which case it has its own articular and synovial structure entirely distinct from the corresponding articulation of the normal finger; or it may articulate with (*b*) the head of the common metacarpal bone or phalanx. In the latter case there may be two separate articulations, with separate joint cavities, or there may be only one synovial cavity common to the articulations of the two digits. Sometimes the metacarpal or phalangeal bone to which the two digits are attached bifurcates and has a separate articulation on each of the two heads. It is important to bear in mind the nature of the articulation in amputating in these cases.

The thumb is not uncommonly the seat of this form of polydactylism, being either bifurcated (Fig 2465) or giving off a supernumerary thumb from its side.

3. Cases in which the supernumerary finger is a practically perfect and fully developed digit, complete in itself in all its parts, and distinct from the other fingers, having its own phalanges, metacarpal bone, and attachment to the carpus (Fig. 2466). Such fingers are usually as useful and good as the normal fingers. Some cases of double hand may be partly regarded as instances of this form of polydactylism. Supernumerary fingers in rare instances are associated with a corresponding excess of development in the forearm, as with a supernumerary radius.

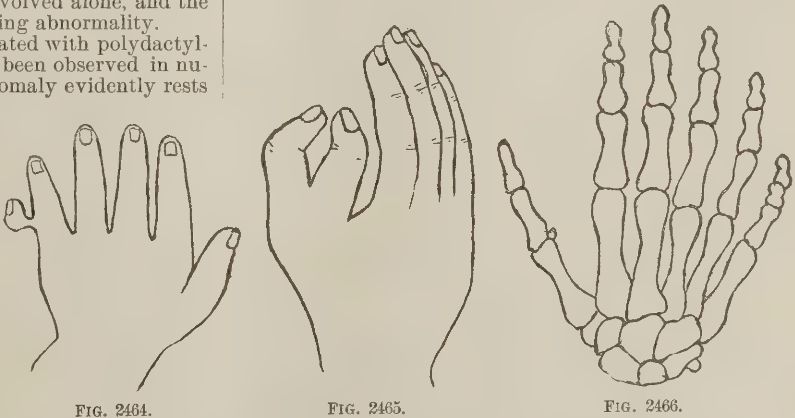

FIG. 2464. FIG. 2465. FIG. 2466.

FIG. 2464, 2465, AND 2466.—Polydactylism. (Annandale.)

4. Cases in which the supernumerary digit is intimately

united along its whole length to the normal digit—that is, a combination of syndactylism with polydactylism. The supernumerary digit may be more or less well developed, having separate metacarpal and phalangeal bones of its own, or possessing only phalanges which are articulated to the metacarpal bone or a phalangeal bone common to it and the normal digit. Such a double finger is broad and is apt to possess two nails. The thumb is said to be oftenest affected in this manner.

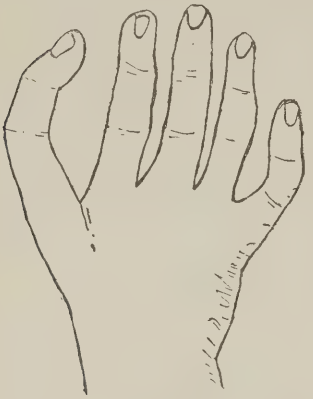

FIG. 2467.—Polyphalangism, the Thumb Possessing a Supernumerary Phalanx. (Annandale.)

The treatment of polydactylism consists in amputation of the supernumerary digits, for the purpose of improving the appearance of the hand or removing useless structures that may be an actual impediment to the function of the hand or impair its proper development. As a supernumerary digit tends to retard and impair the development of the normal finger to which it may be attached, amputation should be performed as early in life as is practicable and convenient. In some instances there has been observed a tendency for new rudimentary digits to grow out from the stumps of amputated supernumerary fingers.

In considering and practising amputation, however, careful attention must be paid to the danger and consequences of injuring a joint of one of the normal fingers and thus causing an ankylosed and stiffened digit that may be worse than the original polydactylic condition. When the supernumerary finger is connected by soft tissues only, or has its own distinct and separate articulation and joint cavity, the operation is simple and void of evil consequences if properly carried out so as not to interfere with other joints. But in those cases in which the extra digit has an articulation in common with the normal digit or articulates with the common carpal joint, it must be remembered that the process of disarticulation will necessarily cause an opening to be made into the joint of the finger that is to be left, thereby rending it extremely liable to ankylosis. In such cases it may be preferable to amputate by cutting through the base of the bone near the joint, but without opening the joint itself. This will necessitate leaving a small portion of the proximal end of the supernumerary digit, but any slight deformity thus occasioned may be preferable to the impairment of function that will be caused by a stiffened finger. In such cases the use of the x-rays prior to operation may afford valuable information as to the precise relations of the articulations.

FIGS. 2468 TO 2470.—SYNDACTYLISM.

FIG. 2468.—Syndactylism. (Clarke.) The dotted lines represent amputated supernumerary fingers.
FIG. 2469.—Union of Distal Portions of Fingers. (Annandale, after Otto.)
FIG. 2470.—Fusion of Distal Phalanges. (Annandale, after Otto.)

POLYPHALANGISM (or "hyperphalangism") is the very rare condition in which a digit possesses a supernumerary phalanx, or more than the normal number of phalanges (Fig. 2467). In the cases that occur the thumb is the digit oftenest affected, though cases involving the index and middle fingers have been observed. In a very few instances in which a supernumerary phalanx was present, the phalanges generally were so shortened that the condition of brachydactyly or short finger was manifested.

SYNDACTYLISM

consists in the union, fusion, or growth of adjacent digits to each other by their contiguous sides. It usually arises as a true developmental anomaly from an innate aberrant tendency of growth; or it may exceptionally be acquired, either in the intra-uterine period or at any time during life, from the adhesion or growth together of ulcerated digital surfaces or from cicatricial contractions. The site of union may extend the entire length of the fingers; or it may involve only the proximal portion of the fingers, to a varying extent, leaving the distal portions free and separate; or, rarely (probably from the union of ulcerated surfaces), the distal portions of the fingers may be united and the proximal portions separate (Fig. 2469). The union may consist of a thin fold or web of skin stretching across, between, and connecting the two fingers, the true "webbed fingers"; or the connection may be more intimate, involving more or less of the subcutaneous and internal tissues of the fingers, ranging up to cases in which even the bones are united. Cases have been observed in which the distal phalangeal bones were fused together, while the proximal phalanges were separate (Fig. 2470). Two fingers alone may be united, or three, or four, may be connected together; rarely all the digits are bound together in an unshapely deformed mass. The index and middle fingers are not uncommonly united.

Syndactylism is not a very uncommon condition, and is one of the most frequently observed developmental anomalies of the hand. In the true congenital or developmental form of syndactylism, hereditary transmission is often observed, and both the hands are frequently involved together, though the fingers affected may be different on the two sides. The hands and feet are often involved simultaneously. In acquired syndactylism heredity is of course not observable, and only one hand would ordinarily be affected.

Treatment.—The only treatment of this condition is operative. The best age for operating is usually stated as from four to six years, when the fingers are of sufficient size for easy management and control, and before growth is materially interfered with by the deformity. In most cases it is easy enough to effect a separation between the digits, but to prevent the raw surfaces from growing together or to obviate a recurrence of the deformity from cicatricial contraction, is often a matter of some difficulty and requires special plastic surgical measures. It is necessary to pay special attention to the denuded surface in the interdigital angle.

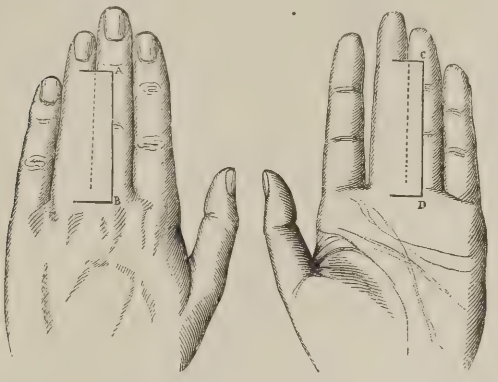

FIG. 2471.—Didot's Operation for Syndactylism, Dorsal and Palmar Views, Showing Primary Incisions. (After Stedman.)

When the web is broad and thin successful and permanent separation of the united digits may be obtainable by the simple method of cutting the web in two longitudinally down its middle line, and suturing the edges of the incised skin together over each finger. The edges of the wound in the interdigital angle should especially be brought together and sutured. The fingers should, as in all operations for syndactylism, be dressed separately, so as to keep the wounded surfaces apart until healing is complete. Recurrence may, however, follow this procedure.

In some cases, especially when the union is very close, as the preliminary step in treatment an opening may be made through the tissues connecting the digits at the proximal end of the contemplated separation. In this opening a glass or metal tube, wire, or a bundle of silkworm gut is kept until the sides of the hole heal over and become completely lined with epithelium. When this is well accomplished the fingers are cut apart for the remainder of the distance, and the edges of the wounds are approximated and sutured in the best manner practicable. The preliminary establishment of a healed surface at the interdigital angle or commissure prevents the recurrence of union from that point.

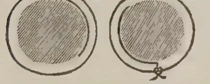

FIG. 2472.—Didot's Operation for Syndactylism, in Cross Section, Showing Method of Dissecting Off and Suturing the Flaps. (After Stedman.)

Didot's plastic operation (Figs. 2471 and 2472) appears to be the most frequently employed for syndactylism, especially for cases with a long and thick web. By this method longitudinal incisions are first made through the skin along the middorsal line of one finger and the median palmar line of the other finger (Fig. 2471). Beginning at these incisions rectangular flaps are then dissected off, and the tissues uniting the two fingers are cut through so that one of the digits has a flap adhering to its dorsal surface and the other a flap adhering to its palmar surface. Each flap is then brought around the finger to which it is attached and its margin sutured neatly to the edge of the skin so as to cover the surface denuded by dissecting off the flaps. The method of forming the flaps and of suturing them in their new positions is graphically illustrated in Fig. 2472. This procedure keeps the healing surfaces well separated, and thus obviates readherence. It is probable that flaps should also be drawn together and sutured in some such manner as is employed in Norton's operation in order to close and cover the raw surface in the interdigital angle. From the stretching of the flaps sometimes necessitated there may at times be some tendency to sloughing of the tissues; but in general the results of Didot's operation are very satisfactory and successful.

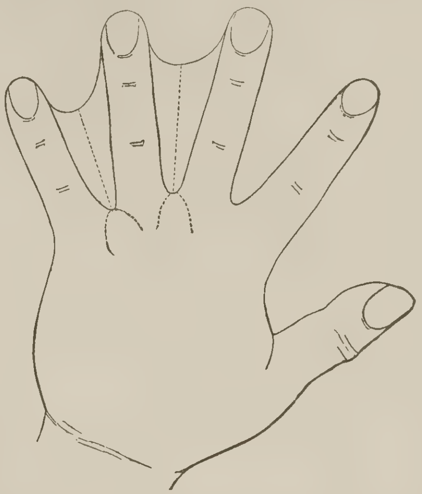

FIG. 2473.—Norton's Operation for Syndactylism. (From Bradford and Lovett.)

Norton's operation (Fig. 2473), which is recommended for cases in which there is a short but ample web, consists in the formation of horseshoe-shaped flaps, dorsal and palmar, which are stretched and sutured together so as to cover the interdigital angle. The web is divided lengthwise, and the divided edges are brought together along each finger.

Zeller's operation (Fig. 2474), which is recommended for cases similar to those for which Norton's is employed, consists in the formation of a triangular dorsal flap, which after section of the web is brought into the interdigital angle and sutured in place. Agnew's operation is similar to Zeller's.

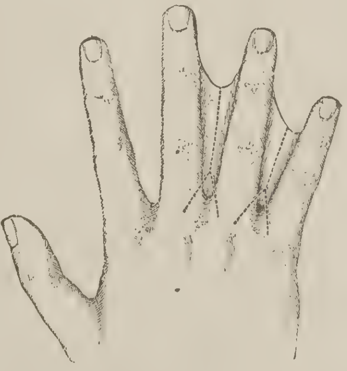

FIG. 2474.—Zeller's Operation for Syndactylism, Showing Lines of Incision and Outlines of Flaps (which are not shown sufficiently long). (Treves.)

Fowler's operation (Dennis' "System of Surgery," vol. ii., p. 186) is recommended for obstinate and intractable cases. In this procedure a preliminary longitudinal opening or slit is made through the web between the proximal ends of the proximal phalanges, at the site of the future interdigital angle. From the dorsum of the hand two long narrow flaps are then cut, one on each side of this opening and with their attached bases near the slit. The flaps are then twisted around a quarter of a circle and drawn through the slit so that the skin surfaces of the flap are opposed to each other and their denuded surfaces are brought in contact with the raw surfaces of the slit, with which they are designed to become united. The flaps should be long enough to project through the palmar aspect of the slit about a centimetre, and they do not require to be sutured in place. The areas left by the removal of the flaps on the back of the hand can be closed by sutures. When the wounds heal, there will be a permanent opening through the web, lined with skin. The remainder of the web is then divided, and the healed commissure will prevent recurrence of the mal-union.

Cleft Hand.

The contrary condition to syndactylism, the union of parts normally separate, is cleft hand, or a separation of parts normally united. Cleft hand consists in the separation of, or division between, adjacent fingers extending farther toward the carpus than normal, that is, into the metacarpal region. It is a very rare condition, and is almost invariably associated with other developmental anomalies. In nearly every case it is associated with ectrodactylism, especially with lack of the middle finger (see Figs. 2457 and 2458); other anomalies, as syndactylism, may also be present. In a case reported by Charles N. Dowd (*Annals of Surgery*, Philadelphia, vol. xxiv., 1896, p. 211), the number of fingers was normal, but there was syndactylic union of the metacarpal bones of the ring and little fingers; the unsightly appearance of this case was relieved by a plastic operation. This condition should not be confounded with dicheiria, to which the term "bifid hand" is often rather inappropriately applied.

Congenital Constrictions.

Congenital annular constrictions of the fingers, as well as of other portions of the extremities, have been observed, but are very rare. They are apparently produced by tight turns of the umbilical cord or of amniotic bands around the members, constricting the tissues; they are hence produced in the same manner as are intra-uterine amputations but with the constriction not carried to a sufficient degree to cause complete amputation.

Deflections of the Hand and Fingers.

A large proportion of the deformities of the hand consists of deflections or deviations of the hand, fingers, or phalanges from their normal direction or position. The deflection may be in a forward or palmar direction (that of flexion), a backward or dorsal direction (superextension), or a lateral direction (either to the radial or to the ulnar side), or in intermediate directions. These deviations are often called contractions; but this designation is not very satisfactory as a general term, since all the deflections are not due to a contraction or pull.

The point of deflection is in almost all cases at one of the joints, either the wrist joint, or the metacarpo-phalangeal joints, or the interphalangeal joints. Occasionally the deflection may arise in the course of the bones, as in mal-union at an angle after fracture, or curvature of the bones in osteomalacia.

No complete and systematic classification and nomenclature for these deflections have been formulated. Deflections of the hand at the wrist joint in the different directions, especially the congenital cases, have been called "club hand," after the analogy of club foot. No such designations as club-finger or club phalanx have been employed, though such terms or their equivalents would be useful. The term "clinodactyly" has been employed as a generic designation for deflections of the fingers (Fort), but has not come into general use.

Using as a basis the situation and the direction of the deflection, the following scheme for the anatomical classification and nomenclature of the various deflections of the hand and fingers is proposed and will be used here:

Deflections of the hand at the wrist joint—"club hand"; forward deviations, *manus flexus;* backward deviations, *manus superextensus;* deflection to the radial side, *manus varus;* deflection to the ulnar side, *manus valgus.*

Deflections of the fingers—"clinodactyly": forward, *digitus flexus;* backward, *digitus superextensus;* to the radial side, *digitus varus;** to the ulnar side, *digitus valgus.** For the thumb, the terms *pollex flexus, pollex superextensus, pollex varus,* and *pollex valgus* can be used for the corresponding deflections. These terms relating to the fingers could be employed for deflections at either the metacarpo-phalangeal or interphalangeal articulations; but if greater precision were desirable where the deviation was at an interphalangeal joint and the bending involved only the middle or distal phalanx, the terms *phalanx flexa, phalanx superextensa, phalanx vara,* and *phalanx valga* could be employed for the forward, backward, radial, and ulnar deflections respectively.

For deflections in the intermediate directions compound terms could be employed as in talipes.

This terminological classification would be practical and useful for placing and designating the anatomical condition or particular form of deviation present in particular cases; but it would not be a satisfactory classification from an etiological or pathological standpoint or for clinical purposes, since different deflections may be produced by the same cause, or the same deflection may arise from different causes. In most cases the deflections are simple and distinct enough to permit of ready classification.

Deflections of the hand or fingers may be congenital, arising from developmental anomalies, or acquired. They occur in connection with a considerable variety of etiological and pathological conditions, which may be briefly summarized as follows:

Dermatogenous deflections, in which the deformity is produced by lesions of the skin, as scleroderma.

Desmogenous deflections, produced by lesions of connective-tissue structures, fascias, ligaments, etc., as cicatricial contractions, Dupuytren's contraction of the palmar fascia, hammer finger, contraction of the digital fascia.

Arthrogenous deflections, produced by lesions of the articulations, as arthritis of various forms (gouty, rheumatic, rheumatoid, tuberculous, etc.), dislocations, altered configuration of joints (developmental, senile, inflammatory), ankylosis in malposition.

Osteogenous deflections, from lesions in the bones, mal-union after fracture, osteomalacia, abnormal development.

Tendinous deflections, from injuries, division, or adhesions of tendons.

Muscular or myopathic deflections, from abnormal muscular conditions, as abnormal development, myositis, atrophies, ischæmic paralysis, and abnormal innervation.

Nervous or neuropathic deflections, from paralytic, spastic, or trophic conditions.

Deflections of the fingers and phalanges from their normal position and direction are much commoner than are deflections of the hand at the wrist joint, partly because the small digital articulations are more subject to arthritic conditions, partly because the muscular and motor mechanism of the fingers is more extensive and more complicated, and hence more exposed to morbid influences. Of the deflections of the fingers the forward deviations are much the commonest and most varied as to cause, while the lateral and backward deviations are much less frequent.

As there is so great a diversity in the etiological and pathological nature of these deflections, it is more satisfactory to treat the different varieties in connection with the various pathological conditions with which they are associated than to consider all the hand and finger deflections in one general group. Consequently at this point consideration will be given only to club hand, congenital deflections of the fingers, lateral deflections of the fingers, and backward deflections of the fingers, reserving the remaining forms of deviation for treatment in their appropriate connections.

---

* These designations are as proposed by Joachimstal.

Club Hand.—This term in its most general sense could be applied to all deflections of the hand at the wrist joint, congenital or acquired, but as ordinarily used it is chiefly employed to designate only the congenital forms of the deformity.

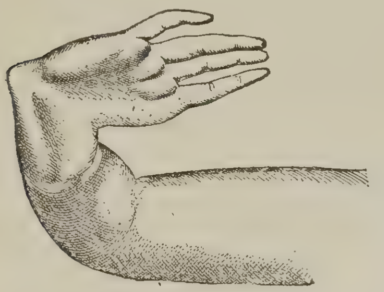

Fig. 2475.—Congenital Club Hand, with Absence of Radius and Thumb. (Hoffa.)

The cases of congenital club hand, which is a rare condition, may be divided into some three classes, as follows:

1. The first class comprises those cases depending on contractions and altered anatomical conditions of the carpal structures in a manner entirely analogous to congenital club foot. This form of congenital club hand is exceedingly rare, as the hand is very little subject to the developmental anomalies and intra-uterine conditions that give rise to talipes.

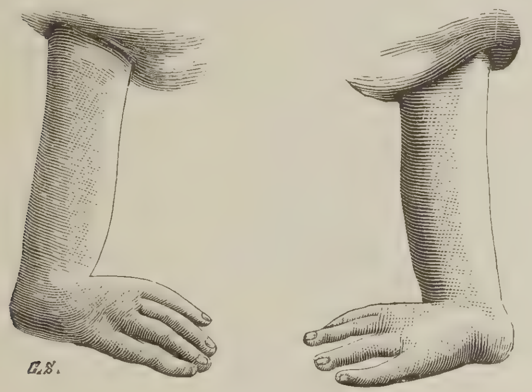

Fig. 2476.—Congenital Club Hand, with Deficiency of Radius, Dorsal View.

2. Of the rare cases of congenital club hand that do occur, the largest proportion consist of anomalies associated with developmental deficiency or absence of the radius. This and the following class of deformities are caused by conditions quite different from those that give rise to ordinary talipes; the term club hand is, however, generally extended to the cases associated with defective development of the bones of the forearm. In this form of club hand the radius is either totally absent or only partially developed, the distal extremity being deficient in the latter case. The hand is articulated on the lateral aspect of the ulna in the position of manus varus (Figs. 2477, 2478) at a considerable and even a right angle to its normal situation. The thumb and corresponding carpal bones are usually lacking, though exceptionally present, as in Fig. 2477, in a rudimentary condition and transposed situation.

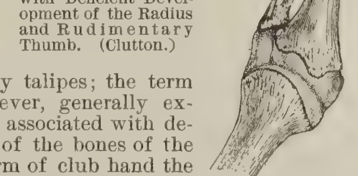

Fig. 2477.—Club Hand, with Deficient Development of the Radius and Rudimentary Thumb. (Clutton.)

3. Much more rarely than the radius, the ulna is absent or defective, giving rise to an abnormal position and ectrodactylous condition of the hand corresponding to the radial deformity.

The treatment of congenital club hand, if undertaken sufficiently early in life while the joint structures are pliable and adaptable, consists of gradual correction of the deformed position with maintenance of the hand in the improved position until permanent results are attained. Violent and abrupt measures are not generally desirable, but the correction should be accomplished by gradual steps, apparatus (Fig. 2479), splints, or plaster-of-Paris dressings being employed in the intervals to maintain and render permanent each step gained. Massage and electricity may be useful to improve the nutrition of the muscles of the forearm.

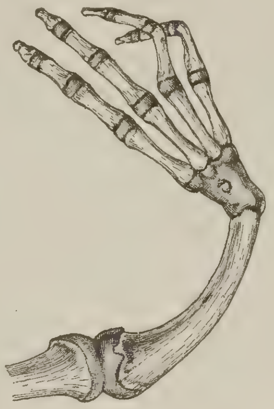

Fig. 2478.—Club Hand, with Congenital Absence of Radius and Thumb. (Clutton.) From same case as that illustrated in Fig. 2477.

In older patients the joint is apt to become so fixed that attempts at correction of the deformity may result in impairing the usefulness of a hand, which, though deformed and unsightly, still has good functional power and is a useful member. Treatment in such cases should be very conservative, and utility should not be sacrificed for the sake of appearance.

Congenital and Developmental Deflections of the Fingers.—Congenital deflections of the fingers are rare, while the acquired deviations are common. The common form of hammer finger is a developmental anomaly scarcely manifest at birth but gradually appearing during the period of development. Tamplin reported an instance of congenital contraction of the thumb in a flexed and adducted position, in a case of double talipes and contraction of the knee. Congenital deflections of the digits or phalanges are most commonly in a lateral direction.

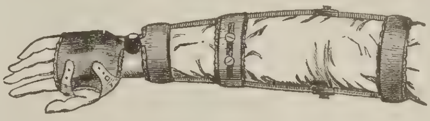

Fig. 2479.—Apparatus for Treatment of Club Hand. (After Dubreuil.) At the wrist is a universal joint to allow for movement and fixation in various positions.

Lateral Deflections of the Fingers or Phalanges may be congenital and developmental, or acquired. The acquired forms arise chiefly from cicatricial contractions, joint changes (especially arthritis deformans), dislocations, injuries, ankylosis in malposition, senile changes, or in association with hypertrophied fingers. Of these a general deviation of the four ulnar fingers toward the ulnar side is a com-

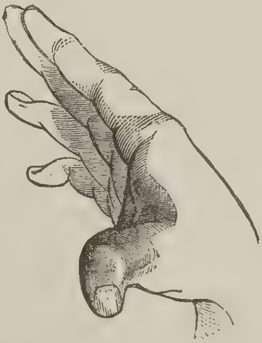

Fig. 2480.—Congenital Radial Deflection of Distal Phalanx of Thumb. (Gross.)

mon and characteristic condition in certain senile and rheumatoid cases.

A small number of cases have been reported in which the distal phalanx of the thumb has been congenitally bent laterally, either to the ulnar or to the radial side, at a sharp angle. Some of these cases were hereditary, others were associated with other deformities, as club foot; the cause of this abnormity is hence developmental. The treatment, if undertaken sufficiently early, should consist in gradual correction of the deformity and fixation by splints until permanent improvement is obtained. Removal of a wedge-shaped piece of bone from the phalanx has proven successful in one case; while division of the lateral ligament and exsection of a portion of the head of the phalanx did not give satisfactory results in another instance.

There is another well-marked class of lateral deflections of the phalanges, affecting chiefly the little fingers, which occurs occasionally, often associated to a certain degree with hammer finger. Exceptionally the deflection may be toward the ulnar side, or the middle phalanx may be the one bent, or the ring finger, or some finger other than the little finger, may be affected; but usually this abnormity manifests itself as a radial deflection of the terminal phalanx of the little finger (phalanx vara). The deviation is not generally more than about twenty-five or thirty degrees, and both little fingers are usually affected together. Anderson states that among eight hundred school children there were six cases of such lateral deflections, in five of which the little finger on both hands was affected, and in one the ring finger of one hand was involved. This lateral phalanx deflection is not infrequently exhibited by little fingers that are also affected with the condition termed hammer finger; and the writer has observed one case of phalanx vara of both little fingers in a woman who had a hammer toe but no hammer fingers, but whose mother and mother's brother had hammer fingers. Radial deflection of the distal phalanx of the little finger is said to be common in idiots of the so-called Mongol type. The condition is of developmental origin caused by irregular development of the phalangeal articulation. The abnormity is somewhat unsightly, but is not troublesome in any other way. The only advisable treatment is the use of splints for a time to straighten the finger.

Backward Deflections of the Fingers (digitus superextensus).—Superextensions of the fingers or phalanges are among the less common of the deflections of the fingers; they are mostly acquired, and are due to various conditions.

The terminal phalanx of the thumb in many persons is capable of extension backward from the straight line to a marked degree, flexion not being interfered with; this is a normal developmental condition. The terminal phalanges of the other fingers are occasionally markedly extensible backward, and in such cases power of flexion is sometimes somewhat impaired.

Cicatricial contractions following dorsal ulcers, contractions of the dorsal digital fascia, joint lesions like arthritis deformans, adhesions of extensor tendons, section of flexor tendons, spasm of extensor muscles, paralysis of flexor muscles, are the other principal causes of superextended fingers or phalanges. In a considerable proportion of cases of hammer finger there is a hyperextended condition of the proximal phalanges of the affected fingers; and superextension of the distal phalanges in hammer fingers has been observed. In Dupuytren's contraction the writer has seen in one case a superextension of the distal phalanx caused by a band of contracted fascia that crossed from the palmar to the dorsal aspect of the finger. In dactylomegaly there is not infrequently phalangeal superextension.

The treatment of digital and phalangeal superextensions must be guided by general principles and the conditions present. Some cases will hardly require treatment, others are insusceptible of improvement. Gradual or forcible correction of the deformity with fixation by splints, division of contracting tendons or fibrous bands, or lengthening or shortening of tendons by plastic procedures may result in lessening the deformity and impairment of function.

Microcheiria and Microdactylism,

or abnormally small size of hand or fingers, may be due to retarded, deficient, or arrested development, or to atrophy or retrogression after full development has been once attained. Both congenital and acquired cases are distinguishable.

Brachydactyly, or short finger, is a form of microdactyly in which the deficiency in size affects especially the length of the finger.

In dwarfs and in conditions like achondroplasia, the hand and fingers are small but not diminished in size in proportion to the rest of the body or of the upper extremity; such cases are hardly to be classed as real microcheiria or microdactyly, in which the small size is relative as well as absolute.

Brachydactyly is caused by congenital absence of phalanges (hypophalangism) or by abnormal shortness of the phalanges or metacarpal bones. Cases have been observed in which a supernumerary phalanx even was present, but with sufficient abbreviation of the phalanges to constitute a condition of brachydactyly. Brachydactyly and other forms of congenital microdactyly are rare. Deficient size of the thumb, apparently developmental, occurs in a certain proportion of the cases of ossifying myositis; in this disease a corresponding anomaly of the great toes occurs much more frequently. Fingers associated with developmental abnormities, such as supernumerary or syndactylic digits, are apt to be retarded or stunted in development unless the impediment is early removed. Injuries or diseases affecting digits during the period of development, in infancy or childhood, may arrest or retard their growth so that they may not attain full development. Loss of tissue or destruction of bone from injuries, inflammation (tuberculosis, etc.), ulceration, and the like, will if not replaced result in diminution of size. After full growth is attained atrophy and decrease in size may result from injuries, local disease, trophic influences from nervous lesions, etc.

Hypertrophy of the Hand or Fingers

(cheiromegaly or macrocheiria, dactylomegaly, megalodactylism, or macrodactylism).—Aside from such conditions as neoplasms, œdema, and dactylitis, enlargements and hypertrophies of the hand and fingers are mostly comprehended under the following groups:

Congenital and idiopathic hypertrophy.
Elephantiasis.
Gigantism.
Acromegaly.
Hypertrophic pulmonary osteo-arthropathy.
Hippocratic or clubbed fingers.
Myxœdema.
Syringomyelia.

Congenital and Idiopathic Hypertrophy.—The fingers, hand, and more or less of the upper extremity are sometimes the seat of a peculiar hypertrophy, which, though rare, presents a well-marked clinical type. This hypertrophy is of the same general nature as the condition called "congenital hypertrophy" which affects various other parts of the body, though the fingers are a favorite seat. Sometimes other parts of the body are affected along with the hand, as in the unilateral hypertrophy where the upper and lower extremity on the same side are enlarged.

When the upper extremity is involved it is far commoner for a portion only of the fingers or of the hand to be hypertrophied, the remaining fingers being normal; very rarely the entire extremity may be enlarged. Sometimes even when there is a general enlargement of the limb, some of the fingers are relatively much more enlarged than the others.

The hypertrophy is often, though not always, manifest at birth, the affected fingers being then appreciably and materially larger than the others. Further enlargement proceeds progressively, or may take place rapidly at some time during the period of development. Cases of a high degree of hypertrophy and deformity are exhibited in young children, though the enlargement may develop even in adults. The cause of the hypertrophy is apparently some idiopathic developmental derangement, the precise nature of which is unknown. The condition is sometimes called congenital elephantiasis, and has been thought by some to be a form of elephantiasis. Some of the cases reported, indeed, may have been real instances of elephantiasis. But if the term elephantiasis be limited to hypertrophies produced by occlusion of the lymph vessels, especially by the filaria, there is probably a genuine difference between the two conditions. Hereditary transmission of congenital dactylomegaly has not been especially noted.

The hypertrophy often does not involve all the tissues uniformly, but affects especially the bony, fatty, and vascular tissues. The bones are hypertrophied, and sometimes there are joint lesions. The adipose tissues are often relatively increased, even to the production of lipomatous tumors. Areas of excessive development of vascular structures are frequently exhibited, in the form of angiomata, angiectases, vascular nævi, varicose veins, lymphangiomata, etc. The arteries are said not to be enlarged so much as the veins and capillaries. Muscular strength is sometimes increased, often not, but the usefulness of the member is often impaired. The skin is usually not greatly altered. Syndactylism is sometimes present. Frequently some of the hypertrophied phalanges or fingers are deflected laterally or backward, from articular changes. The metacarpal portions of the affected fingers may, or may not, partake of the hypertrophy.

The enlargement is both in length and, markedly, in thickness. Various gradations of hypertrophy may occur, from slight enlargement up to great deformity and disability. In typical cases the overgrowth is frequently gigantic, so that the member may be highly deformed, unsightly, and useless. Increase of the middle finger, for instance, to a length of 13, 14, or 16 cm. (6½ in.), and to a circumference at its base of 32 cm. (13 in.), has been noted in more than one case. In one instance the hand weighed twelve pounds.

This hypertrophy is in the great majority of cases unilateral, and only exceptionally are both hands affected. In the unilateral cases the right and left hands are involved with about equal frequency, with perhaps a slight difference in favor of the right. In the bilateral cases different fingers may be affected on the two hands. The middle and index fingers are much the most frequently involved, the middle more often than the index finger. The thumb is affected in a considerable proportion of the cases, the ring and little fingers infrequently. The three radial digits are therefore much the most liable to the disease. It is more usual for two or more adjacent fingers to be hypertrophied together than for one finger to be affected alone, though any of the digits may be enlarged alone. The commonest combinations are for the thumb, index, and middle fingers, or for the index and middle fingers to be affected together, next for the middle finger to be hypertrophied alone; the other fingers and combinations are less frequently involved.

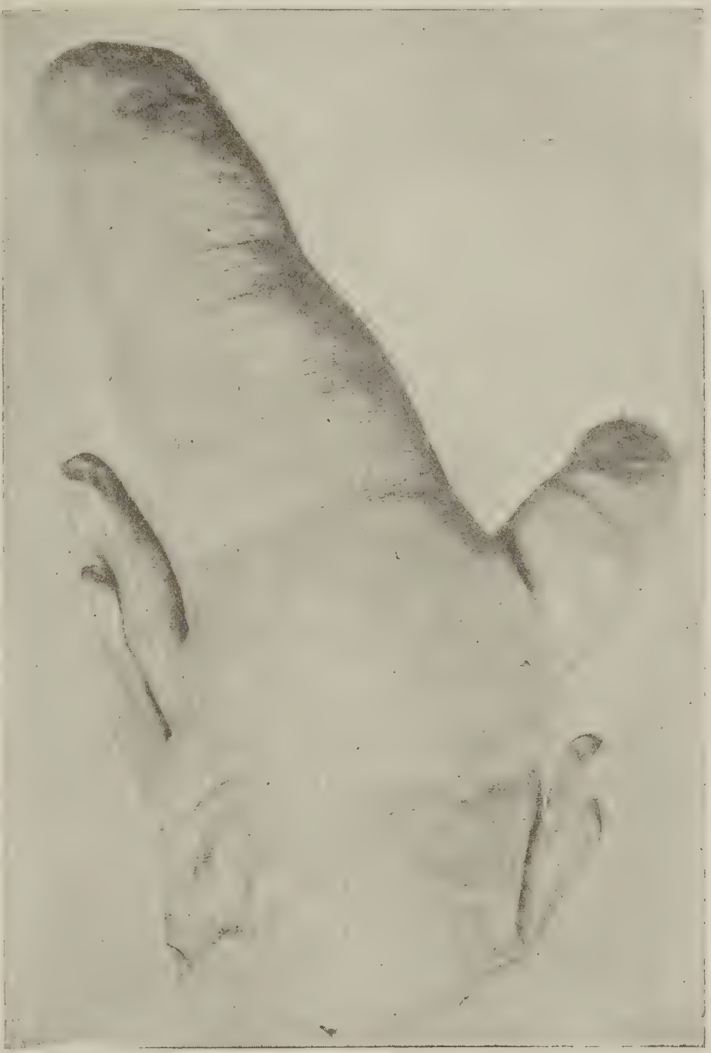

FIG. 2481.—Congenital Hypertrophy of Middle and Index Fingers in Mulatto Girl Aged Eleven Years; Reported as a Case of Congenital Elephantiasis. (T. L. Terry.)

Treatment of congenital dactylomegaly: In incipient cases ligation of the tributary arteries may be tried with a view of diminishing the supply of nutriment and hence retarding the hypertrophic process; success cannot be very confidently expected for this procedure. Compression of the growing fingers offers little hope of successful results. When fully developed amputation may be requisite to improve the appearance and usefulness of the hand, or to prevent the extension of the hypertrophic process to the remaining portion of the hand or limb.

Elephantiasis.—Exceedingly rarely is the hand or upper extremity the seat of true elephantiasis, that is, hypertrophy from lymph stasis, especially due to occlusion of lymph vessels by filaria, though a few cases are said to have been observed. Elephantiasis and the idiopathic hypertrophy just considered have points of resemblance and have been confounded with each other in some instances, but there is doubtless a definite pathological distinction between the two conditions. The treatment is the same as that of congenital dactylomegaly and of elephantiasis.

An elephantiasiform hypertrophy sometimes follows healing of lupus vulgaris on the hand, from chronic œdema produced by occlusion and obliteration of lymph and blood-vessels, with tendency to recurrent dermatitis, cellulitis, and lymphangitis.

Gigantism.—In this condition the hand and fingers participate in the general enlargement of the body, but their development is not proportionally greater than that of the rest of the body.

Acromegaly.—In this rare condition the hands, along with the feet and bones of the head, undergo general hypertrophy, with, later, constitutional disturbances. It occurs rather more commonly in females, and usually begins to develop at the age of about twenty-five to thirty years. Etiologically and pathologically it is supposed to be usually associated with some morbid condition of the pituitary body. It is a chronic and slowly progressing condition.

In the upper extremity the lesions are chiefly confined to the hand and wrist, which are enlarged by a general hypertrophy of all the tissues, soft and hard. One of the first manifestations of the disease is an increase in thickness of the fingers, so that gloves and rings become too small. When the trouble is fully developed, the hand is enlarged generally, and is described as having a "spade-like" appearance. Its function and usefulness are unimpaired. The fingers are broad and sausage-shaped, and the terminal phalanges are not bulbous or larger than the rest of the digit. The nails are usually broad, flat, grooved, and friable.

Along with the hands the feet, face, and head are correspondingly affected. The results of treatment have not been very satisfactory.

Hypertrophic Pulmonary Osteo-arthropathy.—This is a rare condition in which the hands and feet, with the distal portions of the forearms and legs, undergo hypertrophy in association with chronic pulmonary, pleural, or bronchial disease, such as phthisis, tuberculosis, empyema, pneumonia, syphilitic and malignant thoracic disease, chronic bronchitis, etc., mostly conditions in which the arterialization of the blood is impaired. The condition is rare, only about sixty cases being recorded. Adults and males are affected most frequently, though children and females are not exempt. Usually the hypertrophic condition develops insidiously, gradually, and slowly, but in exceptional instances it has a sudden onset and rapid development, becoming well defined in the course of six or twelve weeks.

The hypertrophic condition consists in a general and symmetrical enlargement of the hands and feet and the distal extremities of the forearms and legs, other parts of the body being scarcely affected. In the members involved the bones are especially affected, being increased in length and thickness, partly by increased subperiosteal bone formation, partly from the development of wart-like bony nodules; the joints are also somewhat involved, from synovial effusion, erosion of articular cartilages, etc.; the soft parts are less implicated. In the upper extremity, the lower ends of the radius and ulna, the carpal, metacarpal, and phalangeal bones may all be involved. The terminal phalanges are usually markedly enlarged, giving the digits a club-shaped or drumstick appearance. The nails are much increased in size and very convex, both transversely and longitudinally, and arch over the ends of the fingers.

Pain, sometimes severe, is present in the hands in most cases, at least at some period in the course of the disease.

Among the features by which this condition can be differentially distinguished from acromegaly may be mentioned the association with pulmonary disease, the absence of any enlargement of the bones of the head, such as occurs in acromegaly, and the bulbous enlargement of the terminal phalanges and the shape of the nail, which are not manifested in acromegaly.

The essential pathological nature and cause of hypertrophic pulmonary osteo-arthropathy are not yet determined. The prevalent French theory is that the enlargement is produced by chronic inflammatory processes induced by toxæmic irritation. The condition probably has some relationship, and is even perhaps identical, with clubbed or Hippocratic fingers.

There is no definite treatment.

Hippocratic or Clubbed Fingers.—The term clubbed finger is employed to designate conditions in which the terminal phalanges or ends of the digits are enlarged and bulbous, that is, larger than the remainder of the fingers, giving them a club or drumstick shape. The fingers in hypertrophic pulmonary osteo-arthropathy and sometimes in myxœdema exhibit this condition. The term clubbed fingers is commonly used, and the term Hippocratic fingers is specifically used to designate a bulbous enlargement of the ends of the fingers, with a longitudinal curvature of the nail, that is occasionally present in chronic conditions in which the circulation is weakened, especially in pulmonary tuberculosis and heart diseases. The enlargement of the finger tips is brought about by a chronic state of or tendency to passive congestion, which occurs in these parts because, from their peripheral situation and distance from the heart, the strength of the circulation is here at a minimum. The condition can be treated only by attention to the general disturbance which causes it.

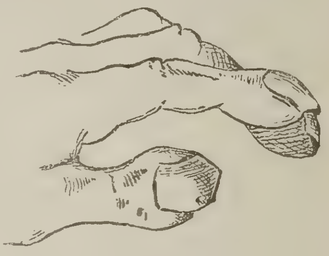

FIG. 2482.—Hippocratic Fingers. (Meillet and Richer.)

Myxœdema.—The hands and fingers share in the general enlargement of myxœdema, which it is unnecessary to consider generally here. There is no pitting on pressure, the fingers may be clubbed, and the nails are unaffected.

Syringomyelia.—In a very few cases of syringomyelia there has been observed a general increase in size of one of the hands and upper extremities from hypertrophy of all the tissues. It is possible that occasionally cheiromegaly may result from trophic influences in other morbid nervous conditions.

NEOPLASMS

of various kinds may develop upon the hands or fingers, but exhibit few features of special importance different from those manifested in other situations. Conditions more or less simulating tumors occur in various inflammatory, arthritic, tuberculous, syphilitic processes, etc. Aside from warts, this region is not particularly prone to the development of neoplasms. In some cases the tumors are of congenital and developmental origin, in others trauma exerts etiological influence, in many cases the cause is obscure.

The congenital tumors of the hand and fingers compose a group of cases in which the tumor is present at birth. Neoplasms of this class that have been observed are rudimentary supernumerary fingers, dermoid tumors and cysts, fibromata, lipomata, chondromata, and angiomata. Such congenital tumors are not common.

As already stated, *supernumerary fingers* are often of so rudimentary a structure that their digital nature is shown only by the presence of a small amount of osseous or cartilaginous tissue or a nail; such structures practically amount to tumors. These are usually attached by a soft pedicle and are most commonly situated on the ulnar margin of the hand or little finger. If we conceive such structures to be still more rudimentary, lacking all traces of bony or cartilaginous tissue or nail, we will have left simply tumors composed of fibrous tissue covered with skin, and having no distinct digital characteristics. Congenital tumors of this nature have been observed, often pedunculated and on the ulnar side of the hand, and in some cases are doubtless supernumerary digits of extremely rudimentary character.

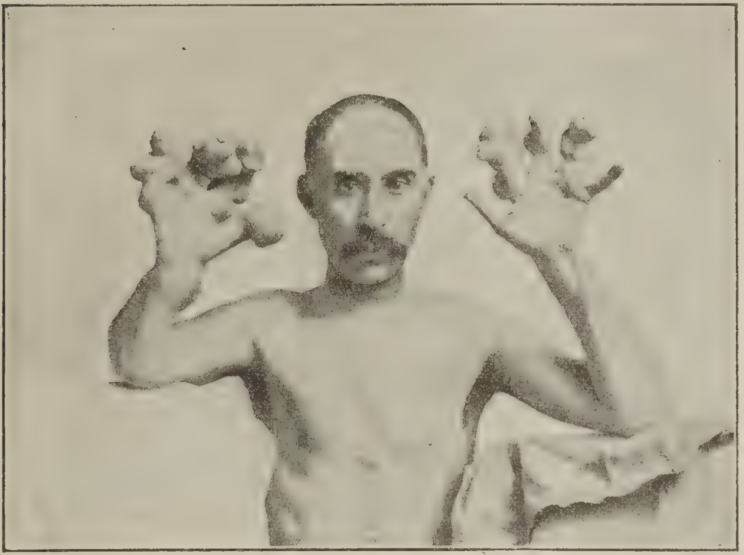

FIG. 2483.—Multiple Osteo-ecchondromata of Hands. (Whittaker.)

Dermoid Cysts or Tumors, congenital, containing epidermal tissue, hair, and sebaceous matter in their interior, are occasionally encountered in the region under consideration. Some of them are also perhaps supernumerary digits of very rudimentary and aberrant type.

Warts—the familiar verruca vulgaris—are very common on the hands and fingers, which are their favorite seats. They are especially common in childhood, occurring singly or in numbers. They consist of hypertrophied and elongated papillæ of the corium surmounted by thickened and horny epidermis. Among the methods of treatment may be mentioned cutting off the growth with knife or scissors and applying caustics—as silver nitrate, potassium hydrate, or chromic acid, solid or in solution —to the denuded surface.

Fibromata occur occasionally, situated in the subcutaneous tissues, or connected with tendons, periosteum, or bone.

Lipomata are rare in this situation. They may occur in connection with congenital dactylomegaly. They are usually diffuse, not circumscribed, and continuous with the subcutaneous tissue.

Chondromata are the commonest (aside from warts) of the benign neoplasms of the hand and fingers. Sometimes they are congenital, sometimes result from traumatism, usually arise without assignable cause. They occasionally develop in the soft tissues, but usually arise from the interior or the surface of the bones, the periosteum, or the joints. They may be firm or soft, may break down and ulcerate, and may ossify. They may be single or multiple, may involve one or several fingers, one hand or both hands. Often they attain a large size and occasion great deformity and disability, so that amputation may be required.

Osteomata and exostoses occur occasionally, arising especially from the bones or periosteum, and may occur in association with chondromata. *Neuromata* are said to have been observed in the hand. *Angiomata,* nævi, and erectile tumors sometimes occur in this situation.

Epithelioma develops in the skin of the hand, as in other situations. *Sarcoma* may attack the hand, originating especially in bone or periosteum; it occurs in its various forms, may attain great size, and may involve more than one finger.

The treatment of neoplasms of the hand and fingers must be guided by general principles and the circumstances of the case. Removal or excision of the tumor, or amputation if deformity is extreme, are the ordinary procedures. The malignant tumors require complete removal or amputation.

CYSTS

occasionally develop in this region. Dermoid cysts have been mentioned. Sebaceous cysts occasionally occur, sometimes induced by traumatism; cysts resembling wens in all respects even occur on the palmar surfaces, which are free from hair and sebaceous glands. Aneurisms and hydatid and cysticercus cysts rarely occur here. Ganglion will be considered subsequently.

TRAUMATISMS AND INJURIES.

From its exposed situation the hand is very subject to injuries of external origin, mechanical, chemical, thermic, etc. Mechanical traumatisms cause wounds, contusions, sprains, dislocations, fractures. Various chemical substances produce irritation, inflammation, ulceration, or necrosis. Heat causes burns and scalds; cold produces frost bite.

Wounds of all kinds—incised, lacerated, contused, punctured, gunshot—are of common occurrence. Not infrequently portions of fingers or entire digits are cut or torn completely off. The treatment is that of wounds in general, the chief objects aimed at being hæmostasis, asepsis, coaptation. Aseptic wounds heal well and rapidly in this situation, but if infection occurs healing may be very slow; asepsis is therefore highly important, especially after bites of animals. Tendons and nerves, if severed, should be carefully sutured to avoid subsequent impairment of function. The hand should be immobilized while healing.

When portions of the fingers are entirely cut off or hang by a small neck or shred of tissue, there is some hope of obtaining complete reunion of the severed portion. The parts should be well cleaned and sutured nicely together. Well-authenticated cases are on record in which a part of a finger completely cut off has perfectly reunited to the stump when sutured back in place, so that an attempt should at least be made to save the finger in all such cases. A case has been reported in which the hand was almost severed from the forearm at the wrist, all the blood-vessels and muscles and most of the

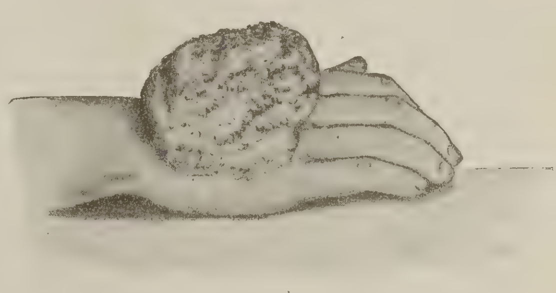

FIG. 2484.—Epithelioma of Hand. (B. F. Curtis.)

bones being divided, leaving only the ulna and a small portion of skin intact; even in this case good union was obtained with re-establishment of the circulation and function of the hand. Such cases illustrate the advisability of conservative treatment of wounds of the hand, and of the attempt to save as much of the member as possible.

Contusions and crush injuries of the hand and fingers are very common, and exhibit all gradations from slight bruises to cases in which the hand is crushed and lacerated into a shapeless mass, as in machinery injuries. The treatment is to be guided by the circumstances, but it should be as conservative as possible, and it should be remembered that this region possesses great reparative power if uninfected. Complete destruction of the ends of the fingers by crush injuries, the nail and all the soft tissues to the bone being destroyed, may be followed by regeneration so complete that scarcely any trace of the injury will be perceptible. Unlike the lower extremity, lost parts of the hand or upper extremity cannot be satisfactorily replaced by mechanical apparatus, so that in injuries every attempt should be made to save as much as possible of this useful and unreplaceable member. Parts should not be amputated unless or until it is evident that repair is impossible.

Foreign bodies, like bullets or splinters lodged in the member, *bites* and *stings* of insects, and other poisoned wounds, etc., should receive the customary treatment, infection being especially guarded against. *Sprains* and *dislocations* will be considered in connection with the affections of the joints. *Fractures* of the metacarpal or phalangeal bones are simple of treatment, requiring reduction and immobilization.

Burns and scalds of the hand are very common, causing superficial dermatitis, ulceration, or more or less necrosis. If the destruction of tissue is extensive they are exceedingly apt to be followed by deforming and disabling cicatricial contractions.

Frost Bite.—From their small size, exposed situation, and distance from the circulatory centres, the fingers are often frozen, being exceeded in their liability to this accident only by the ears and toes. Frost bite is apt to cause complete necrosis of the tissues involved, though the gangrene may be slow, even weeks, in attaining its full development. The frozen parts should at first be thawed out very slowly, as by the use of cold water, in order to avoid inflammatory reaction. The subsequent treatment is that of the necrosis which may supervene, removal of the sloughs by poulticing, caustics, or excision, asepsis, and protection of the resulting ulcer; and if the gangrene is extensive enough and when the limits of the necrotic process are demarked, amputation, preserving as much viable tissue as possible.

INFLAMMATORY CONDITIONS

in the hand and fingers may arise from mechanical, chemical, or thermic irritation, or from trophic impressions in some nervous diseases; but they are chiefly produced, and to a more serious degree, by infection with the pyogenic and other micro-organisms.

Inflammation in the hand may occur in any part of the member; it may affect special tissues or structures exclusively (as the joints, tendon sheaths, bones, etc., to be considered subsequently), or it may involve various contiguous tissues. Inflammation affecting the tissues of a digit in general is termed dactylitis, though this designation is chiefly employed in connection with tuberculous and syphilitic dactylitis. Lesions of trophic origin will be considered in connection with the corresponding nervous disorders. Inflammations of infectious origin are intimately associated with the other pathological processes presented by the infection, so that often practically the two can scarcely be separated. The treatment of simple inflammations must be guided by the circumstances of the case, the cause, and the associated conditions.

INFECTIOUS AND PARASITIC CONDITIONS.

From its exposed location the hand is especially liable to infections. Pathogenic micro-organisms are very easily introduced through wounds, often so minute as to escape notice at the time, through blisters, through bites and scratches of animals and insects; a considerable variety of infections may thus become established. Much the most frequent of the infectious conditions of this member are those of suppurative nature. A small proportion of infections are represented by tuberculosis, syphilis, gonorrhœal lesions, leprosy, scabies, tinea, and others.

SUPPURATIVE AND RELATED INFLAMMATORY CONDITIONS, caused principally by the pyogenic staphylococci and streptococci, are the commonest of the infections of the hand, and occur in a variety of forms, as infected wounds, cellulitis, erysipelas, and abscess. In the initial stages of these conditions the morbid process may be purely inflammatory, suppuration setting in later. In some mild cases the morbid process does not pass beyond the stage of simple inflammation, being arrested before suppuration occurs. In some forms of erysipelas also typical suppuration does not occur.

The simplest form of pyogenic infection is that exhibited by *infected wounds*, in which the tissues adjacent to the injury are inflamed or suppurating.

In more severe cases the infection extends to tissues more distant from the wound. The treatment is the same as that of similar conditions elsewhere.

The terms cellulitis and erysipelas are in certain cases used interchangeably. Three forms may be distinguished —indurative, exudative, and suppurative.

Indurative Erysipelas is the form characterized by a slightly elevated, red, indurated, inflamed area on the skin, advancing into healthy tissue. This is the form commonly encountered in facial erysipelas; it occasionally occurs on the hand, originating from minute wounds, and only exceptionally proceeds to suppuration. Its treatment is that of the facial form, a variety of procedures being available, as cold applications, tincture of iodine, painting with solution of silver nitrate, injections of antiseptics, moist antiseptic applications, sedatives and emollients, etc.

Exudative Cellulitis is an infectious condition that often involves the upper extremity. The infecting organism gains entrance at a wound about the fingers or hand, often insignificant and unnoticed. The earliest symptom, often overlooked, is a faint red and inflamed streak, perhaps a little tender, extending from the point of infection up the arm; this is caused by an inflammation of the subcutaneous lymphatic channels, up which the infection rapidly extends. Next a large accumulation of serous fluid occurs in the subcutaneous tissues, causing a great distention and swelling of the fingers, hand, forearm, and more or less of the entire upper extremity. This lasts for several days before it subsides, and is accompanied by fever and much pain (from the tension). Sometimes the case proceeds to a general phlegmonous cellulitis, often resolution takes place without suppuration. The treatment consists in disinfection of the original focus of infection if it is discoverable; immersion of the swollen parts in ice water, for hours and even days to mitigate and arrest the process; multiple incisions through the skin if necessary to relieve tension and pain and allow escape of fluid; application of moist antiseptic and sedative applications; tight bandaging to keep the swelling down, etc.

Suppurative Cellulitis (phlegmonous erysipelas, abscess, etc.) is a suppurative inflammation of the connective tissues beneath the skin. It may be diffuse or circumscribed. It may involve an extensive area, with considerable danger to life, or it may be localized and confined to a small region (abscess). The portal of infection may be obvious, or the origin may be quite obscure. The process begins with a simple inflammation, gradually proceeding to suppuration; or in mild and abortive cases the trouble may at no time proceed as far as definite suppuration. The treatment, in general, is that of such conditions generally: in the early stages attempts to abort the process and avert suppuration by cold, application of tincture of iodine, and the like; when suppuration is manifestly inevitable it may be encouraged by poultices and warm applications; and as soon as suppuration fairly sets in, free incision and open treatment of the abscess. Suppurative processes in the hand and fingers are apt to run a very slow and protracted course before final recovery, this member not appearing to have rapid and vigorous reactive and reparative power in such conditions.

No part of the hand is exempt from suppurative inflammations or abscesses, but certain regions are so subject to these infections and exhibit such special features that a few special forms of the inflammatory process are plainly distinguishable and require special attention, namely, paronychia, whitlow, palmar abscess.

Boils and carbuncles may occur in this situation, but the hand is not a favorite seat of these lesions.

Paronychia (Infectious).—The ordinary acute paronychia, popularly termed "run-around" or "ring-around," is an inflammation, sometimes running on to suppuration, of the tissues at the sides and root of the nails. It is produced by the various pyogenic bacteria, which gain access at the root of the nail; there are also syphilitic and tuberculous forms of paronychia which are more chronic. The inflammation involves the cutaneous and subcutaneous tissues of the circumungual region, only one finger, as a rule, being affected at a time. At first the ordinary phenomena of inflammation are manifested —redness, pain, tumefaction. The pain and tenderness are not usually severe, but are sufficient to cause considerable annoyance and irritation. Many cases do not go beyond simple inflammation, but others proceed to suppuration, and in severe cases the nails may be cast off, and ulceration may ensue. While usually acute and of short duration, the course of paronychia may sometimes be subacute and prolonged. The inflammation is apt to be more severe and more prolonged in those of generally lowered constitutional condition or with specific taint. Paronychia is a common affection.

In the early stages, with the view of checking further progress of the inflammation and to relieve pain, applications of iodine, cold, emollients, sedatives, or poultices may be employed. To promote suppuration when inevitable, poultices are useful, and when pus formation is established free incision should be practised and the lesion treated like ordinary abscesses. The trouble usually yields readily to treatment. In cases of debility or specific taint constitutional treatment may facilitate healing.

Whitlow, Felon, or Panaritium (panaris), is a localized suppurative inflammation of the tissues of the palmar portions of the digits. Abscess may affect the dorsal tissues, but is much more frequent in the palmar regions of the fingers, where it presents special features. As regards pain, duration of disability, and loss of tissue, whitlow is a condition of no little gravity. Very often there is no perceptible wound by which the infecting bacteria gained entrance. Sometimes the condition arises after a slight bruise, blister, or other traumatism unaccompanied by any solution of continuity of the surface skin, a slight contusion of the tissues probably producing a local lowering of vitality and lessening of resistance that determine the development of infection at the point. A lowered constitutional condition may sometimes be a predisposing cause. Destructive processes in the fingers, often called whitlows, are generated by trophic influences in certain nervous affections, notably syringomyelia, but these have rather a necrotic character than the infectious nature of true whitlows. Any of the phalanges of the finger may be affected, more frequently and often more seriously the distal phalanx. Only one finger is ordinarily involved at a time, and whitlow is a quite common affection.

Three groups of tissues may be involved in the inflammation—the skin and subcutaneous tissues, the periosteum and bone, and the tendons and their sheaths. The inflammatory process may originate in any of these tissues, but usually extends from one group to another. The course of the disease varies according to which phalanx is affected.

The *distal phalanges* are somewhat more frequently affected than the middle or proximal ones. If the inflammation begins in the superficial tissues the skin shows the signs of inflammation—redness, swelling, pain. If the infective process starts deeper, the skin will not itself be red or inflamed, but the subcutaneous tissues will be œdematous from the inflammatory exudate, and the finger at this point will be tense and swollen and the seat of severe throbbing pain. In the distal phalanges there are no tendons and sheaths to enter into the case, but the subcutaneous fibrous tissues are intimately united with the periosteum, and inflammation of the subcutaneous tissues is almost certain to extend to the periosteum and bone, especially if thorough incision is not early practised. This involvement of the bone in the inflammatory process is what renders whitlow in the distal phalanx a rather serious condition. At first the morbid process is purely of inflammatory nature, but very early suppuration develops. Osteomyelitis sets in, and the phalangeal bone becomes carious and necrotic. The course of the trouble is exceedingly slow and protracted, and weeks often elapse before healing is complete.

The fingers possess quite slight resistance and reactive powers against deep-seated suppurative processes, perhaps from the relative circulatory weakness of these distal members. Pain is marked, often excruciating. The tissues at the height of the process are boggy and infiltrated with serous and purulent fluid, and the inflammation tends to extend proximally. Owing to the frequent deep situation and confinement of the infected area, the inflammation is apt to extend deep and far, causing great destruction of important structures before it will make an opening spontaneously through the skin. Granulation is slow to develop, but when well established the sinus is in a healing condition and on the way to obliteration.

Whitlows involving the *middle* or *proximal phalanges* are rather less common and generally less serious and protracted than in the distal phalanx. In these situations the tendinous structures are interposed between the subcutaneous tissues and the periosteum and bone, and to a large extent protect the latter from involvement. The escape of the bony structures from inflammation considerably mitigates the severity of the case. The morbid process readily extends along the tendons and tendon sheaths, and from destruction of their tissue or the formation of adhesions may cause considerable permanent disability and impairment of function. Aside from the special conditions offered by the presence of the tendons and the partial protection of the bone, the clinical features of whitlow in the two proximal phalanges are much the same as in the terminal phalanges. The inflammation may begin deep in the tissues, the more superficial structures being œdematous and swollen, and the surface not especially reddened. The infection may extend greatly in the tendon sheaths if an opening is not made in time through the overlying tissues. There is special liability to extension of inflammation along the tendon sheaths of the thumb and little finger into the palm. Pain is severe and healing is slow.

In treatment of whitlows, at their very inception an attempt may be made to abort the inflammation by tincture of iodine, application of cold, or subcutaneous injections of antiseptics like phenol. Such measures will not often be successful, and if the infective process continues to advance, radical treatment should be early adopted. Deep and thorough incision into the inflamed tissues is then necessary. Mere incision through the skin is not sufficient unless the trouble is all superficial; the opening must be carried down into the focus of infection. To secure thorough opening, therefore, in the distal phalanx the incision should be carried down to the periosteum; in the other phalanges incision to the tendinous structures will usually be sufficient. Free exposure of the affected region relieves tension and pain and provides a sort of safety vent, tending to prevent the further deep extension of suppuration. All fragments of necrotic bone should be removed, and curetting may be necessary. Poultices are useful both before and after the incision is made, to promote pus formation, relieve pain, and stimulate granulation. Drainage should be provided for, and the incision not allowed to close prematurely. Packing with iodoform gauze affords drainage and stimulates healing. Anodynes to relieve pain will often be required, and in debilitated patients general tonic treatment is indicated. Healing must be expected to be very slow, and some permanent deformity or impairment of the motor powers often follows.

Palmar Abscess.—Abscesses in the palm of the hand often involve the sheath of the flexor tendons in this situation, either primarily, or by extension from the digital tendon sheaths or from the subcutaneous tissues and fascias of the palm. The anatomical arrangement of the sheaths of the flexor tendons in the digits and palm is an important factor in palmar abscess. In the palm is a large synovial sheath common to the flexor tendons; this is continuous with the sheath of the tendons belonging to the thumb and little finger; but the flexor tendon sheaths of the index, middle, and ring fingers are closed at their proximal ends, and are not connected with the large common sheath in the palm. Consequently inflammation of the tendinous structures of the thumb and little finger can easily extend into the large palmar tendon sheath, and vice versa, while in the other three digits inflammatory processes do not extend from digits to palm. In whitlows of the thumb and little finger special care should therefore be taken to prevent extension into the palm. The inflammatory process may extend widely, especially if not adequately treated, involving more or less of the tissues of the entire hand, even to necrosis of the metacarpal or carpal bones. Palmar abscess is manifested by swelling, severe pain, heat, constitutional disturbance, fever, etc. It is quite a serious condition, and may result in more or less stiffening of the fingers, permanent injury of the tendons, and impairment of the motor functions of the hand; even death may occur from exhaustion, general sepsis, or hemorrhages.

The main feature of treatment of palmar abscess consists in early and free incision, so as widely to expose the inflamed parts. Care should be taken to open the main suppurating foci, and not to stop with opening into small secondary sinuses or superficial œdematous areas. Radical incision relieves tension and pain and localizes the process so as to prevent further extension. Longitudinal incisions in the palm, along the middle line of the metacarpal bones, can be freely made beyond the level of the web of the thumb without interference with the digital vessels or palmar arches. Aside from the special points mentioned and the greater area involved, the clinical features and treatment of palmar abscess and of whitlow are much the same.

TUBERCULOSIS.—The hand and fingers are subject to tuberculosis like other parts of the body. Infection may arise not only in the usual way, by internal conveyance of the bacilli, but also by direct inoculation through slight wounds from contact with external infectious material, as in the case of persons whose occupation necessitates the handling of diseased and dead tissues, like physicians, nurses, butchers, cooks, cattlemen, tanners. Notwithstanding this exposure to external infection, tuberculous lesions of the hand and fingers are not common. The bones, joints, tendon sheaths, and skin are the structures chiefly affected.

Tuberculous osteomyelitis or osteitis, with enlargement, chronic suppuration, sinus formation, caries, necrosis, loss of considerable osseous substance, and the usual phenomena of this condition, may involve any of the bones of the hand, sometimes primarily (so far as the hand is concerned), sometimes secondarily by extension from a lupus vulgaris, occasionally by extension from a tuberculous joint. Tuberculous arthritis affects by preference the larger joints of the body, though the wrist joint is sometimes affected; tuberculosis of the wrist and joints of the fingers more often arises by extension from foci in the neighboring bones or skin than primarily. Chronic tuberculous inflammation of the tendon sheaths (see below, p. 516) in the forearm and hand may arise, either primarily or by extension. In all these cases the course of the disease is protracted and chronic, though recovery may ensue. Sometimes the tuberculous involvement of the hand occurs in association with tuberculosis elsewhere, as in the vertebræ or lungs; in other cases the infection may make its first appearance in the hand. From the hand the disease may extend to the lymphatic glands of the arm, or general infection of the body may occur; in some cases the system may escape. Great deformity of the hand may follow after healing of the lesions, from cicatricial contractions and loss of tissue.

The chief clinical forms in which tuberculosis of the skin appears in the hand are lupus vulgaris and tuberculosis verrucosa.

Lupus vulgaris affects the face most frequently, but in a considerable proportion of cases attacks the extremities, including the hand and fingers. The dorsum of the hand is the locality chiefly affected, the disease only very rarely beginning in the palm. The disease occurs or begins chiefly in childhood. It runs a very slow and chronic course, though at times it makes rapid progress. Lupus vulgaris sometimes originates directly from external inoculation, but the infecting bacilli are usually derived from sources within the body, and the condition is often secondary to other tuberculous lesions. Clinically the affection arises from soft, brownish-red, painless nodules which develop in the corium singly or in coalescent aggregations and cause a slight projection above the cutaneous surface. The nodules may run their course as such, and undergo involution and absorption, leaving a superficial desquamating area and a sunken cicatrix; or they are very apt to break down and form shallow ulcers; or the affected tissues may proliferate in exuberant fungoid granulations. After pursuing an exceedingly protracted course for months or years, the ulcers may heal, and great cicatricial contraction or elephantiasiform enlargement may result. In the hand the tuberculous process may extend from the skin downward to the subcutaneous tissue, tendons, and bones, causing widespread involvement of the parts (as in tuberculous dactylitis), with suppuration, abscesses, sinuses, caries, and necrosis of bone. After healing from such a condition great deformity is apt to result, the fingers being distorted, mutilated, twisted, thickened, ankylosed, etc., from cicatricial contractions and loss of tissue.

Tuberculosis verrucosa is a form of cutaneous tuberculosis differing in some of its clinical features from lupus vulgaris. It arises chiefly from direct external inoculation of the skin with the tubercle bacilli, and hence occurs mostly in adults whose occupation exposes them to the handling of infected tissues or other material. The hands and fingers, especially their dorsal surfaces, are therefore the commonest seats of tuberculosis verrucosa, though other parts of the body, as the elbows and knees, are also subject to it. The essential lesion of tuberculosis verrucosa begins as a papule in the corium, which becomes pustular, then breaks down and forms a small ulcer, upon which papillary growths develop, and after some time become covered with a horny mass. The characteristic feature of fully developed verrucose tuberculosis is the tendency to horny or warty papillary proliferation. The disease extends slowly from a centre.

The simplest form of the trouble is the *verruca necrogenica,* also called "post-mortem wart" and "anatomical tubercle," which is a small nodule found on the fingers or hand of persons exposed to local inoculation, as physicians or nurses engaged in clinical or autopsy work.

Fully developed tuberculosis verrucosa is similar in nature, but of greater extent. In this condition there are slightly elevated horny, warty patches on the skin, varying in size from small areas to large plaques covering the entire dorsum of the hand and even extending over on the palm. The patches are aggregations of warty nodules and slowly extend at the periphery. They have an erythematous border, inside which is a zone of pustules; the centre of the patch is occupied by an aggregation of warty tubercles covered with crusts and horny material. There may be erosions and fissures, but there is little tendency to ulceration. The centre may undergo resolution, leaving a central cicatrix surrounded by a disease ring. The course of the disease is very slow and chronic, sometimes continuing for years. Usually the general condition is not impaired, and the lesion is not ordinarily followed by serious results; general tuberculosis may, however, originate from the cutaneous infection.

In both lupus vulgaris and verrucous tuberculosis the essential lesion is tubercle formation in the corium, and in both tubercle bacilli have been demonstrated.

In addition to these two types of cutaneous tuberculosis other clinical forms of tuberculous dermatitis and cellulitis may occur. Chronic paronychia of tuberculous origin has been observed; and some cases of "malignant paronychia," in which there is extensive ulceration and a protracted and severe local condition, are supposed to be of tuberculous nature. An inflammatory tuberculous tumor, not of warty nature, has been known to follow a slight wound on the hand caused by the thumb nail, in the case of a physician who at the time was treating two cases of tuberculous laryngitis (Schamberg).

Tuberculous dactylitis, or tuberculous inflammation of various tissues of the digits, though an uncommon condition, presents some distinctive features. It may arise as a secondary extension from lupus vulgaris in the vicinity as already stated, but the more typical cases originate in tuberculous osteomyelitis of the phalanges. Tubercle formation begins in the marrow of the phalangeal bones, especially near the articular ends; the cortical bone becomes gradually involved, while new bone is simultaneously formed by the periosteum. In this manner the phalanx assumes a characteristic fusiform shape, enlarged at its middle. Later, the process may extend to neighboring tissues, joints, and fibrous structures, and there is usually a tendency to suppuration and sinus formation. Caries and necrosis of the bone is apt to follow, and from the destruction of a part of or even an entire phalanx, deformity results after healing, especially shortening of the finger. The skin is thickened, tense, and may be pale, red, or purple. Pain is slight; the affected part may be hard or soft. The disease occurs especially in childhood, and often in association with tuberculosis elsewhere, as in the vertebræ, or there may be a family history of tuberculosis. The disease is very slow and chronic in its course. Recovery from the local trouble may follow, often with deformity; or general tuberculosis may ensue. One digit alone may be affected, or a number (not necessarily adjacent) may be successively involved. The proximal phalanges are apt to be the ones affected.

Tuberculous dactylitis is quite similar in its clinical manifestations to syphilitic dactylitis, and has often been mistaken for the latter. The history (personal and family), the effects of specific treatment, etc., must be taken into account in making the diagnosis. The enlargement of the phalanges is more spindle-shaped in the tuberculous form, more spherical in the syphilitic form. The condition may also resemble whitlow, chondromata, exostoses, sarcoma, and hypertrophic conditions; but the history, the course of the case, the tendency to suppuration, and other clinical features usually permit ready differentiation from these conditions. As to prognosis, a protracted course of the disease is to be expected, but recovery often results and may be usually expected if general tuberculosis does not occur.

The *treatment* of tuberculous lesions in the deeper tissues of the hand is the same as that of such conditions in general—constitutional treatment (cod-liver oil, arsenic, etc.), opening of suppurating foci, curettage, injections of iodoform emulsions, etc. In the cutaneous forms of the disease vigorous local treatment often effects a cure. Curetting is very useful for ulcerating and granulating surfaces, in conjunction with caustics like silver nitrate, arsenic, and salicylic-acid preparations. Nodular and warty lesions are well treated with thermo- or galvanocautery or puncture. Small areas may be excised, but cicatricial contraction or recurrence of the disease in the scar may follow; skin grafting may be useful treatment for ulcers following excision. Scarification, in crossing series of close parallel lines, has been highly recommended, but requires repeated séances and a long time.

SYPHILIS.—Like other parts of the body, the hand and fingers are subject to various manifestations of syphilis, both inherited and acquired forms of the disease; a few special features are exhibited in this region. The chief syphilitic lesions encountered on the hand are the chancre, various syphilides, syphilitic paronychia, syphilitic onychia, gummata and inflammatory processes in the deeper tissues, syphilitic dactylitis.

The fingers and hand are occasionally the seat of the initial *chancre*, the primary inoculation taking place at this point not infrequently in physicians from exposure to the infection in the course of clinical work, or in others, not innocently, from libidinously handling the genitals. The inoculation is apt to take place about the nails, though the chancre may be situated on other parts of the hand, and may resemble paronchyia or whitlow. The chancre is usually red, thickened, elevated, indurated, and circumscribed, but ordinarily does not show much tendency to ulceration. Its course is slow. It is followed by enlargement of the epitrochlear gland, and often of the axillary glands.

Most of the varieties of *syphilides*—macular, papular, vesicular, pustular, tubercular—may affect the skin of the hands. The palms are quite favorite seats for the development of many syphilides, especially the papular and squamous forms, and exhibit a special tendency to desquamation of the lesions. The dorsum of the hands, on the contrary, is comparatively quite exempt from most forms of cutaneous syphilis; the ulcerating tubercular syphilide, however, frequently involves the back of the hand. The moist syphilitic papule may affect the interdigital angles.

Partly owing to its thick epidermis and marked desquamating tendency, the palm (with the sole) exhibits a special form of syphilide, the palmar (and plantar) syphilide. The lesions of this condition consist of irregular patches, only slightly elevated, covered with scales, beneath which is the dull red infiltrated corium. The margins of the patches are especially scaly. The patches may coalesce, forming serpiginous areas, and deep fissures into the corium may develop. Sometimes instead of desquamating the epidermis becomes hard and horny. Subjective symptoms are ordinarily absent. The lesions may occupy only a small area, or may extend over the entire palm, only rarely proceeding to the dorsal surface or beyond the wrist. They may develop early or late in the course of syphilis, are very chronic in their course, exceedingly obstinate and resistant to treatment, and show marked tendency to recurrence.

Syphilitic Paronychia, or involvement of the tissues about the nails (of fingers or toes), exhibits three chief types, a dry or corneous, an inflammatory, and an ulcerative form.

Dry or Corneous Syphilitic Paronychia, the commonest form, is characterized by a horny thickening or proliferation of the circumungual epidermis, with repeated exfoliation. It begins as a small, hard, horny mass at the side of the nail, which increases in size, and may extend entirely around the nail or even invade the entire dorsum of the last phalanx. This thickened epidermis cracks and exfoliates, leaving the surface ragged and scaly. There is slight tenderness, and a yellowish-white color. The corium is more or less infiltrated, and in bad cases may be thickened, fissured, excoriated, and painful. The nails are only slightly affected. The process is very indolent and recurrent, and occurs in the secondary stage of the disease. Several fingers are usually affected successively.

Inflammatory Syphilitic Paronychia begins as a papule or nodule, usually at the side of the nail, sometimes over the matrix, which pursues a very slow course without active inflammation or tendency to suppuration or ulceration, and disappears by absorption. The affected area is hard, dusky red, slightly tender. Onychia only exceptionally coexists. It is often confined to a single digit. It occurs in the secondary stage, especially in those of poor health and often in children with congenital syphilis.

Ulcerative Syphilitic Paronychia is a severe condition caused by a gummatous process, with necrosis, in the corium and subcutaneous tissues. It is a secondary or perhaps rather a tertiary phenomenon, and develops especially in severe neglected or debilitated cases of syphilis. It is often confined to a single finger, and is very chronic in its course. The lesion consists of an indolent ulcer with undermined edges, and surrounded by a raised dusky or red border. An abundant thin sero-purulent discharge is given off. From extension of ulceration to the matrix and nail bed, the nail becomes discolored, undermined, and loosened, and may be cast off. In severe cases the granulations become exuberant and fungous; the cast-off nail is perhaps embedded in their midst as an irritating foreign body; the tissues about the ulcer swell and become indurated; the entire dorsal surface of the phalanx may be invaded; and the digit may become clubbed. If the nail bed and matrix are destroyed no new nail will be formed when the ulcer cicatrizes.

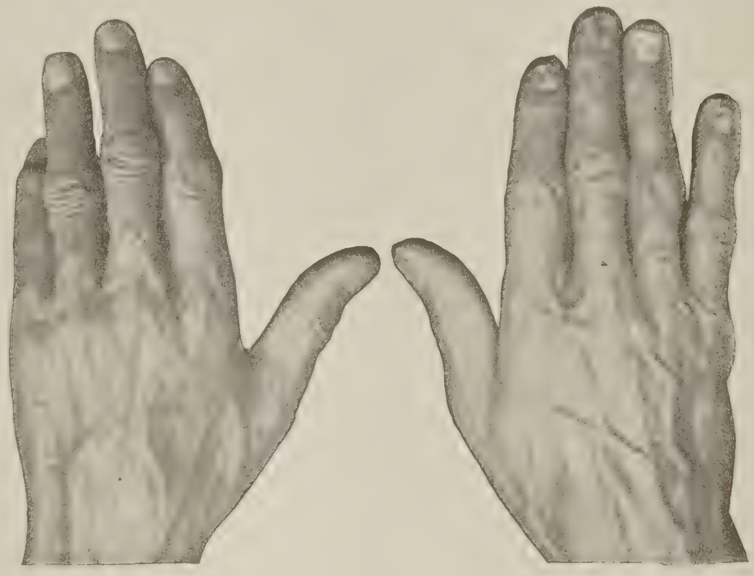

FIG. 2485.—Syphilitic Onychia. (Original.)

In the treatment of syphilitic paronychia, mercury alone or with the iodides is indicated. The iodides should be given especially freely in the ulcerative form. Local treatment should be followed according to the indications. The affected finger tips should be protected from irritation by finger-stalls, etc. In the ulcerative paronychia removal of the nail will often be desirable to prevent its acting as an irritant foreign body.

Syphilitic Onychia is an altered condition of the nails (of both fingers and toes) caused by defective nutrition and not of inflammatory nature. It occurs in the secondary stage of syphilis, both in the acquired and in the congenital forms, and sometimes appears in very young infants. Several nails are usually involved, either simultaneously or successively. It is only exceptionally associated with paronychia. All the forms pursue a very chronic painless course; ultimately recovery is perfect, and normal nails are reproduced.

Syphilitic onychia exhibits a number of different clinical varieties, as follows:

1. In the commonest form, "onyxis craquelé," in mild cases the nail becomes dull and lustreless, yellowish, brittle, and breaks easily on its edge; a similar condition may also occur in other chronic or debilitated conditions. In severe cases the nail in addition becomes marked by parallel ridges, and the free edge thickens and cracks and breaks easily, leaving an irregular broken margin. This condition is sometimes associated with dry paronychia.

2. In a second variety, the nail gradually and insidiously separates from the nail bed, beginning distally and extending toward the root of the nail. The separated portion is discolored. Usually the nail is only partially detached, but occasionally it is entirely cast off.

3. In another form the growth of the nail or formation of the nail substance is entirely or partially arrested. The boundary between the old nail and the new portion is formed by an irregular transverse line, which advances toward the end of the nail. The old nail becomes discolored, ridged, loosened, and finally drops off, and its place is taken by epidermis or by a thin and imperfect nail structure.

4. There is also a hypertrophic form, in which the nail becomes greatly thickened, with its surface dry, uneven, cracked and split, yellowish, dirty, unsightly.

Besides these varieties other forms of syphilitic onychia sometimes occur, similar in their general nature, all being conditions of lowered nutrition. The treatment consists in the administration of mercury (rather than iodide), with tonics, etc., in debilitated conditions. The finger tips should be protected by stalls, etc. The prognosis is good, and well-formed nails are almost always ultimately produced.

Gummatous and Inflammatory Processes may involve the deeper tissues of the hand and fingers in much the same way as in other parts of the body. The subcutaneous tissues may be the seat of gummata, which may break down and ulcerate; the palm, however, is almost exempt from this lesion. The tendon sheaths about the fingers are subject to gummata and to chronic and acute syphilitic inflammation. The bones and periosteum may be affected in various ways, in the form of gummata, periostitis, osteomyelitis, osteitis, caries, necrosis.

Syphilitic Dactylitis is a specific involvement of the tissues of the digits presenting distinctive clinical features, first definitely recognized by R. W. Taylor in 1871. It is one of the tertiary or late manifestations of syphilis, and occurs both in acquired and in inherited forms of the disease, and hence both in children and in adults. The fingers are oftener attacked than the toes. Any of the fingers may be affected, but the middle and ring fingers are said to be oftenest involved. One finger may be affected, or several, simultaneously or successively. The lesion consists essentially in a gummatous infiltration of the soft or hard tissues, which is apt to undergo necrosis and ulceration, together in some cases with chronic inflammation and secondary pyogenic infection. Two varieties of the disease are distinguished: (1) that in which the subcutaneous and ligamentous structures are primarily and chiefly affected, and (2) that in which the bone or periosteum bears the brunt of the disease.

1. In the first variety, or "syphilitic panaris," the subcutaneous fibrous tissues and the ligaments about the joints undergo gummatous infiltration. The dorsal sur-

UNIVERSITY of ILLINOIS

faces are rather more liable to this form than the palmar surfaces, and the proximal phalanges are especially affected. The parts affected increase in size and are tense and hard, or soft and semifluctuating. The overlying skin is purplish or violet in color. The gummata may break down, but do not tend to suppurate. The disease process in the ligaments sometimes extends to the articular structures beneath the synovial membranes, the articular cartilages, or bone; but the joint usually escapes serious involvement. The course of the affection is very chronic and nearly painless, and it is sometimes very resistant to treatment and tends to recur. This condition may be distinguished from gout, acute rheumatic arthritis, or whitlow by its chronic painless course; from rheumatoid arthritis by the location of the initial lesions in the joints, the early deflection of the phalanges, and the non-discoloration of the skin, in the latter, as well as by the concomitant symptoms and history. The prognosis is good, and recovery with a useful finger may be ultimately expected, unless the joints are seriously damaged.

2. In the second and more typical form of syphilitic dactylitis the osseous tissues and periosteum are primarily and especially affected. In a syphilitic child or adult, with or without other syphilitic manifestations, a phalanx in one or more fingers begins to enlarge. The process begins as a gummatous growth, causing marked enlargement, and may be associated with inflammatory conditions (osteitis, osteomyelitis, periostitis). If the marrow cavity is first involved, the symptoms are more acute, pain is more severe, the increase in size more rapid. In connection with gummatous infiltration of the hard bony substance, osteitis occurs, either rarefying osteitis, with destruction of the bone, or, later, formative osteitis causing new formation of bone. Gummatous deposits in the periosteum may produce multiple small tumors.

In typical cases there is marked spherical or fusiform enlargement of the affected phalanx. The soft parts are stretched; the skin is purple, violet, livid or red, shiny or dull. When the gummatous enlargement is advanced the new tissue breaks down into a fluid discharge or cheesy mass; ulceration takes place; secondary infection with the ordinary pyogenic germs may occur, and suppurating sinuses are formed. Extension to the joints may follow, producing synovitis, arthritis, or general gummatous involvement and disorganization of the articlar structures. Pain varies, frequently not being marked, but sometimes severe, often worse at night. Usually only one phalanx in a digit is affected, sometimes more. The proximal phalanx is the one most often invaded; not infrequently the metacarpal bone suffers. The course of the disease is chronic, or often subacute.

After recovery the new tissue may entirely disappear, or permanent changes remain. Decrease in size, with alteration in length or thickness, may follow necrosis and destruction of bony substance; increased size may result from formative osteitis. Cicatricial contractions may supervene. Joints may be destroyed, or false joints may be produced (from non-union after necrosis of bone), constituting a very disabling flail joint. Rarely ankylosis results. The prognosis on the whole is favorable; involvement of a single phalanx without extension to the joint is apt to recover without bad consequences. Loss of substance, the formation of flail joints, ankylosis, or cicatricial contractions may impair appearance and usefulness, and often to a great degree.

The diagnosis of syphilitic dactylitis from tuberculous dactylitis has already been considered. From ordinary whitlow it may be differentiated by its less painful and more chronic course and development, and the history of the case. From cartilaginous and bony tumors it may be distinguished by its less sharp localization, the tendency to necrosis, ulceration, and suppuration, the history, and the results of specific treatment. From various hypertrophic conditions, the clinical course and features and the inflammatory and ulcerating phenomena of syphilitic dactylitis will enable the diagnosis to be made.

In the treatment of syphilitic dactylitis, the iodides, with or without mercury, should be vigorously administered, with tonics if indicated. Too much should not be done locally. Gummata should not be opened or removed, and amputation is contraindicated; but if suppuration sets in it should be treated on ordinary surgical principles, by opening of abscesses and sinuses, curetting, removal of necrosed bone, etc.

OTHER INFECTIONS AND PARASITES.—Infection of wounds with other than the ordinary pyogenic bacteria is liable, from its exposure, to occur in the hand, as in some post-mortem wounds, laboratory infections, infection with the gas bacillus, anthrax, glanders, rabies, tetanus, etc. Some of these infections are very malignant and grave, though fortunately uncommon. The morbid condition is manifested either locally or systemically, or in both ways. The local condition consists in an inflammatory process in the tissues adjacent to the wound, with clinical features varying according to the infective agent.

The systemic manifestations are of septicæmic, metastatic, or toxæmic character, and constitute the element of danger in these cases. In some conditions, as in rabies and tetanus, substantially the entire clinical picture is made up of the constitutional manifestations, there being practically no morbid condition at the point of original entry of the infection.

The treatment of infected wounds of the hand is the same as that of these wounds generally—efforts at local destruction of the infecting parasites and their toxins, and cure of the local inflammatory lesions, with appropriate measures to combat the general manifestations.

Gonorrhœa may affect the hand in the form of gonorrhœal arthritis of the finger joints, which are a rather favorite site for gonorrhœal rheumatism; also occasionally as a gonorrhœal thecitis or other inflammatory affection.

Leprosy affects the hands severely, especially in the anæsthetic variety. In tubercular leprosy the nodular masses may develop in the fingers and hand, though this member does not usually suffer so severely in this respect as other parts of the body; the nodules about the fingers may break down and ulcerate. In anæsthetic leprosy the hand is apt to become exceedingly deformed and mutilated, from disintegration and necrosis of the joints and bones, ulceration of the skin and soft tissues, atrophy of the tissues, and deflections and contractions of the digits. The fingers and even parts of the hand often drop off spontaneously. The parts are anæsthetic, and the course of the affection is very slow and chronic. Claw-hand sometimes occurs in leprous neuritis.

Scabies usually makes its first appearance on the hand, whence it is conveyed to other parts of the body. The sides of the fingers and the interdigital angles are the points particularly attacked. The *trichophyton* fungus frequently invades the back of the hand, in the clinical condition known as tinea circinata. At least three cases of *hydatid* or *cysticercus* cysts in the hand are on record: one in the subcutaneous tissues of the palmar surface of a proximal phalanx, one beneath the palmar fascia in the palm, one originating within a proximal phalangeal bone and causing distention of the phalanx to the size of an orange. *Elephantiasis* has been already mentioned.

NECROTIC CONDITIONS

arise in the hand as elsewhere. Two factors especially conducive to necrosis which are operative in the hand are the exposure of the member to traumatic accidents, and its distant circulatory position, which makes it not only suffer from relative circulatory weakness but also subjects it to the consequences of any impediment to the blood flow at any point between it and the body centres. In this respect the hand suffers less than the foot. Gangrenous and necrotic conditions in the hand arise from various causes, such as destructive violence or chemical action, burns, frost bite; from interference with the circulation, by occlusion of the blood-vessels, in thrombosis, embolisms, traumatisms, endarteritis obliterans (senile gangrene); in association with infectious and inflammatory processes, as in carbuncles and necrosis of bone; in trophic conditions like syringomyelia, leprosy; in ergotism, Raynaud's disease, diabetic gangrene, etc. The clinical features and treatment vary according to the circumstances.

ULCERS

occur in a considerable variety of conditions, as in syphilis, epithelioma, lupus vulgaris, from injuries, inflammatory and infectious processes, trophic influences, and after separation of the slough in gangrenous cases.

CICATRICIAL CONTRACTIONS

often occur about the hands and fingers, with consequences ranging up to extreme deformity and disability, the usefulness of the hand being at times almost completely destroyed. These contractions may develop after the cicatrization of wounds or ulcers of any sort, as after lupus or syphilitic ulcers, but especially after the healing of ulcers from burns. Protracted granulation favors the development of deforming cicatrices. The deformities produced are very various, consisting of palmar, dorsal, or lateral deflections of the fingers, acquired syndactylism, etc.

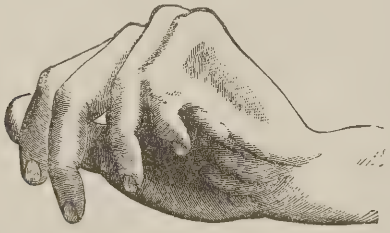

FIG. 2486.—Cicatricial Contraction in the Hand. (Gross.)

The successful treatment of these cases is quite difficult, as there is a strong tendency to recurrence after ordinary plastic procedures. As a prophylactic measure may be mentioned treatment of ulcers likely to be followed by contracting cicatrices in such manner as to shorten the period of granulation and healing, as by attention to asepsis or by skin grafting. Still, in slow-healing ulcers like those from burns there is little certainty of escaping later contraction. Even the keeping of the parts in a corrected or overcorrected position by splints or appliances is not very successful.

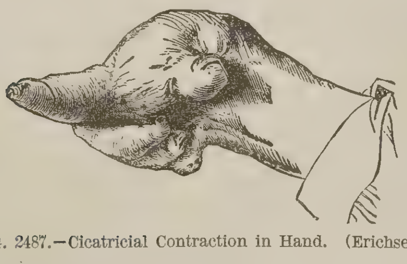

FIG. 2487.—Cicatricial Contraction in Hand. (Erichsen.)

The ordinary plastic operations sometimes succeed, but often do not secure permanent results. Among such procedures may be mentioned the lifting of a V-shaped flap, exsection of the cicatricial tissue, straightening of the parts, and final suturing of the wound in a Y-form. The Thiersch and Reverdin modes of skin-grafting for filling defects after dissecting out the vicious tissue are not very successful. A medicinal method of treatment of this and similar conditions, by the administration of thiosinamin, has been highly commended by a few, but has not come into general use. This drug is said to exert a selective disintegrating action on scar tissue; it is administered hypodermically, 0.1 to 0.2 gm. being injected deep into muscles (triceps or glutei) every three days, or by the mouth, 0.2 daily in capsules, kept up if necessary for weeks.

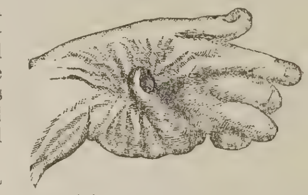

FIG. 2488.—Cicatricial Contraction with Backward Deflection of Little Finger. (Erichsen.)

The treatment recommended as most successful in these cases is a radical transplantation of a skin flap, one end of which is left with its original attachment and vascular supply intact until the flap is firmly united in its new position. The contracting scar tissues are divided and removed as much as possible, and the deformity is corrected. Into the gap thus left a flap of proper size, composed of the entire thickness of the skin, is brought and sutured. One end of the flap, affording the best vascular supply, is left unsevered from its original attachment until, after two to four weeks, the flap is well united in its new position. This flap can be taken in any convenient situation from the thorax, abdomen, or back, and the hand and arm bandaged in place until union is complete, when the flap is entirely detached from its original situation. In some cases it is probable that a similar flap could be taken from the dorsum of the hand and twisted around in position to fill a defect.

In intractable cases of great deformity amputation may be indicated, though it should be remembered that often a poor finger is more useful than no finger at all.

ACQUIRED DEFORMITIES.

The deformities to the acquirement of which the hand is subject are so various in their possible forms and diversities that they are hardly susceptible of useful classification. They may consist in loss of substance or parts, as from traumatisms, amputations, necrosis of bone or other tissue; in abnormal adhesions, in contractions of tissue, in deflections and distortions of fingers and hand from numerous causes, in nutritive alterations, in the results of occupation (occupation deformities). Most of the congenital forms of deformity may be duplicated by acquired conditions, as acquired acheiria, ectrodactylism, or hypophalangism from amputation or necrosis, acquired syndactylism from adhesions, acquired club hand or clinodactyly. The causes and nature of acquired deformities are so various that no general statements as to treatment can be made; each case must be managed according to its character.

EFFECTS OF OCCUPATION ON THE HAND.

The effects of an individual's occupation or habitual mode of life and environment may become marked by reactive consequences, structural and functional, upon various parts of the body, and especially upon the hand, since this member is so actively and constantly exposed and employed. The effects produced on the hand by occupation are not only of some clinical importance but are also of anthropological interest and medico-legal significance. An extensive study of the effects produced by a large number of occupations, especially from a medico-legal standpoint, made by M. Vernois, may be found in the *Annales de l'hygiène publique et de médecine légale*, 1862, 2d series, vol. xvii., pp. 104–190.

Among the many various factors which produce effects on the hand may be mentioned friction and pressure, as from the use of instruments and tools or the manipulation of machinery, which may have hypertrophic, irritative, or destructive consequences; frequent exposure to chemical substances, with irritant, caustic, emollient, staining, or other action; exposure to physical agencies, heat, cold, weather, sun; deposition of foreign matter;

the frequent repetition of slight traumatisms, "occupation insults," ultimately producing cumulative results. Any of the tissues and any part of the hand may be the seat of the alterations produced by occupation, and the changes may be either organic, with definite structural alterations, or functional and without anatomical changes. The particular changes set up vary in their site and nature according to the circumstances. While many avocations do not produce definite effects on the hand, others do produce distinctive and characteristic results.

Only a brief consideration of the general effects produced in the various tissues can be attempted here. For full and detailed information on the subject reference may be made to such works as that of Vernois, already cited.

The epidermis, from its superficial and exposed position, naturally exhibits marked effects from use. From continued pressure or friction it becomes very often hypertrophied, thickened, and hardened, especially on the palm, and either over the whole palmar surface or in circumscribed and distinctive localities (callosities) according to the site of pressure, as on the left finger tips of violinists. Or from exposure to water and other fluids, caustics, alkalies, acids, and similar strong chemicals, the epidermis may be softened, thinned, atrophied, or even entirely destroyed.

The cutis vera may from the action of irritants, etc., undergo inflammatory changes, or present erythema, blisters, pustules, ulcerations, fissures, cracks, etc. Later in such cases the skin exhibits cicatrices. The skin may be discolored from the action of chemicals and dyestuffs or exposure to the sun and weather. Foreign material, powders, flour, etc., in many cases is deposited under the nails or in fissures or folds of the skin. Foreign particles, as of iron or iron oxide in grindstone workers, may become permanently embedded in the skin, producing a tattooage effect similar to the particles of gunpowder often found deposited in the cutis. Impregnation of the skin with substances like resins or sulphur may produce a corresponding distinct odor. Increase or decrease of the delicacy of the sense of touch may be produced by practice or by thinning or thickening of the epidermis. The temperature of the hand may be affected by alterations in the development of the superficial vessels, being lowered in those who work with their hands in cold water, or habitually elevated and increased in those who work in hot places (as bakers).

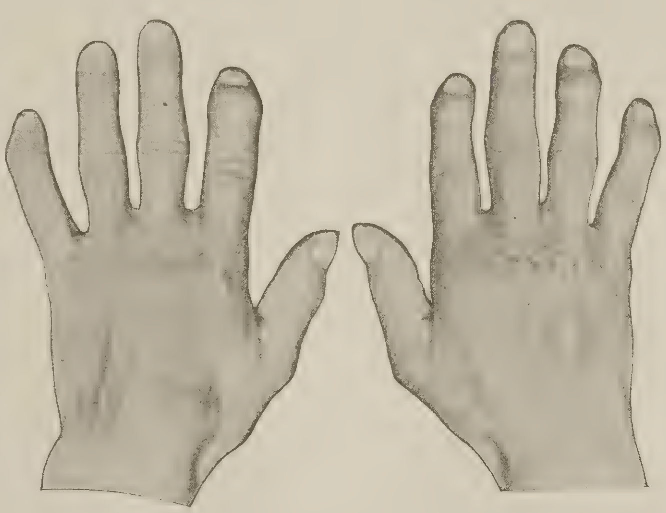

FIG. 2489.—Hands of a Baseball Player, Showing Characteristic Alterations. (Original.)

The nails are subject to special changes, as discoloration by chemicals or dyes, wearing off of the edges, or hypertrophy at particular points. The hairs may be discolored, or destroyed in places by pressure or chemicals.

The subcutaneous tissues may be thinned or thickened by the same factors that produce like results on the cuticle and cutis. The hands of those engaged in hard manual labor often exhibit a marked general palmar induration, the skin and underlying tissues being generally thickened, hard, rigid, and inelastic, and somewhat contracted so that the fingers are held slightly flexed and their full extensibility is somewhat impaired. From the action of irritants subcutaneous œdematous accumulations may be developed. Enlarged bursæ may appear at points exposed to pressure, as on the back of the right wrist in sawyers (Vernois).

The veins of the hand may become dilated from habitual exposure to heat. The muscles may to a certain extent become hypertrophied, atrophied, or shortened, according to their use or disuse. Special muscular activity and mobility and manual dexterity are developed in most occupations, as in pianists and many others. Habitual holding of the hand in certain positions, as with drivers, sometimes results in more or less rigid fixation of the hand or fingers in a flexed or other position—the *occupation* or *habit contracture*. Overuse of groups of muscles sometimes causes them to atrophy—*occupation muscular atrophy*. The nerves do not undergo perceptible anatomical alterations, but various occupations may produce serious functional nervous disorders of the hand, forming the important clinical class known as "occupation neuroses," typified by writers' cramp.

The articulations may be variously affected by occupation. Sometimes the mobility of the joint is increased, sometimes it is diminished, or there may be complete ankylosis. The finger joints may be enlarged, from exposure to repeated injury, as in baseball players. Partial luxations may occur, and deflections of the phalanges may be produced (as a backward deviation or superextensibility of the distal phalanx of the thumb in jewelers). From being kept in habitual special positions, corresponding changes may take place in the articular structures, as pressure atrophies, lengthening or shortening of ligaments, etc. Even the bones may undergo changes, as a spatuliform flattening of the phalanges from pressure.

From this résumé it will be seen that a great variety of changes in the hand may be produced by the occupation, varying in their situation, extent, and character according to the particular causative factors that may be at work in each case. The alterations may be anatomical or physiological, structural or functional. Three or four clinically important groups of conditions may be specially distinguished and mentioned: *occupation deformities*, in which alterations of form are produced; *occupation dermatoses*, embracing in general changes produced in the skin; *occupation dermatitis* and other inflammatory processes consequent upon the occupation; and *occupation neuroses*, covering the morbid functional nervous conditions induced by occupation or habit.

As an example of occupation deformities may be mentioned the effects often produced in the hands of baseball players, which are very characteristic (Fig. 2489). The typical changes in these cases consist in an enlargement of one or more of the distal phalangeal joints, along with slight lateral or palmar deflection of the terminal phalanges, which have a shortened appearance. Sometimes the affected joints are partially or completely ankylosed, though not always so.

No general rules as to treatment can be laid down, as the lesions and factors are so various in different cases. Change of occupation is obviously a therapeutic measure of general applicability in these cases. Occupation dermatitis and occupation neuroses will be referred to subsequently.

AFFECTIONS OF THE NAILS.

These are usually treated in full in works on dermatology, and will be only briefly reviewed here. The lesions of these structures may be divided into inflammatory and necrotic conditions (paronychias), changes in the substance of the nails (nutritive or trophic changes), atrophy, absence, hypertrophy, changes in form, changes in color, and parasitic conditions.

Inflammatory and Necrotic Conditions—Paronychia.—The nail substance from its histological structure cannot itself be the seat of real inflammation. The tissues contiguous to the nail and from which it derives its growth and nutrition (the bed, matrix, and root of the nail), are, however, subject to special forms of inflammation, and to such conditions the terms onychia (or onychitis) and paronychia are variously given. The term onychia is also applied to certain purely nutritive and trophic lesions of the nails. Other affections of these tissues in their clinical features resemble inflammatory paronychias, though primarily rather necrotic in character. The chief varieties of paronychia are the traumatic, infectious, malignant, syphilitic, tuberculous, diabetic, toxic, and trophic forms, besides those forms in which the cutaneous tissues adjacent to the nails are affected with various skin diseases, especially eczema and psoriasis. Of these forms of paronychia, the common acute variety due to infection with pyogenic bacteria and the syphilitic and tuberculous varieties have been already considered.

Traumatic Onychia and Paronychia is that caused by injuries, especially contusions. In cases of great violence the nail may be loosened and immediately cast off. In less severe cases, effusion and transformation of blood may give the nail a black color; in the course of time the nail often becomes slowly and gradually loosened from its bed, in whole or in part, and may be entirely cast off. If infection occurs the case is materially aggravated. The tendency is toward repair and recovery, with ultimate reproduction of a perfect nail. The parts should be kept protected, dead nail should be removed, and infection guarded against.

Malignant Paronychia (or malignant onychia) is an indolent inflammatory, suppurating, necrotic, or ulcerative affection of the nail matrix and bed, originating in a slight traumatism, and confined usually to a single nail. It affects especially persons of lowered vitality and in unhealthy condition, especially those of scrofulous diathesis, diabetics, and those prone to infections; it is commonest in children. It begins with simple inflammation, later proceeding to suppuration and ulceration. The nail becomes thickened, opaque, discolored, loosened, and cast off. The course of the disease is slow and indolent, and may become chronic; or the ulcer may slowly heal, and an imperfect nail be formed. The inflammation frequently extends to the subcutaneous tissues or the bone. In scrofulous cases the process is probably sometimes really tuberculous. The treatment consists in local measures to stimulate healing, and in vigorous constitutional and tonic treatment.

Diabetic Paronychia is the form of diabetic gangrene in which the circumungual tissues are the seat of the necrotic process or tendency, shown by sluggish inflammation or ulceration. The treatment is that of the constitutional disease.

Toxic Paronychia, that produced by the action of toxic agents, is well exemplified by the characteristic local lesions—ulcers at the roots of the nails—produced by arsenic in the hands of those who work with this substance. The obvious treatment is discontinuance of the cause.

Trophic Paronychia is the necrotic and inflammatory process about the nails which results from morbid nervous action in various neuroses such as syringomyelia or Morvan's disease, "glossy skin," Raynaud's disease, leprosy. The process is primarily degenerative and necrotic, but the lowered vitality of the tissues predisposes to sluggish infection and inflammation. The destruction of tissue may be extensive, involving even the bone, and the course is apt to be prolonged. The treatment is local and that of the cause.

Nutritive Alterations of the Nails.—While the nail substance proper is scarcely liable to inflammation, it is subject to nutritive and trophic alterations, mostly of a degenerative character, which may be produced by a considerable variety of causes.

The term onychia is applied to some forms of these alterations. The changes of a degenerative, malnutritive, or trophic character which the nails may exhibit are very various, such as loss of lustre, changes in color (white spots, etc.), softening, brittleness, friability, fragility, thinning, thickening, longitudinal or transverse furrows and ridges, laminations, exfoliation, splitting, irregularity of surface (elevations and depressions), etc.

These trophic alterations may be grouped into three etiological classes: (*a*) those due to local conditions or causes, as paronychia, dermatoses, trauma; (*b*) those due to constitutional diseases, especially those with a lowering of the general nutrition or vitality, and (*c*) those due to morbid trophic influences of nervous origin.

The paronychias do not all cause impairment of the nutrition of the nail, but in some cases, as in malignant paronychia, ulcerative syphilitic paronychia, and trophic or necrotic paronychias, the nail substance is apt to suffer, or may be entirely cast off. Skin diseases affecting the nails or adjacent cutaneous tissues, especially eczema and psoriasis, may cause malnutritive changes in the nails. Similar effects may be produced by trauma, contact with strong chemicals, parasitic affections of the nails, etc.

Severe constitutional diseases in which there is a great drain on the vital powers and the general nutrition is lowered, such as acute fevers, syphilis, scurvy, diabetes, gout, cancer, and others, also senility, may produce trophic changes in the nails. The syphilitic onychias have been already described. After acute diseases the ungual changes appear in the period of convalescence. Transverse furrows or white bands, representing temporary arrest of growth, sometimes appear after typhoid fever and other diseases. In relapsing fever two or three such transverse markings sometimes occur, one following and corresponding to each febrile paroxysm. Longitudinal ridges—"reedy nail"—occur in gout, senility, and other conditions.

In the third class of cases nutritive changes in the nails are produced by morbid, trophic, nervous influences arising from various nervous disorders, as in association with neuritis—multiple neuritis, gouty neuritis, leprosy, "glossy skin"—or with central nervous diseases.

In the treatment of these conditions the nails should be kept trimmed and in good order, protected by a coating of wax, and guarded against injury. The local or general condition giving rise to the ungual lesions should receive the appropriate treatment.

Atrophy of the Nail can scarcely be distinguished from certain forms of nutritive alterations, and is similar in its etiology and pathology to the latter.

Absence of the Nails (*Anonychia*) may be congenital or acquired. Rarely the nails are entirely absent from birth, either without any other developmental anomaly or in association with developmental defects like hypophalangism. The nail may be totally and permanently abolished by traumatisms or diseases causing complete destruction of the nail-forming tissues.

Hypertrophy of the Nail (*Onychauxis*) may consist in an increase in thickness, or in a lateral expansion (ingrowing nail). Both conditions are much commoner in the toes than in the fingers. In many cases enlargement of the nail is a result of nutritive abnormality, the increased nail substance being discolored, friable, brittle, fragile, etc. Hypertrophy of the finger nails occurs in connection with congenital dactylomegaly, traumatism, occupation effects, lack of cleanness, syphilis (hypertrophic syphilitic onychia), fungous growths, chronic skin troubles in the vicinity like eczema and psoriasis, nutritive and neurotrophic influences. The treatment is that of the cause.

Changes in Form of the Nails may result from traumatisms, occupation effects, nutritive or circulatory disturbances, or local disease. An increased transverse curvature is said to be produced by syphilis, hemiplegia, and free perspiration. An increased longitudinal curvature occurs in Hippocratic fingers and hypertrophic pulmonary osteo-arthropathy. "Spoon nail" is a condition in which the nail is concave transversely, with everted edges; it has been observed in connection with wasting diseases. Changes in relative length and breadth of the nails may also occur, as in rickets, in which the nail is said to be relatively shortened.

Changes in Color of the Nails may arise from staining by extrinsic substances or from intrinsic pathological processes.

The commonest change of color is to white, in the form of white spots, white bands, or whiteness of the entire nail. *White spots* on the nail ("flores unguium") are very common in children, usually occurring without perceptible cause; they may also be produced by injuries, trophic alterations, and constitutional diseases. Their pathology is not well understood. They are attributed to the presence of air in the nail substance. *Transverse white bands* sometimes appear after febrile attacks, sometimes occur in persons in good health, sometimes are congenital. *Complete whitening* of the nail occurs rarely, as after severe fevers or in paralytics.

Black Discolorations of the nails are common, from extravasation and transformation of blood pigment after contusions. Small black spots rarely appear on the nails after severe illness.

Parasitic Affections of the Nails.—The nails may be invaded by various parasites, either fungous (onychomycosis) or animal. The commonest form of onychomycosis is that produced by the trichophyton fungus; this, however, is infrequent, and usually secondary to or associated with tinea trichophytina elsewhere. Rarely the nails are affected by favus. Nails invaded by fungous growth are thickened, soft, brittle, lustreless, grayish or yellowish-white, and in a defective nutritive condition. The appearance is similar to that of nails suffering malnutritive or trophic alterations, so that the diagnosis is with most certainty made by microscopical examination.

Scabies occasionally affects the nails.

The treatment of nails infected with parasites consists in removal of the nail by scraping or applications of caustic alkali, with parasiticide applications (creosote, acetic acid, mercury bichloride, sulphur, etc.).

Affections of the Skin.

The consideration of the dermatoses of the hand and fingers belongs to the province of dermatology and can be only very briefly touched upon here. The skin of the hand is in general subject to disease in a similar manner to the rest of the body; but special or peculiar features are exhibited in many of the dermatoses of this locality, caused by exposure of the hand to atmospheric and meteorological conditions, to acute or chronic irritant influences of mechanical or chemical nature, and other factors.

Some dermatoses affect the hands indifferently or similarly or along with other parts of the body, without any peculiar features or special susceptibility or insusceptibility, as pemphigus, dermatitis herpetiformis, lichen ruber, ichthyosis, impetigo herpetiformis, prurigo, herpes zoster, molluscum contagiosum, scleroderma, mycosis fungoides, cornu cutaneum, and many others. To some dermatoses the hand is not at all subject, as seborrhœa, tinea versicolor; or less subject than other localities, as corns, psoriasis. To some dermatoses the hand is especially prone, and more susceptible than are many other parts of the body, though without manifesting any specially distinctive features, as erythema multiforme, herpes iris, pellagra, frambœsia, impetigo, impetigo contagiosa, callosity, warts, glossy skin, pompholyx, tinea circinata, scabies, occupation dermatoses. Some skin affections may exhibit peculiar features about the hand, as some forms of eczema and syphilides. Some dermatoses are peculiar to the hand, or to the hand and foot, as keratosis palmaris, affections of the nails.

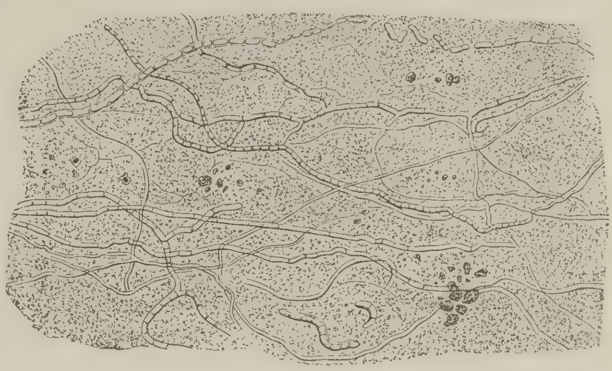

FIG. 2490.—Onychomycosis Trichophytina, Microscopical Appearance, Showing Fungus. (Kaposi.)

In many instances there is a marked difference in the liability of the palmar and dorsal surfaces of the hand to skin disease. Thus, the absence of hairs and sebaceous glands in the palm renders this area insusceptible to diseases of these structures, as acne. The dorsum of the hand is more prone to tuberculous dermatoses, erythema multiforme, keratosis senilis, tinea circinata; while the palm is more subject to most syphilides.

Eczema in its different varieties, acute and chronic, often occurs upon the hands, the liability of which to this dermatosis is increased by the exposure of these members to meteorological influences and to chemical irritants (especially alkalies). The chapping of hands is a form of eczema, induced by exposure to irritating influences. Onychias may result from eczema of the nails or their vicinity. On the palms eczema exhibits special features. Eczema about the hands is apt to be protracted and chronic, and very resistant to treatment. *Psoriasis* may occur both on the palms and backs of the hand, but is less common in this locality than in other situations. Occurring in or about the nails, it may cause an onychia. The backs of the hands are among the commonest seats of *erythema multiforme* and *herpes iris*. The hands are also favorite seats of *impetigo* and *impetigo contagiosa*. The hand may be affected with *dermatitis herpetiformis*, *pemphigus*, *herpes zoster*, *lichen ruber*, *ichthyosis*, and many other skin diseases in a manner similar to or along with other parts of the body. *Tinea circinata* is common on the back of the hands. *Favus* is much more rare in this situation; sometimes the nails become involved from scratching an infected scalp. The hand is the favorite seat of *scabies*. *Ainhum* sometimes occurs here and causes constriction and amputation of the fingers and even of the forearm. *Pompholyx* (or *dysidrosis*) is a rare vesicular affection, running on to maceration and exfoliation of the epidermis, that involves chiefly the palms and soles, though it may extend to or occur in other localities. *Callosities* are very common about the palm, resulting from habitual pressure or friction; manual labor also causes a general hardening of the palmar epidermis. *Corns* occasionally occur on the hand. *Keratosis palmaris* is a rare condition in which the epithelium of the palm becomes converted into a horny plate. *Glossy skin* is a trophic affection of the skin, due to nerve lesions or injuries generally, affecting especially the fingers; the skin undergoes malnutritive changes, or even actual necrosis, with onychia and pain. *Scleroderma* is a rare condition of sclerosis and contraction of the skin by which the hand as well as other parts of the body may be affected; in the hand it may produce great deformity and disability, the fingers being partly flexed, rigid, immovable, sometimes twisted, and in the later stages with atrophic changes. Tuberculous and syphilitic dermatoses, warts, and affections of the nails have been already considered.

Dermatitis of various kinds is common on the hands, due to their exposure to irritating conditions. Dermatitis traumatica results from traumatic irritation, dermatitis calorica from exposure to the rays of the sun or to other sources of heat and cold, burns, frost bites. In dermatitis medicamentosa lesions sometimes appear on the hands (as from the internal use of copaiba and chloral). The hands are very subject to dermatitis venenata, resulting from direct contact (either accidentally, temporarily, or habitually) with irritating or toxic substances, as in rhus dermatitis.

Allied to dermatitis traumatica, calorica, and venenata is a group of conditions which may be collectively designated *occupation dermatoses* or *occupation dermatitis*, to which the hand is very subject from repeated and habitual exposure to a variety of pathogenic influences incident to the occupation pursued. The changes in the epidermis, corium, and subcutaneous layer produced by occupation traumatism have been detailed above. In some occupations acute dermatitis may be set up from time to time. Thus, surgeons are sometimes subject to an acute inflammatory condition of the skin of the hands and forearms from hard scrubbing and prolonged exposure to liquids and to irritant chemicals like soft soap, mercuric bichloride, and oxalic acid.

For detailed information as to the clinical features and treatment of the various dermatoses of the hand reference should be made to works on dermatology.

Affections of the Bursæ.

The bursæ of the wrist, hand, and fingers may undergo development or enlargement, forming a variety of ganglion, either from pressure or irritation (as in some occupations), from rheumatic or gouty causes, or from causes not apparent. Rarely they may undergo inflammation —bursitis.

Affections of the Bones.

The affections of the bones of the hand are not sufficiently distinctive to require special consideration here. The involvement of the bones in developmental abnormalities, hypertrophic conditions, cartilaginous and bony tumors, fractures, infectious conditions, syphilis, and tuberculosis, has been already considered. Osteomyelitis, osteitis, periostitis, and other bone lesions do not present unusual features in the hand. In rickets the hand is little affected; the nails and terminal phalanges are said to be shortened in this condition. In osteomalacia the bones of the hand and fingers may become curved and bent; the distal phalanges especially are flattened, bent backward, blunt, and clubbed. The articular ends of the bones may participate in affections of the joints.

Affections of the Joints.

The articulations of the hand and fingers, while liable like other joints to the various arthropathic conditions, present some distinctive and peculiar pathologic features.

Injuries.—The ordinary injuries which these joints may suffer—wounds, blows, contusions—do not differ in their clinical characteristics or treatment from the like injuries of joints in general. Sprains of the wrist or finger joints require the usual treatment, immobilization, sedative or counterirritant applications, etc.

Dislocations of the joints under consideration may according to site be divided into radiocarpal, carpal, carpometacarpal, metacarpophalangeal, and phalangeal dislocations. From an etiological standpoint they may be divided into three classes: congenital dislocations, spontaneous (acquired) dislocations, and the ordinary traumatic dislocations.

Congenital Dislocations of any of the joints of this region may occur and have been observed, though very rarely.

A few cases of dislocations of the wrist existing at birth have been observed, forming a variety of club hand. The dislocation may be either forward or backward, and is generally associated with a shortening of the forearm. Both hands may be affected. The hands are usually well formed and quite useful.

A few cases are also recorded of congenital dislocation of the phalanges, at either the metacarpophalangeal or interphalangeal articulations, and in a palmar, dorsal, or lateral direction. Several fingers are usually involved simultaneously. The treatment consists in prolonged use of splints or corrective apparatus, with section of ligaments if necessary.

Spontaneous Dislocations or subluxations of the wrist or finger joints may occur in consequence of deforming or destructive joint lesions, as in arthritis deformans, or suppurative, tuberculous, or syphilitic arthritis.

There is a special class of cases in which a *spontaneous anterior subluxation of the wrist* gradually develops in adolescents engaged in hard manual labor. In this condition there is a partial forward dislocation of the carpus, with an undue prominence of the lower ends of the radius and ulna posteriorly, a diminished range of extension, an increased range of flexion, and a prominence of the flexor tendons. The ligaments are lax and the bones soft. Pain is usually present, at least until full growth is attained. This condition develops from about the age of fifteen to twenty-five years, in persons (especially females) engaged in hard manual work while the bones and joint structures are still soft, weak, and undeveloped. The superior strength and excessive action of the flexor muscles is supposed to be the determining cause of the anterior displacement. The deformity is difficult to overcome. The treatment consists in the use of corrective apparatus, stimulation of the strength and nutrition of the extensor muscles by massage, electricity, and exercise, the use of spring apparatus to reinforce and aid the action of the extensors, and suspension of excessive use of the flexors.

Traumatic Dislocations.—Dislocation of the wrist at the *radiocarpal* junction may occur backward or forward, or extremely rarely laterally (outward). This accident is far less common than Colles' fracture of the radius, which usually results from violence at this point. Reduction is effected by traction and direct manipulation.

Dislocation of the distal row of *carpal* bones from the proximal row has been noted in a very few instances. Dislocation of single carpal bones, forward or backward, may also occur. In some persons with weak and lax wrist joints single carpal bones may easily and repeatedly slip backward. Reduction is effected by pressure back into place, with use of a tight bandage to prevent recurrence.

Dislocation of metacarpal bones at the *carpometacarpal* junction rarely occurs. The metacarpal bone of the thumb is the one oftenest dislocated at this joint, the dislocation being forward, backward, or outward. The other metacarpal bones may also, very rarely, be dislocated either forward or backward. The bones may be dislocated singly, or more than one may be involved simultaneously. Reduction is usually easily effected by pressure of the bone into place, after which it should for a time be kept in position by splints or bandages to prevent recurrence.

Dislocations at the *metacarpophalangeal* articulations may be either forward or backward. The anterior luxations do not usually present special difficulties in reduction, which is accomplished by traction or by flexion, together with direct pressure.

The backward dislocation of the proximal phalanx of the thumb is a condition of some seriousness, from the difficulty sometimes encountered in effecting reduction. The phalanx may be superextended, or bent backward at an angle with the metacarpal bone; or in a still worse degree of luxation the base of the phalanx may overlap and lie behind the head of the metacarpal bone, the phalanx lying in the same direction as the metacarpus. The anterior ligament of the joint, which is firmly united with the phalanx but only loosely to the metacarpal bone, is torn loose from the latter bone, and if it becomes interposed between the ends of the two displaced bones it forms a serious obstacle to reduction. The lateral ligaments and the sesamoid bones in the tendons of the flexor brevis pollicis may also intervene between the two bones, while the slipping and retention of the base of the phalanx between the two tendons of insertion of the flexor brevis also interferes with reduction. Premature attempts to flex the dislocated phalanx only aggravate the trouble and should therefore be carefully avoided. In reduction, the metacarpal bone should be pressed toward the palm to relax the flexor brevis; the phalanx should be superextended well backward; the base of the phalanx should then be pushed by direct pressure into place, or until the anterior margin of its articular surface engages the posterior edge of the metacarpal joint surface; then by flexion of the phalanx the bone can be made to come into place. If this fails, rotation of the phalanx to free one side of the joint and then the other, combined with direct pressure or extension, may succeed. Sometimes all methods of manipulation fail, and a cutting operation may be necessary; in this case the anterior ligament may be put in proper position through a median palmar incision, or the tendon of the flexor brevis and the lateral ligament may be divided on one side, or pulled aside. In case of entire failure to effect reduction a moderate degree of movement and usefulness of the thumb will usually be ultimately obtained.

Dislocations of the other fingers at the metacarpophalangeal articulations are less common than of the thumb. They present similar features, sometimes similar difficulties in reduction of the backward luxations, and require the same treatment as in the case of the thumb.

Dislocations of phalanges at the *interphalangeal* articulations are common, and may take place in a palmar, dorsal, or lateral direction. Reduction is usually easily accomplished by traction and pressure.

A backward dislocation of the terminal phalanx occurs especially in baseball players (described by R. Abbe), in which the end of the middle phalanx is tightly caught between the flexor tendons and through an opening in the anterior ligament, rendering reduction difficult and often necessitating incision upon the joint in order to correct the displacement.

Ankylosis of the wrist or smaller joints of the hand and fingers is very common, resulting usually from traumatisms, blows, and wounds. Very slight injuries are often sufficient to cause ankylosis of these joints. Even prolonged immobilization may cause stiffening, even of the wrist; hence, in conditions like fractures, requiring prolonged fixation of the hand or fingers, it is advisable to practise passive movement, massage, etc., of the joints at sufficiently short intervals. . Operations about the finger joints, even if entirely aseptic, are exceedingly apt to be followed by ankylosis; in considering the advisability of operation in various cases this danger should be borne in mind, as the condition desired to be remedied may be preferable to possible or probable ankylosis consequent upon operation. After such operations the joint should be exercised frequently and for a long time to prevent ankylosis as far as possible.

Ankylosis may also be a sequela of inflammatory, infectious, or necrotic conditions. Congenital ankylosis of the small joints of the hand and fingers occurs rarely, sometimes being a hereditary abnormity of development. In a considerable proportion of cases of ossifying myositis a developmental ankylosis of the carpometacarpal, metacarpophalangeal, or interphalangeal articulation of the thumb is present.

There is little chance of completely restoring the mobility of an ankylosed finger joint, though arthrectomy or breaking up of the adhesions and bands may be attempted. If the joint is ankylosed at an inconvenient angle an improvement in the position can at least be obtained by operation.

Arthrogenous Deflections of the hand or fingers may arise from a variety of causes, as altered configuration of the joint structures (as in arthritis deformans), ankylosis in malposition, adhesions and contractions of the articular tissues, inflammatory or necrotic processes, developmental abnormities, dislocations, etc. The clinical features and treatment of these conditions vary with the cause. Hammer finger, due to shortness of the lateral ligaments, is an arthrogenous deflection that will be considered subsequently.

Enlargement of the joints of the hand is very common, and while (unless associated with partial or complete ankylosis) it usually causes little or no disability or impairment of function, it is unsightly. It arises from very diverse causes. Enlarged joints are very frequently produced by injuries (see Fig. 2489), and sometimes only slight injuries are sufficient to cause considerable deformity of this kind. The finger joints are often enlarged in persons engaged in manual labor. Deposits or hyperplastic processes about the joints, as in gout and arthritis deformans, are a common cause of enlarged joints. Another cause is found in neurotrophic influences, as in Charcot's arthropathy of locomotor ataxia and syringomyelia. Systemic conditions may also be etiological factors; thus, the proximal phalangeal joints are said to be enlarged in cases of dilated stomach. Enlarged joints of the hand should be treated according to their cause.

Secondary Alterations may develop in certain circumstances in the joints under consideration. When the joints (not being primarily affected) remain in fixed positions for a long time, as in the contractures of nervous diseases, Dupuytren's contraction, hammer finger, and the like, they after a time undergo compensatory, degenerative, or other secondary changes and become accommodated to their habitual position, so that if the primary cause of the malposition is done away with, the secondary alterations in the joint structures will still interfere with correction of the deformity. It is therefore important to avoid prolonged immobility or submobility of the hand or digits as much as is possible, so as to prevent secondary joint changes that may prove more or less irremediable.

Synovitis and Arthritis.—The inflammatory affections of the joints of the hand are chiefly of traumatic, infectious, tuberculous, syphilitic, gonorrhœal, or rheumatic nature. In addition to these are the rheumatoid arthroses, arthritis deformans, gout, and chronic rheumatism, characterized by abnormal trophic processes or deposition of abnormal material.

Traumatic Arthritis, resulting from injuries, without infection, may in the fingers be followed by ankylosis.

Infectious Arthritis in this member arises from infection by pyogenic bacteria, introduced through wounds or extension from neighboring infected areas.

Tuberculous Arthritis (which has already been referred to) as a primary disease involves especially the large joints of the body, among which the wrist occasionally suffers. The joints of the fingers may rarely be involved in tuberculous processes, but usually only secondarily by extension from tuberculous foci in the neighboring bones or skin.

Syphilitic involvement of the finger joints may occur in connection with syphilitic dactylitis, which has been considered above.

Gonorrhœal Arthritis occurs in the wrist and small joints of the hand in a considerable proportion (upward of ten per cent.) of all the cases of gonorrhœal rheumatism. It runs a course of very variable length, and of varying degrees of severity, from a mild synovitis to severe cases closely resembling infectious arthritis. The synovial membrane is especially affected, granulation tissue is often abundant, and ankylosis is very apt to result.

Neuropathic Arthritis.—In some cases acute inflammation of the finger joints appears to result from nervous influences. Marked trophic alterations of these joints may occur, of nervous origin, as in Charcot's tabetic arthropathy and in syringomyelia.

Rheumatic Arthritis (acute and subacute) affects by preference the large joints of the body, among them the wrist; but exceptionally the small finger joints are the seat of articular rheumatism.

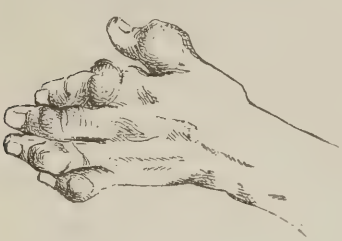

FIG. 2491.—Gouty Hand. (Meillet and Richer.)

Chronic Rheumatism includes a rather indefinite class of cases which in their clinical features merge into or are sometimes difficult to differentiate from arthritis deformans. It occurs independently, or as a sequel of acute rheumatism. It is manifested by thickening of the fibrous structures of the joint, enlargement of the joint, stiffness, ankylosis (fibrous), ulnar deflection of the fingers, chronic synovitis, pain, slight creakiness of the joints. The finger joints may suffer from this condition, though the large joints are its more usual seats.

The treatment of the various inflammatory, infectious, gouty, and rheumatoid affections of the joints of the hand is the same as that of these forms of arthritis or constitutional disease in general. Simple inflammations require rest, sedatives, counterirritants, etc.; suppurating joints should be drained; rheumatism demands the appropriate local and systemic treatment.

Gout.—Next to certain joints of the foot, the joints of the fingers are the most common seats of gouty lesions. These consist of deposits of urates, at first in the articular cartilages, then in the synovial and fibrous structures of the joint, then in the tissues surrounding the joint. These deposits, when in sufficient amount, constitute "tophi" or "chalk stones," and produce characteristic nodular enlargements about the affected finger joints. The mobility of the joints may be impaired. At times the tophi may ulcerate out, or may cause damage to the articulation itself. Urates may be also deposited in the cutaneous or subcutaneous tissues of the palm, or in the tendinous structures. The treatment is that of gout in general.

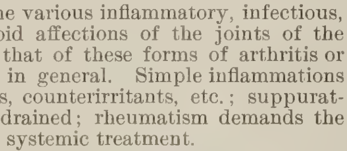

FIG. 2492.—Arthritis Deformans. (Meillet and Richer.)

Arthritis Deformans.—Under this designation is included a group of conditions which, while somewhat distinct in their clinical features, present common characteristics in the nature of the joint lesions. The finger joints are favorite seats for the different varieties of arthritis deformans, though other joints, especially the knees, are also subject to the disease. The characteristic pathological features of the lesions in these cases consist primarily in a proliferation of the cartilaginous structures of the joint. The central portions of these softened cartilages, exposed to pressure and friction, become eroded, leaving the bone bare; the exposed bone then becomes hardened or "eburnated." The marginal portions of the hyperplastic cartilages grow out into nodular masses about the margin of the joint; these outgrowths —"osteophytes"—become ossified. The ligamentous structures become thickened, subperiosteal bone formation is active, the muscles in the vicinity become atrophied. From the altered conformation of the ends of the bones deflections of the phalanges are brought about; the osteophytes limit the motion of the joint or may render it entirely immovable; the naked bony surfaces crepitate roughly.

The manifestations of rheumatoid arthropathy in the hand vary from the mild nodes of Heberden, or a still milder though characteristic ulnar deflection of the fingers, up to typical and extreme deforming and disabling joint lesions.

The typical and well-marked cases of arthritis deformans occur in both acute and chronic forms; while it usually develops in adults, especially in females, and most frequently during the third decade of life, an infrequent form of the disease occurs in children. The changes in the hand are often highly characteristic. The finger joints are enlarged and nodular; their mobility is decreased or they may be entirely immovable; they crepitate harshly; the phalanges are deflected laterally, backward, or forward. The wrist may also be involved. The deformity is unsightly, and the disability may be complete, the locked, distorted, and immovable fingers being incapable of any use. Both hands are affected; and several or all the joints are involved. The disease is progressive for a period, one joint becoming invaded after another, until a period of final arrest occurs. The fingers (all excepting the thumb) are usually deflected toward the ulnar side, at the metacarpophalangeal articulations, in a very characteristic manner; exceptionally radial deflection of the fingers is observed.

In severe cases a rather characteristic deformity may be manifested, consisting in a flexion of the proximal and terminal phalanges, and superextension of the middle phalanges (Fig. 2493).

Little can be accomplished in treatment of these conditions. The damage once done is irreparable, and the most that can be hoped for is arrest of the progress of the disease.

Heberden's Nodes (distinguished by William Heberden, 1782) are small nodular projections or osteophytes which occasionally develop on the fingers, particularly on the sides of the distal phalanges and distal joints. They are said to appear oftener in women, at about thirty to forty years of age. They are usually regarded as a mild manifestation of arthritis deformans, and while not curable are considered as of favorable prognostic significance inasmuch as when they occur the disease does not extend to other joints or produce serious consequences.

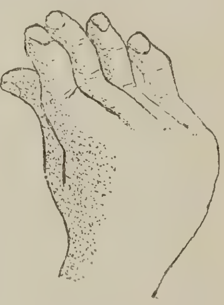

FIG. 2493.—Arthritis Deformans; Radial Deflection of Fingers and Superextension of Middle Phalanges. (Original.)

Ulnar Deflection of the Fingers at the metacarpophalangeal joints often occurs unassociated with any other evidence of rheumatoid articular disease, so that it may perhaps be regarded as a very mild form of arthritis deformans or rheumatoid disease. It is common in elderly persons, as if it were a senile change. It may also appear in earlier adult life as a consequence of acute or subacute articular rheumatism of the metacarpophalangeal joints. This condition, although but a slight deformity, presents a characteristic appearance; the little, ring, middle, and index fingers are slightly flexed, and bent laterally to the ulnar side at the metacarpophalangeal joints.

Changes in Extensibility of Metacarpophalangeal Joint of the Thumb at Different Ages.—In many cases the structures making up the metacarpophalangeal articulation of the thumb undergo progressive changes at different periods of life, such that while in childhood the proximal phalanx of the thumb is markedly lax and superextensible, in old age its extensibility may be diminished very much below the norm of the adult period. The condition of this joint is therefore to be considered in three periods—in childhood, in the adult, and in old age.

1. In young *childhood* in a large proportion of individuals the ligaments of the joint in question are very lax, so that the proximal phalanx can be superextended or bent backward at a marked angle, even to a right angle (see Fig. 2494). Usually the superextension can be accomplished by the free and unassisted action of the extensor muscles; occasionally the superextension can be brought about only by assistance or passive action. The position of superextension is a sort of subluxation of the joint, and the phalanx when extended goes back with a sudden slip. The condition is by the laity often called "double-jointedness." This laxity of the joint is very common in children up to the age of six or seven years, occurring to a greater or less degree in nearly a half of white children. After that age the superextensibility gradually diminishes, until about the age of puberty, when it usually has entirely disappeared. Occasionally, however, superextensibility of the thumb persists to maturity, especially in persons whose finger joints generally are unusually lax, and in those in whom this laxity is developed and maintained by such occupations as piano-playing.

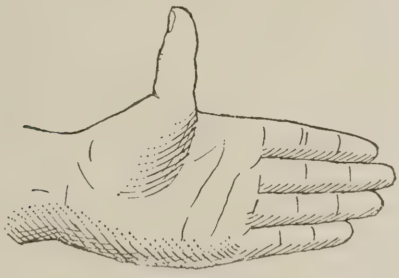

FIG. 2494.—Hand of a Boy Six Years Old, Showing Voluntary Superextension of Thumb. (Original.)

The superextensibility varies in extent, from a slight increase to an extreme degree of laxity. Usually both thumbs are superextensible, though sometimes one thumb, especially the left, may be affected alone. The left thumb appears to be rather more subject to this peculiarity than the right, as shown by its being often superextensible to a greater degree than the right when both thumbs are involved, and by its being most subject when only one thumb is affected. The two sexes are about equally subject to this condition.

In an examination, by the writer, of the hands of 161 white children from three to fourteen years of age the following data as to this condition were found:

Age (years).	THUMBS NOT AT ALL SUPEREXTENSIBLE.			ONE OR BOTH THUMBS MORE OR LESS SUPEREXTENSIBLE.				Total.
				Number.			Per cent.	
	Male.	Female.	Total.	Male.	Female.	Total.		
3–6	4	12	16	10	3	13	45	29
7–10	27	24	51	5	10	15	23	66
11–14	30	28	58	5	3	8	12	66
Total ...	61	64	125	20	16	36	22	161

Of the 36 cases in this series in which one or both thumbs were more or less superextensible, both thumbs were slightly superextensible in 6, and were markedly superextensible in 19; the left thumb alone was superextensible in 10; the right thumb alone was superextensible in 1—total, 36.

Among 73 colored children, 38 girls and 35 boys, aged from two to fifteen years, superextensibility of the proximal phalanx of the thumb was noted in only two instances (girls, aged ten), and that to a slight degree only. This would indicate that the peculiarity is less common in the negro race.

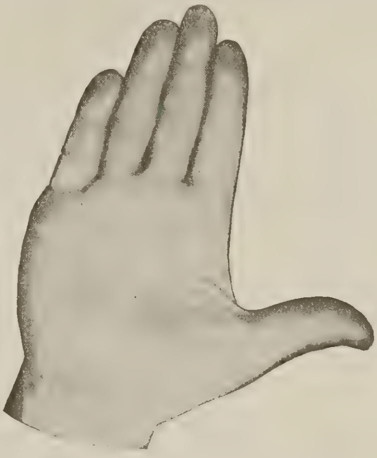

FIG. 2495.—Hand of a Man Aged Thirty-three, Showing Full Normal Adult Extension of Thumb. (Original.)

2. In the *adult* period the first phalanx of the thumb when fully extended normally lies in line with the metacarpal bone, or at an angle slightly short of this line (Fig. 2495).

3. In *old age* not infrequently the proximal phalanx of the thumb is very much decreased in extensibility, so that when fully extended it cannot be brought within a considerable angle (often not within forty-five degrees) of the line of the metacarpal bone extended) (Fig. 2496). With this, the distal phalanx is often considerably superextended and curved backward. The condition occurs alike in those who have or have not been subject to rheumatism, and in those who have or have not pursued laborious manual occupations.

The superextensibility of the thumb in childhood appears to be due to laxity of the ligamentous structures of the metacarpophalangeal joint. Its subextensibility in old age appears to result from shortening of the ligaments or alterations in the configuration of the hard parts of the joint, produced either by senile changes or perhaps by a mild and distinctive form of arthritis deformans.

Senile Joint Changes.—The finger joints in old age often exhibit alterations, which are partly due to mild rheumatoid lesions, partly to real senile changes. The finger joints often have a diminished range of mobility. They sometimes have an en-

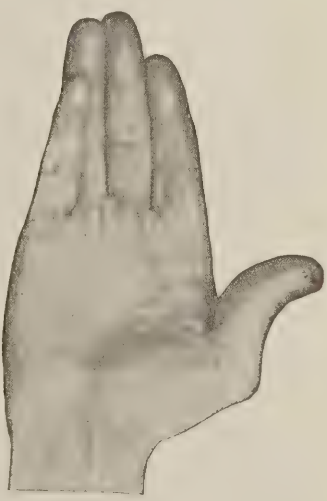

FIG. 2496.—Hand of a Man Aged Sixty-Nine, Showing Full Extension (Much Diminished) of Proximal Phalanx of Thumb. This subject had been a clerk by occupation, doing no manual labor, and had not had rheumatism. (Original.)

larged appearance, partly from real enlargement, partly from atrophy of the soft tissues of the phalanges. Ulnar deflection of the fingers is frequently seen, without other material evidences of rheumatoid arthropathy. As just considered, the metacarpophalangeal joint of the thumb often undergoes a characteristic decrease of extensibility.

Affections of the Tendons and Tendon Sheaths.

Small fibromatous *tumors* occasionally develop on tendons, especially on those of the flexor muscles of the fingers, palpable as subcutaneous nodules moving with the tendons and not causing material trouble unless they interfere with the action of the tendon or become painful from pressure. Some forms of trigger finger are produced by the impediment to motion caused by such tendinous nodules.

Tenosynovitis.—One of the favorite seats of various forms of inflammation of the tendon sheaths is about the wrist, hand, and forearm. Infectious and suppurative inflammation is common in connection with whitlows and palmar abscess; pain is intense, early and free incision is necessary, and the consequences may be serious. Gonorrhœal tenosynovitis sometimes occurs about the hand, and syphilitic involvement of these structures may occur.

Acute non-suppurative tenosynovitis may occur in the hand or forearm, from occupation irritation, contusions or other traumatisms, or spontaneously from undeterminable causes. The symptoms are pain, swelling, friction and crepitation, effusion of fluid.

The treatment consists chiefly of rest and immobilization and sedative or counterirritant applications.

Chronic Tenosynovitis in all or nearly all cases is of tuberculous nature. Most of the cases occur in the forearm and hand. It presents a number of forms—a simple serous effusion into the thecal sac, an effusion with rice-grain bodies, or an exuberant granulating form. It occurs more especially in women, in the delicate and unhealthy, and in those with a family or personal tuberculous taint; manual work, like wringing clothes, sometimes predisposes to it. The onset is gradual and the course very chronic. Pain is not severe.

In the forms with effusion there is an elongated swelling along the course of the tendon, with fluctuation. If the "rice-grain" or "melon-seed" bodies are present, they can be felt and can be rubbed on the tendon or sheath with rough friction. The inflammation may be confined to a limited portion of the tendon, or may extend the entire length of the sheath and to other sheaths.

In the fungous granulating forms the tendon and sheath are involved in an exuberant granulation process, which causes irregular distention along the sheaths, with a peculiar feeling, but no fluctuation.

The site of tuberculous tenosynovitis is especially on the dorsal or palmar aspect of the wrist, though it may extend along the anterior or posterior surfaces of the digits. At the wrist, the annular ligaments passing over the tendon sheaths may cause a constriction in the swelling at that point, forming an hour-glass appearance, sometimes called "compound ganglion."

The tuberculous process may extend to neighboring joints and other tissues. The condition may simulate lipoma, ganglion, chronic abscess, gumma, sarcoma; the diagnosis is made by the presence of fluctuation or rice bodies, the examination of aspirated fluid, and the tuberculous history. The treatment consists in rest, pressure, counterirritation, aspiration, injection of iodoform emulsion; incision with drainage; or incision, cleaning out the cavity, and immediate suture; or curettage, etc.

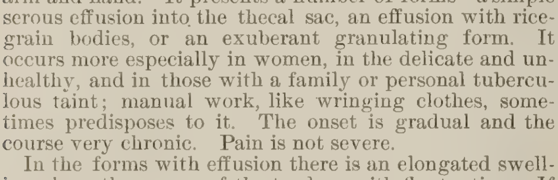

Fig. 2497.—Superextension Resulting from Non-Union of Flexor Tendons of Middle, Ring, and Little Fingers, Severed by an Incised Wound Twenty-Six Years Previously. (Original.)

Ganglion. — This occurs as a small subcutaneous rounded hard swelling, containing a viscid fluid; it is most commonly situated on the back of the wrist, but it also occurs in the palm, fingers, and elsewhere. Exceptionally it may be due to a hernial protrusion of articular synovial membranes or tendon sheaths, or to enlarged bursæ, but usually it is a cystic formation developing in connection with the walls of the tendon sheaths, but not communicating with their cavity. It is usually of slow development and sometimes disappears spontaneously. A soft swelling or ganglion on the back of the wrist is sometimes present in chronic lead poisoning. Its treatment consists in rupture by firm pressure or a blow, or evacuation by aspiration or subcutaneous incision. If it recurs after this treatment the cyst and its wall should be excised.

Injuries.—In incised wounds about the wrist, hand, and fingers, the tendons are frequently divided, partially or completely. When the section is complete corresponding impairment of function results, and if the tendon is not reunited permanent damage will ensue. In non-union of divided tendons, the action of the muscles involved is abolished, while unrestrained action of the opposing muscles causes a habitual or excessive deflection, in the opposite direction, of the bony parts supplied. Thus, section of the extensor tendons causes flexion and inextensibility of the phalanges, while division of the flexor tendons results in inflexibility, extension, or even superextension of the phalanges (Fig. 2497).

The consequences, as to the usefulness and appearance of the hand, of non-union of severed tendons are so serious that in all wounds of this region particular care should be taken to determine if any tendons are divided; and if so, the ends should be sutured together with catgut and the parts afterward kept at rest until union is obtained.

Subcutaneous rupture of the extensor tendons inserted into the distal phalanges sometimes occurs, giving rise to the condition known as mallet finger.

Adhesions of digital tendons to their sheaths or surrounding tissues are not uncommon from tenosynovitis, especially from whitlow or palmar abscess, or from cicatricial involvement after healing of wounds. Adherent tendons cause a corresponding loss of mobility of the parts supplied by them, or even a greater or less immobility in normal or abnormal positions—the so-called "tendinous ankylosis." In conditions in which adhesions of the tendons threaten to result, attempts should be made to prevent such a consequence. During immobilization of the hand in fractures early and frequent passive movement of the fingers should be practised to obviate tendinous adhesions. After thecal inflammations and wounds similar exercise of the fingers may prevent adhesions.

After firm adhesions are once established it is difficult or impossible to free the tendons, though a faulty position of a finger might be improved by operative measures.

Mallet or Drop Finger is an uncommon condition in which the essential lesion is a subcutaneous rupture of the extensor tendon inserted into the distal phalanx of a finger. It is caused by violence, often slight and insignificant, such as catching the finger tip in the clothing, or a slight push in the direction of flexion on the end of the finger. The tendon is torn at or near its insertion into the base of the terminal phalanx. The rupture may be complete; or it may be partial, a thinning or fraying and stretching of the tendon. In consequence of the rupture the power of extension (except passively) of the distal phalanx is lost, and from unopposed action of the flexor the phalanx drops limply forward and stands flexed at an angle (up to a right angle) with the finger.

Immediately after the injury there may be some inflammatory symptoms; but as these subside the phalanx is left helpless and inextensible in a flexed position.

The condition is said to be sometimes curable by keeping the phalanx well extended by splints for three or four weeks. If this fails operation is necessary. A longitudinal incision is made over the back of the joint, and the ruptured extensor tendon exposed; the severed ends of the tendon are then to be sewed together, shortening them if necessary; or the proximal end may be advanced and sutured into the periosteum or into the skin near the root of the nail. After the latter procedure the nail is sometimes temporarily lost.

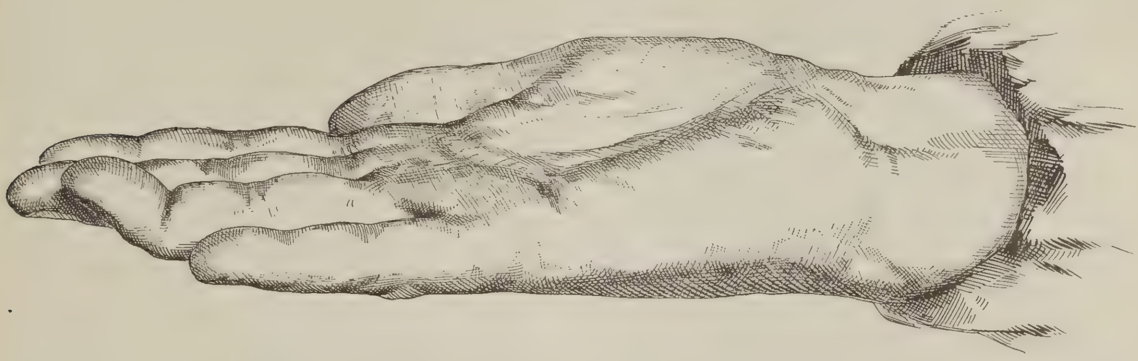

FIG. 2498.—Mallet Finger. (Abbe.)

AFFECTIONS OF CONNECTIVE-TISSUE STRUCTURES.

Aside from inflammatory and infectious processes in these tissues, the fascial and ligamentous structures of the hand are subject to certain characteristic affections, namely, Dupuytren's contraction of the palmar fascia, contraction of digital fascia, hammer finger, and general palmar induration.

DUPUYTREN'S CONTRACTION OF THE PALMAR FASCIA.

This not uncommon affection consists in a hypertrophy of definite tracts of the palmar fascia, with shortening of the hypertrophied band, resulting in flexions or contractions of the phalanges and changes in the configuration of the palm.

While not previously entirely unknown, the true nature of this condition was first demonstrated by G. Dupuytren, whose original deliverance on the subject was given in 1831. Numerous studies of the disease have since been made, an extensive literature has been produced, and several hundred cases have been recorded. Its morbid anatomy and mechanism have been settled by numerous operations and post-mortem dissections, but its etiology is still obscure.

The primary seat of this affection is in the palmar fascia or aponeurosis, a knowledge of the anatomy of which is essential to an adequate understanding of the pathology and mechanism of Dupuytren's contraction. The palmar fascia is a triangular or fan-shaped expansion of firm fibrous tissue radiating over the metacarpus, with the apex of the triangle situated at the depression between the thenar and hypothenar eminences (the "interthenar depression"), where the fascia is continuous with the annular ligament of the wrist and the tendon of the palmaris longus muscle. Opposite the metacarpophalangeal articulations there is a well-marked transverse fibrous band, the "superficial transverse ligament of the palm"; at this point many of the longitudinal fibres in the fan-shaped palmar fascia terminate, leaving a few fibres to pass to each of the digits, where they are attached to the skin and fibrous investments of the phalanges. At the web of the fingers there is another transverse fibrous band, the "fibres of Gerdy," or the "superficial transverse ligament of the fingers." The palmar fascia is situated immediately beneath the skin of the palm, from which it is separated only by thin masses of fatty and areolar tissue. The fascia is intimately connected with the skin by numerous fibrous bands—a point to be borne in mind in connection with the mechanism of Dupuytren's contraction. Microscopically, the fascia consists of coarse longitudinal and transverse bundles of dense white fibrous tissue, which in places are connected with the corium by smaller fibrous bands crossing through the fatty layer which separates the fascia from the cutis. Among the fibres elongated connective-tissue cells are numerous, and minute blood-vessels penetrate and accompany the fibrous fasciculi (see Fig. 2499).

Dupuytren's contraction consists essentially of a hypertrophy or hyperplasia of limited longitudinal portions or fasciculi of the fascia of the palm and fingers, together with, usually, contraction or shortening of the hypertrophied band in a longitudinal direction. This condition results in (1) flexions or contractions of the phalanges of the fingers caused by the traction of the shortened bands; and (2) induration and changes in the surface configuration of the palm, caused mostly by traction on the small fibres connecting the band with the overlying corium,

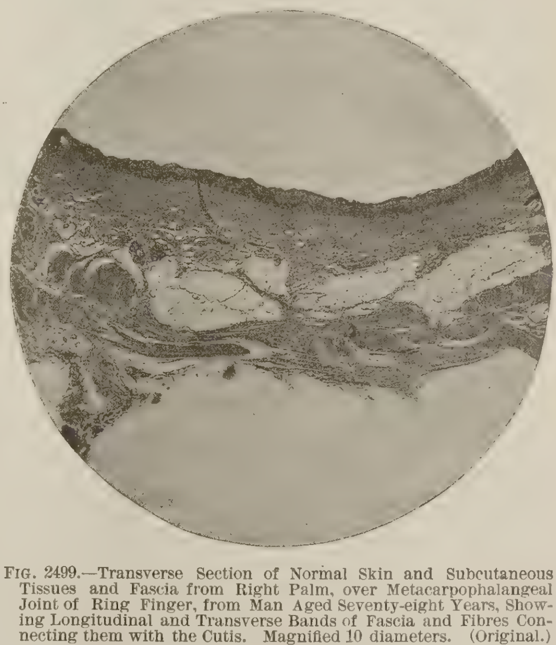

FIG. 2499.—Transverse Section of Normal Skin and Subcutaneous Tissues and Fascia from Right Palm, over Metacarpophalangeal Joint of Ring Finger, from Man Aged Seventy-eight Years, Showing Longitudinal and Transverse Bands of Fascia and Fibres Connecting them with the Cutis. Magnified 10 diameters. (Original.)

or by the thickened and elevated tissues beneath lifting up the skin. Whether the lesion is a hypertrophy or a neoplasm has been a point of discussion. The flexor tendons, which lie beneath the palmar fascia, are not in the least affected, though the bending of the fingers strongly suggests a muscular or tendinous pull. Prolonged malposition and immobilization of the joint in some cases produce changes in the affected articulations; involvement of the tendon sheaths has also been reported.

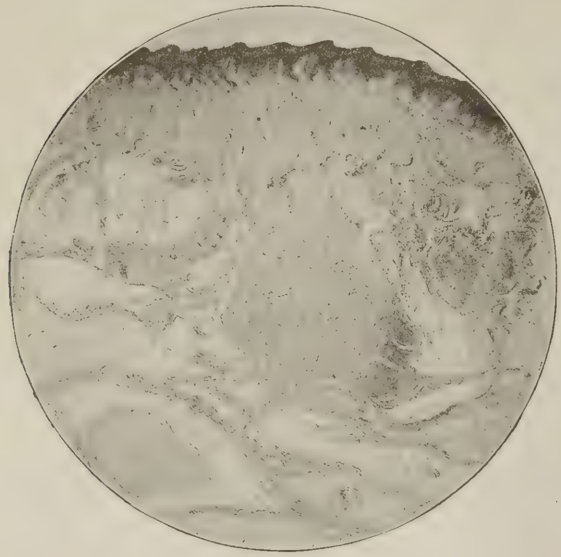

FIG. 2500.—Transverse Section of Skin and Band of Contracted Fascia Leading to Little Finger, Right Palm. Magnified 10 diameters. (Author's case.)

A few microscopical examinations of the lesion have been made, which afford some information as to its histology. The band causing the contraction, plainly visible to the naked eye, is a prominent rounded or oval longitudinal band of dense fibrous tissue, 2 to 5 mm. in diameter, belonging to the palmar fascia and situated in the subcutaneous tissue. The band may lie in contact with the cutis vera with nothing intervening, though the tissues of the corium and the band are usually distinctly marked off from each other without merging or being continuous together; or the band in places may be separated from the corium by an interval occupied by areolar and adipose tissue.

Microscopically (Fig. 2500) the contracted band is seen to consist of a dense aggregation of longitudinal fasciculi of white fibres, among which are elongated fusiform connective-tissue cells and small vascular channels in greater or less abundance. The tissue is essentially identical with that of the normal palmar fascia, being a hypertrophic or hyperplastic development of the latter. The skin in some instances is rather thickened and indurated, but aside from this all the other elements of the skin and adjacent structures are unaffected.

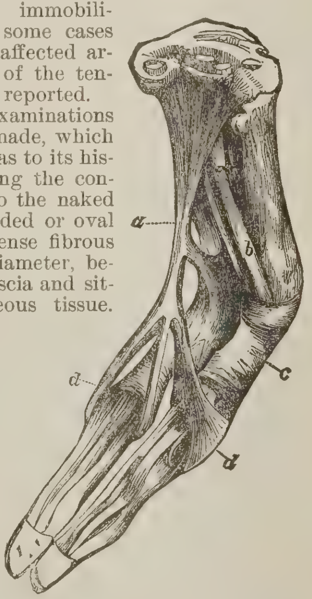

FIG. 2501.—Dissection of Dupuytren's Contraction of Middle and Ring Fingers, from a Specimen in St. Bartholomew's Hospital Museum. *a*, Contracted band of palmar fascia; *b*, flexor tendons; *c*, sheath of flexor tendons; *d*, insertion of contracted bands into base of middle phalanx. (Adams.)

In the early and developing period of Dupuytren's contraction the cellular and vascular elements are exceedingly abundant among the fibrous fasciculi of the contracted band. In this stage there may especially be observable a great accumulation of young connective-tissue cells, small, round, or spindle cells, in the adventitia of, or the tissues immediately surrounding, the small blood-vessels, which are also relatively numerous. Some young fasciculi are composed almost entirely of connective-tissue cells or fibroblasts, the fibrous elements being in process of formation. As the condition becomes of longer standing and in a stationary stage the vessels and connective-tissue cells decrease in relative abundance, and in old and long-established cases cells and vessels may be in very small number or altogether absent, leaving the fibrous band a dense sclerotic mass.

The condition seems to begin, then, as a rather active proliferation of connective-tissue cells about the small blood-vessels, which themselves become somewhat increased in number. The cells thus proliferating become fibroblasts and develop the fibrous fasciculi which constitute the contracted band. The process is therefore a fibrosis, limited to circumscribed longitudinal tracts of the palmar fascia, and is quite identical with the cirrhoses of the viscera or with the process often styled chronic interstitial inflammation. It is practically a hyperplasia or hypertrophy of longitudinal tracts of the palmar fascia, together with, usually, a longitudinal contraction of the affected tissue, the thickening being manifested in the transverse diameters.

Cases of Dupuytren's contraction may be in general divided into two clinical groups: 1. The ordinary typical cases in which there is contraction of one or more fingers together with the characteristic manifestations in the palm of the hand. The flexion of the fingers varies from marked deformity and disability to only slight limitation to the extensibility of the digit. This class, therefore, merges gradually into the next group without sharp dividing lines. 2. Cases in which the lesion is confined to the palm, there being hypertrophy of the palmar fascia and the characteristic thickening, induration, and altered conformation of the surface in the palm, but without contraction of the fingers. These cases are usually slight, yet they sometimes amount to considerable deformity.

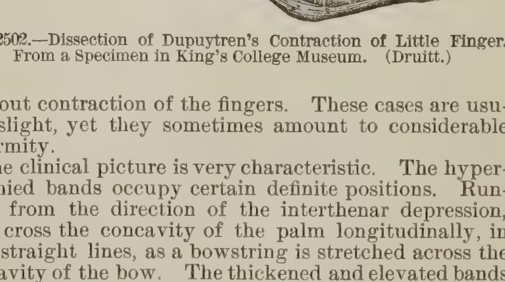

FIG. 2502.—Dissection of Dupuytren's Contraction of Little Finger, From a Specimen in King's College Museum. (Druitt.)

The clinical picture is very characteristic. The hypertrophied bands occupy certain definite positions. Running from the direction of the interthenar depression, they cross the concavity of the palm longitudinally, in taut straight lines, as a bowstring is stretched across the concavity of the bow. The thickened and elevated bands form prominent ridges across the palm, very apparent to sight and feeling. The bands pass in direct and definite lines to the fingers, having a definite locus and relation with the metacarpal bones, and do not take the direction of the interspaces between the digits. In the fingers the band usually follows the mid-palmar line; but occasionally, especially in the little finger, the band crosses the proximal phalanx obliquely, or lies toward one side. Ordinarily the bands in the palm do not branch, each finger having its band distinct from the others; but sometimes a band going to one finger divides near the metacarpophalangeal joint and sends a branch to an adjacent finger.

Besides the ridges formed by the elevated and thickened fascia bands, there are other characteristic alterations of the configuration of the surface of the palm (see Fig. 2503). Minute punctate depressions of the skin, pointing inward and often wristward, are common; they are caused by traction on bands connected with the cutis. Nodules like callosities, formed by indurations of the skin and fascia, are of frequent occurrence. The metacarpophalangeal articulations (especially of the ring finger) are favorite localities for these indurations and inversions of the skin, though they may occur anywhere over the proximal phalanges. The transverse line in the palm over the metacarpophalangeal articulations is often much deepened by the flexion of the fingers. The traction sometimes produces tension or stretching of the skin.

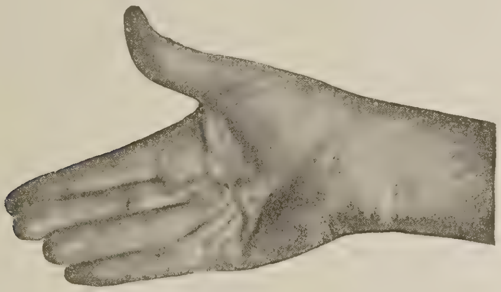

FIG. 2503.—Dupuytren's Contraction of Palmar Fascia, Showing Marked Changes in the Palm, with Slight Contraction of Ring and Middle Fingers. (Notice punctate depression of skin at distal end of proximal phalanx of middle finger.) (Original.)

The mode of distal termination of the bands varies somewhat. Many small fibres terminate in and are connected with the cutis, causing the characteristic depressions of the skin. In many of the cases in which the lesion is confined to the palm the bands terminate near the metacarpophalangeal joints, expending their force on the skin and subcutaneous tissues at those points instead of drawing on the fingers. Occasionally a thick and well-marked band proceeds some distance up a finger, yet (not being shortened) without producing any flexion of the phalanges. Many bands terminate by a general blending with the skin or subcutaneous fibrous investments of the finger, usually around the proximal phalanx; many others have a more or less distinct insertion, especially at the proximal end of the middle phalanx.

The contraction of the fingers is caused by the traction exerted by the shortened palmar bands, and consists in a limitation of the extensibility of the finger; within the limits allowed by the contracting band flexion and extension are unimpeded, but beyond them further extension is impossible. The degree of contraction varies from complete flexion of the finger into and against the palm to only slight limitation of the full extensibility of the finger. The contracting force may be exerted on any of the three phalanges, though almost always on the proximal or middle and only very infrequently on the distal phalanx. When the traction is exerted on the proximal phalanx, mostly by a general pull on the skin and fibrous investments, the finger is flexed as a whole on the metacarpophalangeal joint, the extensibility of the middle and terminal phalanges being unaffected. When the traction is on the middle phalanx, this is flexed on the proximal phalanx; and if, as commonly occurs, the band is sufficiently shortened, the proximal phalanx is also flexed on the metacarpus, although the band may not be connected with this phalanx. The distal phalanges are flexed and connected with the contracted band in only a very small proportion of the cases. Fingers adjacent to one strongly contracted are frequently slightly bent from traction of the fibres of Gerdy or the web of the fingers.

Either hand may be affected alone, or both hands may be involved together. In 184 cases collected by W. W. Keen, the right hand was involved alone in 58, the left hand alone in 23, both hands in 103. In 49 cases examined by the writer the right hand was affected in 12, the left hand in 15, both hands in 22.

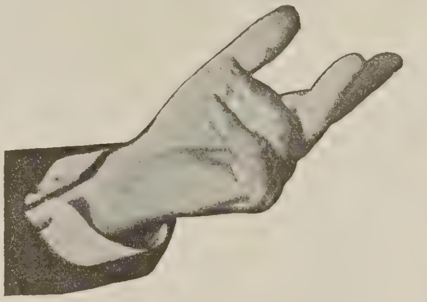

FIG. 2504.—Dupuytren's Contraction of Ring and Little Fingers. (Clarke.)

Any of the digits may be involved, but the thumb and index finger are rarely affected. The ring finger is much oftenest contracted, and the little finger in a large proportion of the cases; the middle finger is frequently involved, but not so often as the ring and little fingers. In 263 cases (214 collected by Keen, 49 observed by the writer) 572 fingers were affected in all, as follows: 12 thumbs, 24 forefingers, 93 middle fingers, 249 ring fingers, 194 little fingers.

One finger may be affected alone, or two or more fingers on the same hand may be contracted together. The commonest conditions are for the ring finger to be contracted alone, little finger alone, ring and little fingers, middle and ring fingers, in about the order stated. When two or more fingers on a hand are contracted, they are usually adjacent, though not always.

When both hands are affected, the contraction always or almost always begins in one hand before the other. Usually the two hands are affected to unequal degrees. Sometimes there is very little difference in the extent of the contraction in the two hands; in numerous other cases the hands are very unequally affected, one hand showing marked finger contractions while the other may exhibit only slight stigmata of the disease in the palm. The hand first affected is usually the one worse affected. The lesions are not exactly symmetrical in most cases, but have different locations in the two hands; thus, the ring finger of one hand and the ring and little fingers of the other may be the ones involved, or the ring finger of one and the middle finger of the other, and so on for a large number of possible combinations; still, in some cases the same digits are affected on the two hands. In the great majority of the bilateral cases, therefore, the two hands differ in the time of onset of the disease, the degree of the contractions, and the location of the lesions.

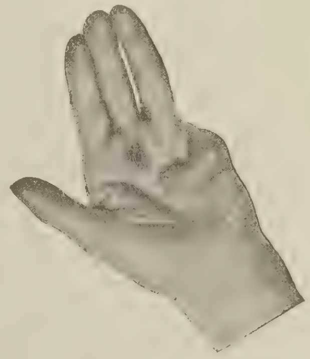

FIG. 2505. — Extreme Dupuytren's Contraction of Little Finger. (Original.)

As to the frequency of Dupuytren's contraction, William Anderson states that of 2,600 adults of the poorer classes in certain English infirmaries, about five-sixths of whom were over middle age, 33, or 1.27 per cent., were affected in various degrees, while of 800 children under sixteen none was affected. Noble Smith among 700 elderly inmates of English workhouses found 70 cases (10 per cent.) of Dupuytren's contraction, in 15 of which the disease was confined to the palm; in 444 women examined by him 11 had well-marked finger contractions and 15 others had simply palmar induration; this would leave 256 men among whom occurred 44 cases (17 per cent.). In an examination made by the writer of this article of the hands of 1,000 men, all ex-soldiers, ranging in age from twenty-one to eighty-five years and averaging about fifty-three years, 39 cases (3.9 per cent.) of Dupuytren's contraction were found; in 13 of these cases the palm only was affected, without contraction of fingers, leaving 26 (or 2.6 per cent. of the whole) having material contraction of the fingers.

Both sexes are liable to the disease, but women are affected much less frequently than men.

The influence of heredity in the causation of the disease is marked, a hereditary or family history of the occurrence of the affection being obtainable in about a fourth or a fifth of the cases.

The disease develops not only in the hands of persons engaged in manual occupations, but also, in large numbers, in persons not engaged in manual labor, and even in persons completely idle.

Dupuytren's disease is a disease of the adult and senile period of life, the favorite age of onset being from fifty to seventy years. Cases do, however, develop during the first half of life, and it is said that even congenital cases occur. It is possible that many of the cases alleged to have appeared at an early age were in reality cases of hammer finger, a condition that has only recently been distinctly differentiated. In 90 cases collected by Keen the ages of onset were as follows: after forty years, 47 cases; from thirty to forty years, 18 cases; under thirty years, 25 cases, of which 4 or 5 were congenital. In 45 cases examined by the writer the ages of onset were as follows: under twenty years, 1 case; from thirty to forty years, 7 cases; from forty to fifty years, 6 cases; from fifty to sixty years, 16 cases; from sixty to seventy years, 12 cases; over seventy years, 3 cases. The latter figures indicate that the disease is rare under thirty years of age.

The onset and development of Dupuytren's contraction are usually gradual and insidious, being manifested by slow development of the induration and deformity without subjective symptoms. Rarely pain or other symptoms in the affected area may precede the appearance of the contraction. As a rule the disease has a definite period of development, and then remains stationary. The period of development of the contraction usually ranges from a few months to three or four years; occasionally the lesions may develop within a few weeks, while in other cases the process of contraction may continue for many years. Sometimes there is a certain amount of intermittency in the development of the contractions; the lesions develop to a certain degree, remain unchanged for months or years, and then have another period of increase. This is especially manifest in the bilateral cases, in which after full development of the lesions in one hand a quiescent period of perhaps years may elapse, when the other hand becomes affected.

Subjective symptoms, pain, tenderness, or abnormal sensations, connected with and located in the seat of the contraction occur in only a small proportion of the cases. In some instances the pain is worse or exists only during the early period, though it may occur at intervals after the full establishment of the contraction as well as during the period of development. The abnormal sensations are often an occasional stinging or pricking feeling in the affected region; also a sensation of numbness or itching, dull aching pains, or sharp shooting pains. Tenderness is occasionally present, especially from exposure of the projecting surfaces to irritation; a feeling of tension in the palm is sometimes noted.

The milder degrees of the disease do not cause trouble or discomfort, and only exceptionally are any of the cases attended with pain. The severer forms of the contraction cause material deformity and disability, the exposed areas in the palm being unduly subjected to pressure and irritation in the use of the hand, the bent finger being awkward and in the way, and the function of the finger being impaired by its lack of extensibility. Occupations requiring the use of the hand may be interfered with. The condition once established is permanent unless obviated by surgical measures.

The diagnosis of the condition from other affections of the hand is usually easy. The bent finger, the ridge in the palm corresponding to the contracted band, the rounded, callus-like indurations, the small wristward inversions of the skin, and the definite location of the lesions are characteristic features which even in mild cases distinguish the affection. Even faint stigmata of the disease are quite distinguishable. Contractions from tendon lesions do not exhibit the characteristic surface changes of fascia contraction. In cicatricial contractions there is the history of injury, the scar tissue, the absence of the typical features of Dupuytren's disease. Arthrogenous deformities are recognizable by the history, the anatomical features present, or the constitutional condition; arthroses may coexist with Dupuytren's disease, however, introducing an element of doubt as to the precise share either may have in the production of the deformity present. In contractions limited to the digital fascia, surface and palmar changes are absent. Hammer finger exhibits no palmar or cutaneous changes, and is sufficiently characteristic to be readily distinguishable; it is probable that some of the cases diagnosticated and recorded as Dupuytren's disease, especially among the alleged congenital cases and those stated to have developed in early life, were in reality instances of hammer finger.

The etiology of Dupuytren's contraction has not been satisfactorily determined, and very diverse theories as to its causation have been advanced.

One prominent theory, held among others by Dupuytren, is that the disease is induced by slight local traumatisms or by continuous use and irritation of the palm incident to manual labor. In probably a majority of cases there is a complete absence of any history of local causes to which the lesions are attributed. In a smaller proportion of the cases the disease is attributed by the subject of it to local traumatisms like wounds, abscesses, blisters, irritation, or occupation incidents; but only rarely is the history sufficiently distinct or the connection sufficiently authentic to warrant any such conclusions. The assumption that in all cases a forgotten traumatism must have occurred is not logically justifiable. Persons not engaged in manual occupations are as subject to Dupuytren's disease, indeed rather more so, than are persons who habitually do manual work, and the disease may develop in the hands of persons entirely idle. The nature of the occupation is not altogether a safe criterion, since the soft hand of the nonworker is more easily irritated by occasional unusual use or strain.

On the whole, the statistics of numbers of cases are adverse to the theory of the local traumatic causation of the disease. There are other considerations opposed to the theory of traumatic origin and in favor of the contrary view of the idiopathic origin of the affection. The left hand is not materially less susceptible than the more-used right, and the ulnar half of the hand is much more frequently involved than the radial half, which bears the brunt of use to an equal if not greater degree. The favorite age of onset is after middle life, years after the period of active labor begins. The marked influence of heredity, the limitation of the disease to definite longitudinal tracts, the secondary development of contractions in the other hand after one has become affected, are unexplainable on the local traumatic theory. There is little doubt that Dupuytren's contraction is essentially of idiopathic origin, and that local traumatisms have no more than, perhaps, some occasional influence in lighting up the disease.

A germ theory of the disease has been presented by William Anderson, who considers the condition to be a chronic inflammatory process probably set up by a microorganism. This theory has not been substantiated, and does not seem probable in view of the protracted and benign course of the disease and the absence of inflammatory phenomena; and especially as it throws no light on the bilateral occurrence of the lesions and the influence of heredity.

The theory that the disease is a manifestation of some constitutional condition, especially of gout or rheumatism, is at present the one most generally held. These diseases occur in many cases of Dupuytren's contraction; but it has not been shown that rheumatism or gout affects persons with the palmar disease in a greater proportion of cases than they would a like number of individuals of the same class and age free from palmar contraction. In many cases there is absolutely no history of gout or rheumatism, family or personal. By many authorities gout is strenuously asserted to be the specific cause of Dupuytren's contraction, but this can hardly be successfully maintained. The disease occurs in America, where typical gout is uncommon, and often among social classes not subject to gout. In only a very few of the cases observed by the writer was there any history that could be construed as gouty. In many of the cases cited in support of the gouty theory the evidences of gout are vague, remote, and doubtful, and there is little to indicate that the coexistence of the two conditions is more than coincidental. The argument that when no other gouty manifestation is present the contraction is itself the symptom which shows the existence of gout is an instance of circular reasoning. The disease does not appear to be a manifestation of, or to be essentially and specifically caused by, rheumatic or rheumatoid disease, gout, diabetes, syphilis, or any other such constitutional condition.

The possibility of the nervous origin of the disease is worthy of consideration. The marked predilection of the disease for the ulnar side of the hand shows to some degree a relation with the distribution of the ulnar nerve. The pricking or tingling sensation specified in most of the few cases complaining of pain is quite suggestive of the paræsthesia of nervous lesions. The involvement of both hands, one being affected subsequently to and to a less degree than the other, may point to the operation of sympathetic (nervous) action in reproducing the disease on the side opposite to that first affected. Sometimes very suggestive cases occur in which Dupuytren's contraction is associated with nervous disease producing trophic lesions, as syringomyelia, anterior poliomyelitis. In a case reported by Lange, a woman who had a contraction of both ring fingers had an attack of left hemiplegia, almost immediately after which the contraction in the left hand disappeared, the right palm remaining unchanged; this was a sort of reversed trophic action. In the majority of cases of Dupuytren's contraction there is no history of concomitant nervous disorder; and it would perhaps be difficult to show that in the comparatively few cases accompanied by nervous disease the coexistence is not merely coincidental. It is of course possible that obscure trophic influences might occur sufficient to cause this disease, but without other manifestations. While a neuropathic or trophic theory of the pathology of Dupuytren's disease is supported by some considerations, and is not improbable, it cannot be regarded as having sufficient basis for definite acceptance.

According to Robert Abbe's detailed neuropathic theory of this disease, the original cause is a slight traumatism of the palm, often forgotten; this peripheral irritation produces a central spinal impression which then sends a reflex influence back to the part originally hurt and incites a contraction of the fascia. This contraction then sets up a second series of reflex symptoms, and by sympathetic action causes a reproduction of the trouble in the opposite hand. Abbe lays stress on the irritation of the original traumatism or the tense contractions being an exciting cause of neuralgias, local and distant, joint inflammations, and other symptoms simulating rheumatism and gout, and various general symptoms and neuroses, and cites cases in which these disorders were relieved by operation on the contracted fascia. The cases on which this theory was based must have been exceptional. Ordinary cases, in which the lesion is the seat of little or no irritation and is perfectly benign and innocuous, do not bear out this theory.

Dupuytren's contraction is one of the scleroses, a hypertrophy or hyperplasia of connective-tissue elements, and is hence to a certain extent allied to the visceral cirrhoses, as of the liver, kidney, and lungs, arteriosclerosis, and the spinal scleroses. Cirrhoses of the liver and kidney are largely due to prolonged irritation of toxic substances circulating in the blood. Arteriosclerosis is due to similar causes, also to the irritating action of constant overdistention and to hereditary influences. These disorders show a marked association with toxæmic and other irritation, and this relationship suggests a similar causation for Dupuytren's disease. This recalls the theory of the connection of this disease with gout, or lithiasis, which is a form of toxæmia. Dupuytren's contraction, however, differs from the visceral scleroses in being sharply circumscribed while the latter are diffuse and general. Why the palm should be selected to suffer in this manner from irritants circulating in the blood, and especially why the hypertrophy should be limited to specific longitudinal fasciculi, does not appear. One would expect more general consequences from local or toxic irritation. Toxæmia does not appear to be a very probable cause of Dupuytren's contraction.

The only conclusion as to etiology that seems warranted is that Dupuytren's disease is of idiopathic origin, most apt to occur in the senile period, and showing marked hereditary influence. There is no one constitutional disease with which it is exclusively associated or of which alone it is a manifestation. It does not appear to be specifically caused by local irritation or traumatism, though this factor, as well as local or constitutional pathological conditions, may at times have some exciting or contributing influence. Perhaps it is a neuropathic or trophic condition.

Contractions of the plantar fascia have been reported analogous to those of the palm; induration or contraction of the penis, associated with Dupuytren's contraction, has also been observed. Keloid, fibromata, and cicatrices are allied in some respects to fascia contraction. The contraction of ligaments in talipes and arthropathies, and of cicatrices, also presents some analogies, especially with respect to longitudinal shortening.

Treatment.—The only hope of relief in Dupuytren's contraction rests in operative intervention, for which a variety of methods have been practised.

One of the most popular and efficient procedures is that of *subcutaneous division* of the contracted fascial band, especially advocated by William Adams. A small straight tenotome is introduced between the skin and the band, and the latter cautiously cut downward. This is done at as many points as is necessary to free the finger and enable it to be straightened; as many as twenty or twenty-five punctures may be required. The sections are made along the entire band, from its proximal to its digital end, as needed. The hand is then dressed, with an anterior splint, with the fingers extended. The results of this operation have been very satisfactory in the hands of numerous operators. Before the days of antiseptic surgery it was doubtless the most advisable procedure, but with the introduction of aseptic technique many of the former objections to open operations have become obsolete. Even at the present time the subcutaneous method is preferred by some surgeons; Adams states that it is less liable to be followed by recurrence than the open operation.

Transverse division of the cord at one or more places, sufficient to free the finger, has been practised by some operators, followed immediately or after some days by the use of splints. Dupuytren and others have made open transverse incisions through both skin and band. In Goyrand's method the fascial band was exposed by a longitudinal incision through the overlying skin, and the band itself then divided transversely.

Excision of the fascia band in many cases is a rational and preferable procedure, though at times when the fascia is closely connected with the skin it may be difficult to separate it well. A longitudinal incision is made through the skin over the cord, and the band then carefully dissected out, after which the wound is sutured.

In *Busch's operation* a long triangular skin flap is cut, having its base corresponding to the contracted phalanx and its apex in the palm at the proximal end of the band. This flap is dissected up, the fascia exposed, and the contracting fibres are divided until the finger can be completely extended. The flap retracts, and the resulting open wound, originally V-shaped, is sutured (without exerting too much tension on the skin) into a Y-form. Extension is applied after the wound is healed. This operation does not appear to have come into general use.

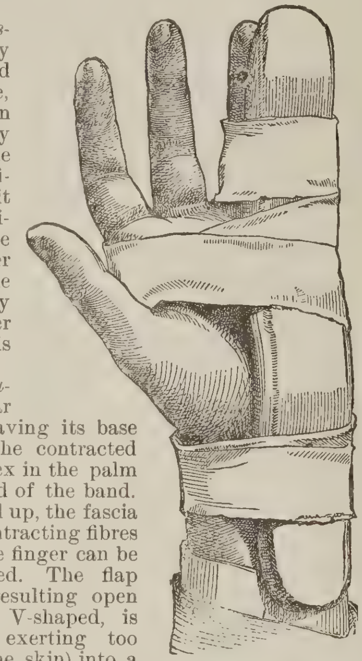

FIG. 2506. — Splint Employed After Operation for Dupuytren's Contraction. (Adams.)

A *plastic operation* is described by William Anderson as having been performed by him in one case. He made a transverse incision through the skin and fascia at the root of the finger, straightened the digit, and filled the gaping wound thus created by a flap of skin cut from the side of the finger and twisted around and sutured in place.

There is thus some choice possible as to the operation to be done. Wherever practicable,—that is, when the contracted band is well marked and easily separable from the skin,—it is probable that the band should be dissected out carefully through a longitudinal incision. But when the contracting tissues are poorly defined or the skin is extensively involved, multiple transverse sections of the band, open or subcutaneous, may be indicated.

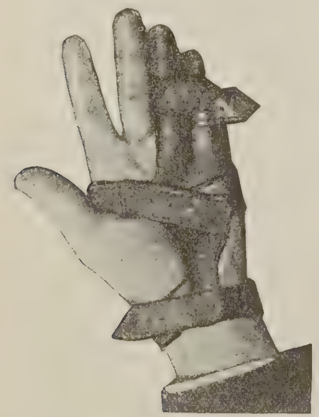

FIG. 2507.—Apparatus Employed After Operation for Dupuytren's Contraction. (Clarke.)

The post-operative treatment is very important, consisting of extension by splints or apparatus for a period sufficiently long to overcome the contraction or the tendency to recurrence. Operators have varied as to the time allowed to elapse after operation before mechanical extension is begun, some applying splints immediately, others not for several days afterward. It is probable that no greater degree of extension should be applied immediately after operation than can be employed without too great tension being exerted on the wound. After healing takes place, firm extension of the fingers by splints or apparatus (Figs. 2506, 2507) can be maintained for a few weeks, at first constantly, later intermittently, until a permanent result is obtained.

The final results of operative treatment of Dupuytren's contraction are generally satisfactory, though sometimes recurrence takes place.

CONTRACTION OF DIGITAL FASCIA.

The subcutaneous fascias of the fingers undergo contraction along with those of the palm in typical cases of Dupuytren's disease; and in some cases of hammer finger secondary digital fibrous contractions may perhaps be present. But aside from these, cases occasionally occur of fingers bent by hypertrophied and shortened bands of the digital fascia alone. There is little literature on the subject, but the writer has observed a very few cases of finger contractions caused by bands of digital fascia.

One case was that of an old man, from whom no reliable history was obtainable. The middle phalanx of his left little finger was flexed on the proximal phalanx at an angle of about 135°, and the terminal phalanx was slightly flexed on the middle one. A subcutaneous band could be plainly felt running along the ulnar side of the finger. A post-mortem dissection of this finger showed the presence of a firm thickened fibrous band attached to the fibrous investment surrounding the flexor-tendon sheaths, situated on the ulnar side of the palmar aspect of the digit; it extended the entire length of the finger and was the cause of the flexed condition of the latter.

A second case was that of a pensioner who at the age of fifty had a palmar abscess at the base of the right little finger, which was lanced on the radial side of the proximal phalanx. On healing, this finger became flexed at the proximal interphalangeal joint; the middle phalanx could not be extended beyond an angle of about 95°, motion within this limit being unimpeded. Along the radial side of the proximal phalanx, anteriorly, a subcutaneous band could be felt running to the middle phalanx. When examined the old scars were scarcely perceptible, and none was present over the contracted band.

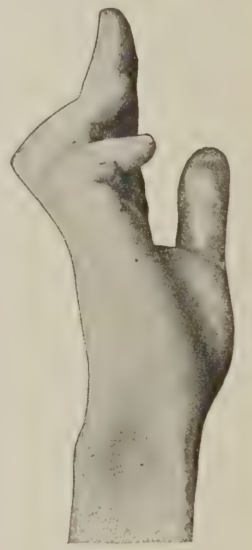

FIG. 2508.—Deformity Resulting from Contracted Subcutaneous Digital Fascia and Other Lesions. (Original.)

In a third case, a woman at the age of forty-three had an attack of cellulitis of the left hand and upper extremity, with much œdema or exudation, for which incisions were made at the base of the little finger and other points. After the attack subsided the middle phalanx of the little finger was bent to an angle of about 135°. The deflection subsequently increased. When examined at the age of eighty, the left little finger was flexed at both interphalangeal joints, the middle phalanx at a right angle, the distal on the middle phalanx to about 135°. The middle phalanx of the left ring finger also was flexed to an angle of about 130°. A tense subcutaneous band could be felt along the front of the proximal phalanx of each of the affected fingers, extending from the base of the middle phalanges toward the metacarpophalangeal articulation of the ring finger, where the two bands came together.

In a fourth case, a grocer aged about forty-five years had a severe and prolonged attack of cellulitis of both upper extremities and the right foot, following a slight infected wound in the left thumb. Incisions were made into the dorsal surfaces of the proximal phalanges, and about the wrists. After recovery a marked deformity of mixed flexion and superextension of the fingers of both hands existed. When examined, about twelve years afterward, the middle phalanges of the right ring and little fingers were flexed at a right angle; their proximal phalanges were superextended or bent backward about 45°, and their power of flexion toward the palm was very greatly impaired (Fig. 2508). The middle phalanx of the left little finger was flexed at an angle of about 100°, and its proximal phalanx was so superextended that it could not be brought within 45° of the straight line; the range of flexion of the proximal phalanges of the left ring, middle, and index fingers was also very much diminished. Along the front of the proximal phalanx of the right ring and little and left little fingers were tense elevated subcutaneous bands running from the bases of the flexed middle phalanges to the palm; these bands were probably fibrous, though they may possibly have been shortened flexor tendons. The superextension of the proximal phalanges was perhaps due to adhesions or shortening of the extensor tendons. Several hammer toes were present. The appearance of the hands was very similar to that of a variety of hammer finger described by Adams.

None of these cases showed the slightest signs of the changes in the skin and palm characteristic of Dupuytren's contraction, and the contracted bands seemed less superficial than in the latter affection. The typical appearances of cicatricial contraction were also absent.

These cases, and especially the one dissection, demonstrate that there sometimes occurs a condition of thickening and contraction of subcutaneous digital fibrous tissues resulting in a flexion and limitation of the extensibility of the phalanges. Further observations and dissections are needed to elucidate this condition and its position as a distinct affection. The little finger seems to be the digit most susceptible to this abnormity, at its proximal interphalangeal joint, precisely as in hammer finger. The affection is mostly unilateral, acquired, and may develop after local inflammatory conditions. It appears to be a disease process *sui generis*, and entirely distinct from cicatricial contraction and Dupuytren's contraction. It presents marked analogies to hammer finger, notably in its situation, and perhaps it may be regarded as a variety of hammer finger; still, to a certain extent at least, a distinction can be made between finger flexions due to fascia contractions and those due to shortened lateral articular ligaments as in typical hammer finger.

In diagnosis, finger deformities due to digital fascia contractions would have to be differentiated from those due to ankylosis, arthritic conditions, tendinous adhesions or shortening, cicatricial contractions, Dupuytren's disease, hammer finger (shortened ligaments), and such conditions. The cardinal feature indicative of fascia contraction is the presence of a subcutaneous fibrous band evident to the senses; it is conceivable, however (though perhaps not possible), that cases might occur in which a shortened and unusually elevated tendon might to the examining finger be undistinguishable from a fascial band. Moreover, cases might occur in which the subcutaneous fibrous tissues might be sufficiently shortened to cause deformity but yet not be palpable as distinct contracting bands; such cases might present difficulty in making a definite diagnosis.

The obvious treatment of this condition would be to divide or excise the contracting bands.

HAMMER FINGER.

There is a well-marked class of contractions or anterior deflections of the fingers, not very uncommon, manifested especially by a flexion of the little finger at the proximal interphalangeal joint, which is of distinctive nature. The affection has received very little attention in medical literature. It was described and figured in 1846 by R. W. Tamplin, who attributed it to contraction of the skin. After that it was occasionally mentioned by authors, but the fullest studies of the subject are those of William Adams and William Anderson, both originally published in 1891. The condition has mostly been called "congenital contraction of the finger," but Anderson applied the term "hammer finger" to it. The latter is the preferable designation, as it is concise, has sufficient metaphorical significance, expresses the analogy of the condition to hammer toe, and is non-committal as to the pathology of the affection or as to its being in all cases congenital.

Hammer finger is usually described as a congenital condition; but I have observed a few cases, exhibiting all the external and clinical features of hammer finger, which were distinctly acquired. Two varieties of the affection may therefore be considered: the developmental or congenital, and the acquired.

Developmental Hammer Finger.—This deformity typically consists in a flexion of the middle phalanx upon the proximal phalanx of the little finger at varying angles up to a right angle,—usually at an angle of about 135°. Slight limitations to full extensibility of the middle phalanx of the little finger are common, but unless the flexion amounts to about twenty degrees or more it is hardly worth while to regard it as abnormal. Within their respective limits flexion and extension of the affected phalanges are unimpeded; but beyond them further extension is impossible without the use of unusual force. In most cases the proximal phalanx is unaffected; but according to Adams it is sometimes bent backward or superextended (the middle phalanges being flexed), as is commonly the case with the corresponding phalanges in old cases of hammer toe (see Fig. 2508). The distal phalanges are also usually unaffected; but they are sometimes flexed instead of the middle phalanges, and in one case reported by Adams they were superextended, the middle phalanges being flexed. Some of the other fingers (especially the ring and middle fingers) are sometimes similarly affected in conjunction with the little finger, but to a less degree than the latter. In the congenital form the affection is usually bilateral, the hands being affected together though not always equally.

The skin over the anterior aspect of the finger is sometimes shortened or forms a longitudinal fold stretching across the concavity of the affected interphalangeal joint, increasing the antero-posterior diameter of the proximal phalanx. According to Adams, there are often present subcutaneous bands of contracted fascia, centrally or laterally located, sometimes with fibres inserted into the skin; but according to other authorities fascia contractions are absent. The author has not been able to detect contracted fascial bands in any of the developmental cases of hammer finger which he has observed; and in the pure uncomplicated developmental form of the affection it is probable that fascia contraction plays no essential part. In some cases there is some secondary shortening of the flexor tendons of the finger. Often the distal end of the first phalanx projects slightly at the angle of the articulation, but there is no subluxation of the joint. The lateral ligaments of the joint are shortened, and there may be other developmental or secondary changes in the joint. The contraction is entirely unassociated with injuries or arthritic or paralytic conditions. The contraction is not the seat of any pain or other subjective phenomena, but in its extreme forms may cause considerable deformity, unsightliness, and inconvenience.

The affection is markedly hereditary. Numerous cases have been observed of its transmission from parents to children and of its coexistence in brothers and sisters. It is frequently associated with hammer toe, either in the same individual or in the family. It is not a very uncommon condition, but is not often brought to the notice of the surgeon; it is much less common than hammer toe. It is said to affect females more frequently than males. In 800 school children Anderson found two cases among boys and five cases among girls. Among 1,000 adult men I found about five cases (one-half per cent.) of developmental hammer finger; possibly some cases were overlooked in this series before I learned to recognize this class of deflections. Among 177 white children under sixteen years of age the writer found two cases of slight hammer finger, one of the left hand in a girl, one of both hands in a boy; among 86 colored chidren no case was found.

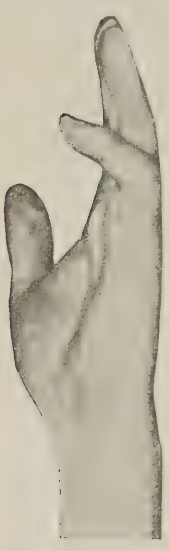

FIG. 2509.—Developmental Hammer Finger. (Original.)

While this form of hammer finger may or may not be manifest at birth, it usually makes its appearance very early, probably in the first two or three years of life. Adults affected will state that their fingers have been bent as far back as they can remember. Sometimes the contraction makes its appearance at a later age, even up to eighteen or twenty years, but always before maturity is reached. It is therefore a disease of the developmental period of life, and in that sense is congenital. The contraction slowly and continuously progresses for years, until the maximum is attained.

The essential pathological nature of hammer finger is only partially determined; opportunities for operation or dissection are not often presented. Several observers have regarded the flexed condition as due to shortening or contraction of the skin over the proximal phalanx; but this change in the skin, when present, is undoubtedly a secondary alteration and not the primary cause of the flexion. According to Adams, the deformity is due, partly at least, to shortened subcutaneous fascial bands. C. B. Lockwood, in a dissection of an amputated hammer finger, found a thickening and shortening of the fascia over the flexor aspect of the proximal interphalangeal joint, which caused the flexion; he did not state the condition of the articular ligaments. Other observers, however, have not found fascia contractions present, and they are certainly not an essential feature of developmental hammer finger, but only of secondary, occasional, and exceptional occurrence. The flexor muscles or tendons are not regarded as being the primary cause of the contraction, though they may be secondarily shortened. E. M. Little cut the tendons in one case, but without relaxing the finger; on the contrary, Anderson after cutting the other structures found that the flexors kept up the contraction.

The primary cause of hammer finger is apparently an abnormality, frequently hereditary, in the development of the component parts of the affected joint, resulting in a disproportion in the osseous, cartilaginous, and ligamentous articular tissues; the developmental abnormity results practically in a shortness of the lateral and anterior ligaments of the phalangeal joint, which interferes with full extension of the finger. The ligamentous shortening becomes manifest during the period of development. This is Anderson's view of the etiology of hammer finger, though he does not report any dissection. In a dissection made by the writer the contraction was found due, chiefly at least, to much-shortened lateral ligaments.

In long-established cases, in addition to ligamentous shortening, other changes are present; namely, alterations in the articular surfaces and shortening of the flexor tendons, fibrous tissues, and the skin over the proximal phalanx. These alterations are doubtless secondary changes, caused by the accommodation of these structures to the prolonged abnormal position. These secondary changes must be taken into account in operative procedures, as in old cases division of the lateral ligaments alone is apt not to be sufficient to correct the deformity entirely, as in a case operated on by Anderson and another by the writer.

Why the little finger, and the proximal interphalangeal joint of this finger, should be the especial seat of this abnormity, is a point that is not clear. The cause of superextension of the proximal phalanges as reported by Adams is also obscure. Hammer finger is allied in many respects to hammer toe. It is a distinctive condition, *sui generis*, easily recognizable, and entirely different from Dupuytren's contraction of the palmar fascia.

Acquired Hammer Finger.—I have observed a very few cases of flexion of the little finger at the proximal interphalangeal joint exhibiting almost precisely the same external appearances that developmental hammer finger presents, but which developed in adult life; that is, were acquired rather than congenital. An acquired form of the affection is recognized in the literature only by Tamplin.

In two cases bilateral hammer finger began to develop at the ages of eighteen and twenty years, and in both cases was attributed to slight irritation or blistering from manual work. These were probably developmental forms of the affection appearing unusually late; or the flexion may have begun earlier but been unrecognized. In one of these cases very slight stigmata of Dupuytren's contraction appeared in one palm nearly thirty years afterward, but no contracted bands were present.

In one case, a soldier at the age of thirty-seven suffered much exposure during a campaign and contracted rheumatism. At the same time both little fingers gradually or during a short period became contracted, and remained so unchanged for many years. The left little finger exhibited an extreme flexion into and against the palm caused by what appeared a Dupuytren's contraction of the palmar fascia (illustrated in Fig. 2505). The right little finger was bent at about a right angle at the proximal interphalangeal joint (Fig. 2510); there was no apparent thickening or contraction of the fascia either in the palm or in the finger, no change in the skin, no joint lesion, no sign of injury. Within the limits of the contraction the middle phalanx was freely movable, but beyond a right angle extension was impossible. The right little finger had the precise appearance of a hammer finger, and was distinctly not a Dupuytren's contraction, while the corresponding finger of the other hand was flexed by a subcutaneous palmar band.

In a second case, a laborer at the age of thirty to thirty-five years had a very slight Dupuytren's contraction of the fascia, in line with the ring and little fingers, develop in both palms, without bending the fingers; this continued without change. At the age of thirty-nine he sustained a slight wound in the palmar surface of the proximal phalanx of the left little finger, which healed in a few days. About a year later he noticed that this finger was bent; the contraction increased for a few years until at the age of forty-eight the middle phalanx was flexed at an angle of about 110°; no subcutaneous bands or contracted fascia could be distinguished.

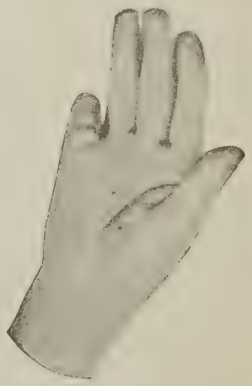

FIG. 2510.—Acquired Hammer Finger. (Original.)

In a third case, a soldier at the age of thirty-one had an abscess in the ulnar portion of the right palm, well toward the wrist, which was opened. Subsequently the middle phalanx of the right little finger became flexed at an angle of about 135°; there were no arthritic changes or subcutaneous bands, and no perceptible connection with the cicatrix in the palm.

These three cases show the possibility of the occurrence of an acquired deformity in appearance and seat precisely similar to developmental hammer finger. As compared with the latter the acquired affection is (so far as these cases show) unilateral, the degree of flexion rather greater, the skin less stretched. Within the limits of the contraction motion of the phalanx is unimpeded. In some of the cases the hammer condition is associated with Dupuytren's contraction of the palmar fascia, though in no way dependent on the latter. In some instances there is a possible relationship with antecedent traumatism. No contracted subcutaneous fibrous bands are perceptible, and no other lesions capable of causing the deformity can be detected.

In the absence of dissections the cause and anatomical changes of these acquired hammer fingers are obscure. They are not due to ankylosis, subluxations, or other joint changes, to cicatricial contractions, to skin changes, nor to perceptible fascia bands. Tendinous lesions might be possible causes. The deformity is probably due to shortening of some of the fibrous structures about the affected joint; whether the ligaments or the more superficial fibrous and fascial tissues, or both, remains to be determined. If the latter, the tissues must be generally shortened, and not thickened into bands perceptible to touch. The association with Dupuytren's disease may indicate the action of a common cause tending to produce shortening of fibrous structures in different situations. The peculiar susceptibility of one particular joint is an obscure point.

So far as the writer's observations show, acquired hammer finger bears a certain relationship to contractions of the digital fascia. The distinguishing point between them is the presence of evident subcutaneous bands in the latter. The significant fact that the proximal interphalangeal joint of the little finger is the articulation exclusively or chiefly affected in developmental hammer finger, acquired hammer finger, and digital fascia contractions constitutes a common point of relationship between these three affections, and indicates the existence of unknown specific etiological factors that render this particular joint especially liable to such changes.

The diagnosis of developmental and acquired hammer finger should ordinarily present no difficulty. The cases, especially congenital cases, are quite characteristic in their appearance, seat, and history. Flexions of the fingers due to injuries, arthritic changes, paralytic or spastic conditions, cicatricial contractions, section of extensor tendons, are usually easily distinguishable by their respective characteristics. Contractions of digital fascia are distinguished by the palpable presence of fibrous bands. Deformities produced by adhesions of flexor tendons or by fibrous ankylosis of the joints might be difficult to differentiate. To a certain degree the diagnosis, of the acquired form especially, is negative; that is, finger contractions of this type whose cause is obscure might for convenience be classed as hammer finger. Deformities due to Dupuytren's contraction are recognizable by an evident relation of the flexion of the finger with the palmar lesion; this relation is plainly demonstrable in Dupuytren's disease; although the two affections are entirely distinct, it is probable that cases of hammer finger have been diagnosticated Dupuytren's contraction, especially in alleged congenital cases of the latter affection.

Treatment of Hammer Finger.—The minor degrees of hammer finger do not cause sufficient trouble to require treatment. For the worse forms of the contraction treatment may be sought on account of the inconvenience or awkwardness of the bent finger or for the sake of appearance.

In young and mild cases, when the contraction is not too rigid and unyielding, passive motion and mechanical extension on a splint or special apparatus will often yield satisfactory results in the correction of existing deformity or the prevention of further deformity. To be effective and permanent such treatment must be kept up constantly and faithfully for a long time. The splint should be worn day and night for months, and then at night or at intervals, for a long time, until the persistent tendency to recontract is overcome. Special forms of apparatus have been devised for maintaining extension of the fingers.

In adults and cases of long standing, when the tissues are rigidly contracted and secondary alterations greatly augment the difficulties of treatment, the results of treatment are apt to be unsatisfactory. In such cases operative treatment is the only procedure offering any hope of relief. In considering the advisability of operative interference the liability of subsequent ankylosis from entering the joint, or of impaired mobility from interference with the tendons, should be borne in mind. Stiffening after operation on hammer toes does not affect the usefulness of the member. Stiffening of a finger in an extended position, however, is a material inconvenience and disadvantage, and no improvement over the hammer condition. The finger joints are very apt to become ankylosed by only slight injuries, and the risk and disadvantages of such a result or of unsightly enlargement of the joints should be remembered in considering operation. Recontraction is apt to occur.

Few cases of hammer finger have been operated on, so that data as to results or the best technique are scanty. The object aimed at is to divide all the structures causing the contraction. The shortened lateral ligaments should be cut, either through an open wound or subcutaneously. In inveterate cases a division of the ligaments alone may not suffice to free the finger, owing to secondary contraction of the skin, flexor tendons, and fibrous tissues. It will therefore be necessary to divide all the contracting structures—skin, fascia, tendons—until the finger can be straightened. Vogt claimed good results from plastic operations on the skin, as by cutting a V-shaped flap, straightening the finger, and suturing the resulting wound in a Y-shape; this would obviously afford relief only when the contraction is due to shortening and tension of the skin and superficial tissues. Contracted fibrous bands may be divided subcutaneously, as recommended by Adams. Shortened tendons may be and have been divided, or they might be lengthened by a plastic operation. Interference with the tendons, however, has been and is apt to be followed by non-union or adhesions, resulting in a very undesirable impairment of the motility of the finger. After operation extension of the digit by splints or apparatus should be maintained for a long time to overcome all remaining deformity and to prevent recurrence. Passive motion of the joints should be practised early and frequently to obviate ankylosis. Perfect results are, however, difficult to obtain, though improvement may be effected.

Forcible divulsion was employed by Little in one case. Under full anæsthesia the finger was forcibly straightened and the contracting tissues were ruptured; this was followed by the prolonged use of a splint, with good results except for some tendency to recontraction. In treatment of this kind in children care should be taken not to cause separation of the epiphyses of the phalanges.

In cases of extreme deformity and unsightliness amputation has been proposed and actually performed.

General Palmar Induration.—Cases are frequent in which the skin and subcutaneous fibrous tissues of the palmar surface of the hand and fingers are generally hardened, indurated, and slightly contracted, so that the fingers are held slightly flexed or arched on their metacarpophalangeal and phalangeal articulations, and are not easily capable of full extension. This condition is common in hard manual workers, as the result of occupation irritation. It is also occasionally exhibited by old and senile persons, in whom the skin may not be abnormally hardened, but in whom the fingers or some of them (especially on the ulnar side) are somewhat flexed by, apparently, a slight general shortening of the palmar fascias. This may develop as a senile change, without antecedent occupation irritation.

Trigger Finger.

Also called spring finger, snap finger, jerk finger, stuck finger, doigt à ressort (French), schnellender Finger, federnder Finger (German), digitus recellens. Trigger finger is a condition in which a finger during flexion or extension, or both, is suddenly arrested in its movement, and then after the exercise of extra force is suddenly released and completes the movement of flexion or extension with a sudden jerk, resembling the action of a trigger or blade of a pocket knife.

This affection was first described in 1850 by A. Notta. Since then about a hundred and thirty or a hundred and fifty cases have been recorded and a comparatively voluminous literature on the subject been produced.

The characteristic feature of the disease is the impediment to motion, the abrupt arrest of movement of the finger and its subsequent trigger-like release and sudden completion of movement (the "ressort"). The arrest always takes place at a certain point and angle, and may occur during flexion alone, during extension alone, or more frequently during both. Up to the point of arrest flexion and extension proceed normally, but at that point the motion is abruptly arrested and the finger seems to become set or locked at a sharp angle, often an acute or right angle. Then by an extra muscular effort the finger is suddenly released and completes its movement of flexion or extension with a sudden sharp jerk. The muscular exertion required to free the finger varies, sometimes requiring extreme effort, or even assistance from the other hand; one patient had to sit on the finger before the movement could be accomplished. At the instant of release a distinct click or sound can often be heard. Flexion is usually (though not always) more easily accomplished than extension, owing partly to the greater strength of the flexor muscles.

Pain, variable in degree and location, usually occurs associated with the condition, though exceptionally it is absent. In intensity it ranges from slight to excruciating. It is most severe at the time of the "ressort," but in some cases is excited by any movement of the finger. Tenderness on pressure may also exist. The seat of maximum pain is usually in the vicinity of the metacarpophalangeal articulation, but it may extend into, or be felt in, other parts of the finger, the hand, or even the forearm. Occasionally there is crepitation on movement of the flexor tendons, and various paræsthesiæ have been observed, especially in the earlier stages of the affection.

In the great majority of cases (upward of seventy-five per cent.) a nodule can be plainly felt on the flexor tendon of the finger, and movable with it, being manifestly attached to the tendons. This is in almost all cases situated near the metacarpophalangeal articulation, but in three or four cases such a nodule has been observed over the proximal or distal interphalangeal joint. In a very few cases a similar nodule has been perceptible, but did not move with the tendon, being connected with the tendon sheath. The nodosity plays an important part in the mechanism of the affection; still, in numerous cases it is not to be felt. The impediment to motion is sometimes overcome by pressure on the node; also by manipulation of the distal phalanx.

The affection is uncommon. It may occur at any age, having been reported at the age of three months (regarded as congenital), seventeen months, and two years, up to ninety years. It is much the most frequent in the adult period, however, from twenty to seventy years of age. It occurs in females rather more frequently than in males, in the proportion of about three to two. A similar trigger condition has been observed in the toes, knees, and other joints, and also in animals; and one or two cases have been reported in which lateral movements of the fingers exhibited the same kind of impediment.

Usually one finger alone is involved, but more than one may be affected, either at the same time or in succession. In one case all the fingers of both hands were involved. In some cases the abnormality occurs symmetrically on both hands. Of the two hands the right is much the more liable to the affection, being involved in over twice as many cases as the left hand.

The middle finger, ring finger, and thumb are the ones much the most subject to the affection, in about the order named; the index and little fingers are much less frequently affected. In the left hand, the thumb and middle finger suffer less frequently than they do in the right hand.

V. Carlier, who in 1889 collected 105 cases of trigger finger, gives the following statistics as to the number of times each finger was affected:

	Right hand.	Left hand.	Total.
Middle finger	32	9	41
Ring finger	20	18	38
Thumb	26	7	33
Little finger	6	3	9
Index finger	8	1	9
	92	38	130

The joint at which the trigger condition is chiefly manifested is the interphalangeal articulation of the thumb and proximal interphalangeal joint of the other digits, the second phalanx in the position of arrested movement being flexed on the proximal phalanx. Sometimes, however, the distal interphalangeal joint is the one involved; rarely the metacarpophalangeal articulation.

The chief conditions associated with trigger finger as etiological factors in the reported cases are occupation, traumatism, rheumatism, and neurotic temperament.

The factor cited as causative of the condition in the greatest proportion of cases is occupation irritation, as in seamstresses, soldiers, brushmakers, etc. Pressure upon or irritation of circumscribed portions of the palm is supposed to cause the tendinous and other lesions that are responsible for the trouble. Thus, in the case of a tennis player the pressure of the racquet handle in the palm was supposed to have caused the development of a tendinous nodule that produced the trigger condition. This effect of occupation irritation is held to explain the greater liability of the right hand to the disease. Another explanation of the effects of occupation attributes the trigger condition to the excessive use of single fingers, in much the same manner as writer's cramp and other occupation neuroses are produced.

A considerable proportion of the cases originate distinctly from traumatisms of the affected part, the injuries producing the particular inflammatory or other lesions necessary to set up the trigger condition. Many cases have with greater or less probability been attributed to rheumatism and lesions of rheumatic nature, while the upholders of nervous theories of the affection state that neurotic conditions predispose to it.

It may be concluded that traumatisms and occupation irritation certainly, and perhaps rheumatism, are capable of producing trigger finger; but in some cases, as those in children and the bilateral cases, other causative factors must operate.

The disease usually has a gradual onset, varying in symptoms and duration. The cases produced by traumatism develop most rapidly, within a few days or two or three weeks after the injury. Other cases develop more slowly, over a period of weeks and months and even of years. The initiatory symptoms may be a slight inconvenience or awkwardness in movement of the finger; this difficulty gradually increases to the fully developed trigger condition. Vague pains appear in the affected part, increasing in intensity. Sometimes a rustling or grating movement of the flexor tendon is early felt, resembling the crepitation of tenosynovitis. In other cases paræsthesiæ early appear in the region involved, as numbness, "going to sleep," formication.

The anatomical cause and mechanism of trigger finger have given rise to considerable discussion, and various explanations have been presented.

Most of the cases are undoubtedly due to lesions of the flexor tendons or their sheaths, especially those in which the nodule is perceptible. This nodule is in most cases attached to the tendon, near the metacarpophalangeal joint; it is of inflammatory, fibrous, or neoplastic (fibromatous, osteomatous, etc.) origin. As the tendon moves the nodule is caught at some point, as in transverse bands of the fascia or in constricted portions of the tendon sheath, so that motion is suddenly arrested; by further effort the nodule is forced past the obstruction and the movement is completed rapidly by the excessive muscular tension.

In a few cases it has been demonstrated that the lesions causing the trouble were situated in the tendon sheath, the tendon itself being normal. These lesions consist either of an annular or circumscribed constriction of the sheath, a thickening of the sheath, or a nodular growth in it, which interfere with the movements of the tendon within. Such lesions can be produced by inflammation, neoplasms, etc. In these cases a nodule may or may not be felt, but if present it does not move with the tendon. There may also be lesions of both the sheath and the tendon.

Thickening or stiffening of the synovial sac in such a manner as to interfere with its gliding to-and-fro movement between the tendon and its sheath has been advanced as a cause of trigger finger, and may possibly be a factor sometimes. Intrasynovial floating bodies have also been suggested as a cause of the trouble.

Some authorities have considered abnormal conditions in the phalangeal articulations to be capable of causing trigger finger. The particular abnormalities that have been mentioned in this connection are (*a*) abnormal configuration of the joint, (*b*) short lateral ligaments, and (*c*) projections at the side of the joint. It is conceivable how a certain surface configuration of the joint, as a projecting nodule or ridge or abrupt curvature, could produce a trigger-like action. Shortened lateral ligaments would obstruct the motion of the phalanx at a given angle; but if the ligaments were sufficiently elastic to stretch enough to permit the phalanx to pass beyond the obstruction, the resiliency of the ligaments as well as muscular action would cause a quick jerking completion of the movement. The possibility of such a trigger action of short lateral ligaments I have been able to demonstrate in a dissection of a hammer finger. Bony projections at the side of a joint, by becoming engaged in the lateral ligaments, might also cause an impediment to motion. It is easily conceivable how articular changes of the character mentioned could cause a sort of trigger finger, and it is possible that they may exceptionally be the cause of the condition.

That some cases of trigger finger are of nervous origin and due to muscular spasm has been upheld by a few writers, especially Carlier. Thus, it is supposed that during extension the middle phalanx is suddenly arrested by spasm of the flexor sublimis digitorum; then more energetic contraction of the extensor muscle overcomes this spasm with a jerk. Arrest during flexion is attributed to a momentary impotence of the flexor or perhaps spasm of the extensor, which is followed by brusk contraction of the flexor. According to some views trigger finger is somewhat allied to writers' cramp and similar occupation neuroses, arising in various occupations requiring excessive use of particular fingers. While muscular spasm cannot be a common cause of real trigger finger, yet the affection may perhaps occasionally be of spasmodic nature.

The prognosis of trigger finger is generally favorable. Spontaneous recovery sometimes occurs, and the affection is quite amenable to treatment, though sometimes no improvement is obtainable.

Treatment of non-operative kind often produces good results, especially in the early stages of the affection. One of the most essential parts of the treatment is rest, by immobilization of the part on a splint. Counter-irritants like tincture of iodine, massage, electricity, poultices, etc., are also useful. In inveterate cases operation is necessary. The seat of the trouble should be cut down upon; the nodule on the tendon or sheath should be removed and the sheath of the tendon should be slit open at any constricted portion. Simple incision of the tendon sheath in obscure cases may result in cure.

CIRCULATORY DISORDERS.

The distance of the hands from the heart gives rise to a relative weakness of the circulation in this member, which may become manifest whenever from cardiac or other causes there is a general lowering of the tone of the circulation. The feet suffer from the same cause, and even more than the hand, since in the lower extremities the effect of gravity is an additional embarrassment to the circulation. The hand may also suffer from obstructions anywhere in the course of the vessels of the upper extremity.

Congestion of the hand is frequent in heart disease and other conditions in which the circulatory forces are weakened. The hand is cold, slightly swollen, either dry or clammy, of a purple color; on pressure the blood is forced out, leaving a white spot into which the blood slowly returns after the pressure is removed. The congestion is also diminished by elevation of the hands. Hyperidrosis or excessive sweating is another consequence of weakened blood pressure or lowered vascular tone. Œdema of the hands is common in conditions of general anasarca or under circumstances similar to those causing passive congestion. In systemic affections such vascular disturbances are bilateral; but where the obstruction to the circulation is local, as in trauma, obstructed vessels, aneurism, etc., of one side, the stasis or œdema is unilateral. Gangrene may be an extreme result of vascular obstruction. Clubbed or Hippocratic fingers in cases of cardiac and pulmonary disease may be partly due to passive congestion, partly to real trophic alterations. Angioneurotic œdema may occur on the hand. The treatment of these conditions is that of their cause.

MUSCULAR AFFECTIONS.

The lesions of the muscles of the hand chiefly met with are the atrophies, paralyses, spasms, etc., caused by nervous lesions, considered below. Primary diseases of the muscles are rare here as elsewhere.

Unopposed action of a set of muscles, as after section of the tendons or paralysis of the opposing group, causes corresponding contractures.

Rarely the flexor muscles of the forearm are relatively shortened by arrested development. This causes a flexion of the fingers, not paralytic or spastic in character, but due entirely in a mechanical way to the shortness of the muscles and their tendons. It is manifested by inability to extend the fingers; strong flexion of the wrist, by relaxing the tendons, increases the range of extension of the fingers. The condition may develop alone without the coexistence of other abnormal conditions elsewhere, and becomes manifest during the growing or preadult period; it may also occur in infantile paralyses with other lesions. Attempt may be made to remedy the condition by division or plastic lengthening of the tendons.

Occupation muscular atrophy is an atrophy gradually developed in groups of muscles by continual use or overuse incident to the occupation pursued. It has been observed in the hand and elsewhere in a few cases. It affects especially the thenar muscles in lapidaries and others, and also the hands of writers. It is regarded as more of myopathic than neuropathic origin, and is quite amenable to treatment by rest, electricity, tonics, etc.

Ischæmic myositis or *paralysis* occasionally affects the hand from prolonged anæmia of the muscles of the forearm and hand, caused especially by pressure in this region from the use of tight bandages and splints. The long-continued anæmia causes degenerative and inflammatory changes in the muscle tissue, and sometimes induration and contraction of the muscle. It is manifested by pain, swelling, impaired movement, and sometimes contractions of the hand. The condition should be prevented as far as possible by proper treatment of fractures of the forearm. When developed it can usually be overcome by massage, exercise, electricity, douching, etc.; but sometimes it results in permanent paralysis, contractures, and deformity.

Myositis (suppurative, tuberculous, syphilitic, interstitial, rheumatic, etc.) and gummata or other tumors in the muscles are rare causes of impairment of motility. After such inflammatory conditions contractions from shrinking of the endomysial tissue and cicatrices may result. With ossifying myositis are often associated ankylosis of one or another joint of the thumb, smallness of the thumb, slight deflection of the thumb, and impairment of its motion.

Occupation or *habit contractures* sometimes occur in those whose occupation requires the hand to be held or exercised or overused in prolonged or habitual positions, as a flexion of the fingers in drivers, etc. Such cases demand change of occupation and appropriate local treatment.

NERVOUS AFFECTIONS.

The hand suffers severely and conspicuously in many nervous diseases, and so marked and characteristic are its functional and structural changes that its condition affords data valuable for diagnosis in various nervous affections. The primary nervous lesions causing the changes in the hand are seated in the nervous centres or in the nerve trunks of the upper extremity; only rarely in the hand itself, as in inflammation or injury of the nerves in the hand, or, perhaps, in occupation neuroses.

The functional and structural changes of neuropathic origin to which the hand is subject may be classified as follows:

1. Sensory disorders: Pain; disorders of common sensation.
2. Motor disorders: Paralysis; tonic spasm, contractures, etc.; clonic spasm, tremor, etc.; ataxia.
3. Trophic changes: atrophies, arthropathies, dermatoses, necrosis, etc.
4. Vascular phenomena.

These changes and symptoms do not usually exist singly, but the condition actually presented in given cases is ordinarily a mixture of various classes of symptoms, one nervous disease producing a complex of phenomena.

Pain or neuralgia in the hand occurs in connection with numerous conditions, as in neuritis, locomotor ataxia, Raynaud's disease, etc., besides being a result of gouty, rheumatoid, and inflammatory conditions.

The *disorders of sensation* of the hand include hyperæsthesia, paræsthesiæ, and especially local anæsthesia or hypæsthesia caused by injuries or lesions of the brachial plexus or its branches, besides more general and irregular anæsthesias from central nervous disease. In given nervous lesions sensory disturbances are usually less intense and more quickly recovered from than the corresponding motor paralyses.

Paralysis of any or all of the groups of muscles pertaining to the hand occurs in general paralytic conditions, as hemiplegia, anterior poliomyelitis, progressive muscular atrophy, and numerous others, and in inflammations or injuries of the nerves of the upper extremity. With the paralytic condition is usually associated atrophy, often extreme, of the affected muscles.

The primary effect of any paralytic condition is loss of the corresponding muscular function. Secondarily, from the unopposed action of the muscles antagonistic to the paralyzed muscles, or from the unequal degree in which different groups are affected, muscular *contractures* arise, which may cause various deformities. The contractures are at first of the nature of continuous or tonic spasms, and can be overcome by passive force. Ultimately the prolonged malposition causes vicious secondary alterations and ankylosis in the joints, with atrophic changes or arrested development in various structures resulting in disproportionate relations of the various parts of the member, so that finally the deformity becomes permanent and uncorrectible. Different nervous diseases produce different characteristic deformities of the hand, as the "claw hand" of ulnar paralysis, the "wrist drop" of musculo-spiral paralysis, the "preacher's hand" of cervical pachymeningitis, the club hand of infantile paralysis. *Tonic spasms* of the hand, not associated with paralysis, occur in tetany, tetanus, hysteria, and Thomsen's disease.

Some nervous affections are manifested in the hand by *tremors* and *clonic spasms*, as in multiple sclerosis, paralysis agitans, athetosis, chorea, epilepsy.

Ataxia, or inco-ordination of the movements, may affect the hands as a part of the symptom-ensemble of various central nervous diseases, as in multiple sclerosis, locomotor ataxia, general paresis, Friedrich's ataxia. The occupation neuroses are also largely manifested by ataxic phenomena. The inco-ordination is manifested by difficulty or inability to perform delicate movements or by spasmodic movements on attempting voluntary actions, and is not necessarily associated with any paralysis or decrease of motor strength.

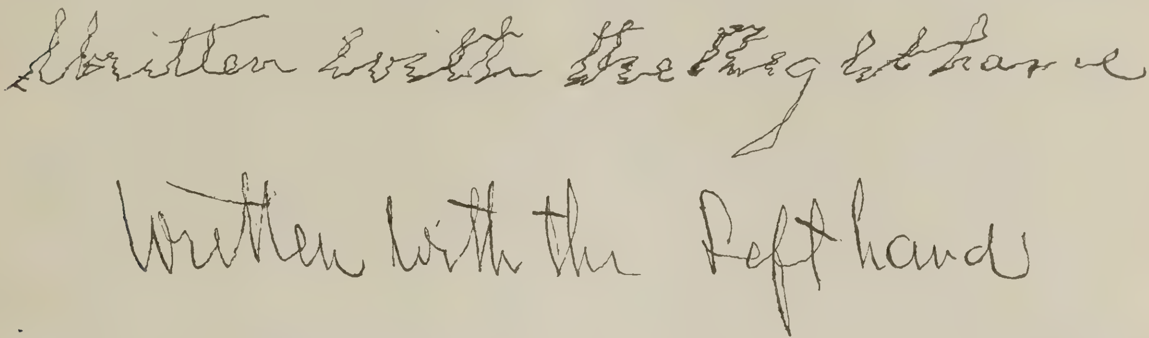
Trophic changes in the hand resulting from morbid nervous impressions may cause great damage, and exhibit considerable variety, as muscular atrophies, skin changes, onychias, joint changes, ulceration, necrosis, hypertrophies. Atrophies of various muscles of the hand, in connection with paralytic and spastic phenomena, are characteristic, severe, and conspicuous lesions in various affections, as progressive muscular atrophy, nerve injuries, and other conditions. Trophic changes in the skin and nails occur, as in the condition termed glossy skin. In many paralytic conditions of the hand the skin is pale, cool, rather smooth, and exhibits a tendency to desquamation; and the subcutaneous tissues are slightly œdematous. Trophic changes in the joints occur rarely, exemplified by Charcot's arthropathy in locomotor ataxia. General hypertrophy of the hand has been noted in a few cases of syringomyelia. Dermatitis, the formation of vesicles and blebs, ulceration, and even necrosis of circumscribed areas occur in syringomyelia, the neuritis of leprosy, Raynaud's disease, and other conditions. In nervous diseases arising during the period of growth, as infantile paralysis and infantile palsies, arrested and irregular development may contribute toward contracture and deformity in later years.

Vascular Phenomena—flushing, pallor, etc.—occur in Raynaud's disease, erythromelalgia, hysteria, and other conditions.

Having briefly summarized the neuropathic functional and structural changes to which the hand is subject, the effects upon the hand of the various nervous diseases remain to be considered.

Occupation Neuroses.—These comprise a class of local functional nervous disturbances produced by the excessive use of definite groups of muscles in performing delicate and complicated actions necessitated in various pursuits, to which the hand from its usage is subject. These affections are characterized by tonic spasms or cramps, tremors, inco-ordination and ataxia, or pain, which are brought on when attempts are made to perform the habitual actions, so that these movements can be executed only with difficulty or not at all. As a rule, other acts requiring equal delicacy and complexity of co-ordination can be performed with ease, the neurosis operating only against the particular movements that produced it. The occupation neuroses present no menace to life or the general health, but they are financially and psychically serious in that they may prevent their subjects from continuing in their accustomed avocation.

No anatomical changes have been demonstrated in these cases. Neuritis is sometimes present, but it is a complication and not an essential feature. The condition is a functional motor disorder and is sometimes styled a local neurasthenia. The affection may develop at any adult age; it is rare under twenty, a large proportion of cases develop between twenty and thirty, and many from thirty to fifty years. Occupation neuroses may attack persons in excellent physical condition, though those of a neurotic tendency or debilitated state are more subject. They develop insidiously, the first symptoms being a certain amount of stiffness, tremulousness, uncertainty, jerkiness, dull aching pain, fatigue, or weakness, during the acts at fault. These troubles slowly increase, until the neurosis is fully established, when on attempting to execute the customary movements the hand is seized with a cramp or tonic spasm, or involuntarily goes into jerky spasmodic or choreic movements, or its movements cannot be co-ordinated, or it becomes tremulous, or paretic, or the seat of a deep dull aching pain. The affection is chronic in its course. The prognosis is unfavorable so far as cure is concerned, as the neurosis is very difficult or impossible to eradicate. The symptoms can be easily ameliorated by rest and change of occupation, but even after long intervals the trouble almost invariably recurs upon resumption of the occupation that caused it.



Written with the right hand
Written with the left hand

FIG. 2511.—Handwriting in a Case of Writers' Cramp (Tremulous Variety) of the Right Hand. The patient was a clerk and had been a good penman with the right hand; after the invasion of the neurosis he learned to write with the left hand. (Original.)

The commonest and best known of the occupation neuroses is *writers' cramp*, which typifies the whole group. Analogous neuroses occur or have been observed in connection with many other occupations, of which the commonest are telegraphers' cramp, typewriters' cramp, musicians' (pianists', violinists') cramp, sewers' cramp, hammer cramp.

The diagnosis of well-marked cases of occupation neuroses usually presents no difficulty. The earlier stages may not be easily distinguishable from the vague incipient symptoms of other nervous affections. A local neuritis may present symptoms simulating occupation neuroses; but in neuritis the motor or ataxic trouble is not so closely related to one particular set of movements, and the electrical reactions may be altered. The prognosis of neuritis is also more favorable.

If symptoms of approaching writers' cramp appear, prophylactic treatment is important. The act of writing should be made as comfortable as possible, by the use of an easy-writing pen (as a gold pen), a penholder that can be held with ease, smooth paper, and the adoption of such arrangements and position as are easiest for writing. The pen should be held lightly and grasped with as little force as is possible. The manner in which the penholder is held by the fingers should be changed. New sets of muscles should be brought into play, and the motions of writing should be altered as much as possible and carried on with the entire hand and forearm rather than with the fingers alone.

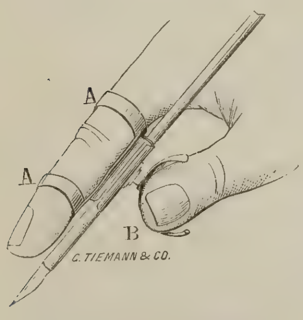


FIG. 2512.—Mathieu's Apparatus for Writer's Cramp. (After Dana.)

The best treatment of incipient or fully developed occupation neuroses is rest and suspension or change of the occupation. The symptoms readily yield to such treatment, but unfortunately these measures are not always practicable. General neurotic or debilitated conditions should receive appropriate treatment. Local massage, gymnastics, and electricity are useful. The unaffected hand may be used, after practice and training, to execute the movements impaired in the other hand, though in such cases the second hand often becomes itself affected by the neurosis. Various forms of apparatus have been devised for use in writers' cramp, for immobilizing the fingers involved, for holding the penholder and so relieving the fingers of the effort of pen-prehension, and for bringing new muscles into play in the act of writing (Figs. 2512, 2513). Such devices may be of service in these cases, but the substitution of type-writing machines for the pen would be far more efficacious.

Diseases and Injuries of the Nerves.—Inflammation of the nerves supplying the hand presents the usual phenomena of neuritis, tenderness over the affected nerve, pains, hyperæsthesia, hypæsthesia, or paræsthesia of the area supplied, motor paralysis, trophic changes, altered electrical reactions. The symptoms vary in their character, location, and intensity in different cases and in different varieties of the disease, as in the traumatic, multiple, rheumatic, gouty, toxic (lead, alcohol, etc.), leprous, and other forms of nerve disease. Neuritis sometimes exists with and complicates occupation neuroses; and an occupation neuritis may be induced in the member by the occupation pursued. Degeneration of the nerves produces corresponding paralytic, spastic, and trophic phenomena.

In chronic *lead poisoning* the extensor muscles of the hands are often paralyzed, producing the "wrist drop" characteristic of this condition; sometimes there is also in plumbism a swelling or ganglion on the back of the wrist. In *alcoholic polyneuritis* wrist drop may also occur, but less frequently than foot drop.

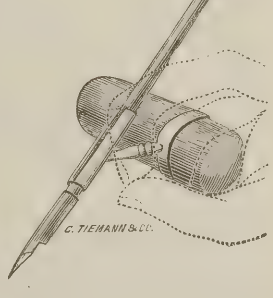

FIG. 2513.—Apparatus for Writers' Cramp. (After Dana.)

Injury or disease of the *brachial plexus*, produced by rheumatic inflammation, by rheumatoid disease of the cervical vertebræ, in connection with dislocations of the shoulder, from the pressure of crutches, or other causes, results in motor paralysis, contractures, sensory disturbances, muscular atrophies, and other trophic changes, corresponding to the manner and extent in which the cords of the plexus are involved.

In division or other causes producing paralysis of the *musculo-spiral nerve,* there is paralysis of all the muscles on the posterior aspect of the forearm and the radial group of muscles, so that the wrist and proximal phalanges of the fingers cannot be extended, and the hand falls limply; this constitutes the condition of "wrist drop" which is a characteristic phenomenon in lead poisoning and other nervous affections. The middle and distal phalanges remain capable of extension from the action of the interossei and lumbricales muscles, which are innervated by the ulnar nerve. The paralyzed muscles may atrophy. Sensation may be lost on the radial portion of the dorsum of the hand, usually over the area corresponding to the thumb, index and middle fingers, and radial half of the ring finger; individual variations in the distribution of the nerves of cutaneous sensation in the hand are, however, frequent.

The *median nerve* furnishes cutaneous sensation to the palmar aspect of the thumb, index, middle, and radial half of ring finger, and innervates the pronator muscles, flexor carpi radialis, flexor longus pollicis, flexor sublimis digitorum, radial half of flexor profundus digitorum, abductor pollicis, opponens pollicis, outer head of flexor brevis pollicis, and the two outer lumbricales. Paralysis of the median nerve produced by section of it above the elbow or other cause results in loss of sensation over the area mentioned, atrophic changes in the muscles of the forearm and the thenar eminence, loss of power of abduction and opposition of the thumb, loss of flexion of last phalanx of the thumb, diminished power of flexion of the proximal phalanx of the thumb, and impairment of flexion especially of the index and middle fingers. The power of pronation is lost and the wrist is flexed only by the flexor carpi ulnaris.

Division of the median nerve at the wrist, below the separation of the branches to the muscles of the forearm, results in loss of power of abduction and opposition of the thumb.

Paralysis of the *ulnar nerve* causes loss of sensation over the ulnar third of the hand and over the little and ulnar half of the ring finger, anteriorly and posteriorly, loss of motor power of the muscles supplied by it (flexor carpi ulnaris, ulnar half of flexor profundus digitorum, the muscles of the little finger, the two ulnar lumbricales, all the dorsal and palmar interossei, adductor pollicis, and inner half of flexor brevis pollicis), together sometimes with atrophic changes, at times extreme, in the muscles affected. Adduction of the thumb and lateral movements of the other fingers are abolished; flexion of the proximal phalanges is interfered with, and these phalanges are held in extension or superextension. From paralysis of the interossei and two lumbricales extension of the middle and distal phalanges is lost or impaired, and these phalanges, especially in the little and ring fingers, are held strongly flexed. The action of the flexor carpi ulnaris is lost. In closing the fist, the distal and middle phalanges are first flexed by the common flexors, and then the proximal phalanges are bent by the continued action of these muscles.

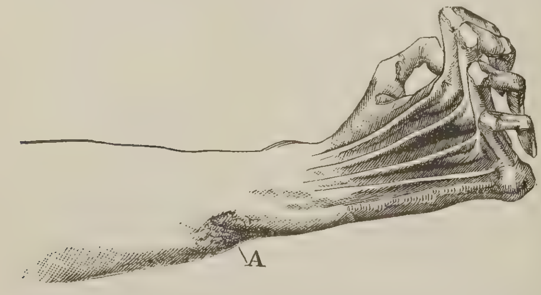

FIG. 2514.—Extreme Atrophy and Contractures from Paralysis of Ulnar Nerve (Caused by Wound at A); an Extreme Instance of "Claw-hand." (Duchenne.)

When the injury or lesion involves the distal portion of the ulnar nerve, near the wrist, beyond the branches given off to the flexor profundus digitorum and flexor carpi ulnaris, these muscles will escape paralysis.

The deformity known as "claw-hand" (main en griffe) is produced by paralysis of the interossei and lumbricales, the common flexors and extensors being at the same time unparalyzed. As these muscles are (with the exception of the two radial lumbricales) supplied by the ulnar nerve, claw hand is a characteristic consequence of paralysis of the ulnar nerve, and occurs in injuries of that nerve (Fig. 2514), and sometimes in progressive muscular atrophy (Fig. 2517), amyotrophic lateral sclerosis, syringomyelia, leprous neuritis, and other conditions. The action of the interossei and lumbricales is to flex the proximal phalanges and extend the middle and distal phalanges, besides acting as abductors and adductors. Paralysis of these muscles results in a superextended position of the proximal phalanges (from the unopposed action of the extensors) and strong flexion of the middle and distal phalanges (from the action of the common flexors); this position of the hand is the one to which the term claw-hand is applied. Along with this paralytic and contractured condition, extreme atrophy of the paralyzed muscles is often present in claw-hand, the palm being hollowed out, and the interosseous spaces on the dorsum of the hand being sunken so as to form deep grooves.

Combined paralysis of the ulnar and median nerves, the musculo-spiral nerve being normal, results in the deformity known as the "preacher's hand" (main du prédicateur emphatique), from its supposed resemblance to the emphatic gestures of public speakers (Fig. 2515). The unopposed action of the extensor muscles causes the hand and proximal phalanges to be habitually held in a position of marked extension and superextension. The "preacher's hand" occurs especially in hypertrophic cervical pachymeningitis, though it occasionally appears in other nervous diseases.

Glossy skin is a rare trophic change sometimes resulting from wounds or other lesions of nerves, which affects the fingers especially. The digits, or one or two of them, are smooth, shining, and glossy, devoid of hair, pinkish or blotched as if by chilblains, and the surface of the skin lacks its natural linear markings. Trophic changes in the nails also occur. The lesions are the seat of burning pain and neuralgia.

Vaso-neuroses.—There are some allied conditions which along with prominent vascular phenomena present pronounced neuropathic features, and hence may be classed as vaso-neuroses. These are Raynaud's disease, erythromelalgia, chilblains, and the condition of vascular spasm described under the name "dead fingers." The hand, along with the foot, is a favorite seat for these affections, which are considered in full elsewhere and can be only briefly touched upon here.

Raynaud's disease (peripheral gangrene, symmetrical gangrene) is a rare condition characterized by small circumscribed areas of vascular disturbance or ischæmia, running on to gangrene, associated with severe neuralgic pains. The lesions are usually several in number, situated on the fingers or toes, sometimes the face; almost always they are bilateral and symmetrical, but the writer has seen a case involving one hand only. In the milder cases or earlier stages the lesions consist of small local areas of anæmia ("local syncope") or of passive congestion ("local asphyxia"). In the severer cases circumscribed moist black gangrenous patches develop; after the slough separates an ulcer is left that heals very slowly. The course of the disease is very slow and protracted, the lesions requiring weeks or months for their evolution and repair. The necrotic process has been known to cause complete spontaneous amputation of the ends of the fingers. In treatment, analgesics are required for the relief of pain, and tonics or other measures for improving the general condition. Local treatment aims at promoting the separation of the slough and stimulating the healing process; this is accomplished by poultices, caustics (silver nitrate, copper sulphate), excision of the sloughs, antisepsis, etc.

Erythromelalgia is an uncommon condition affecting usually the feet, but also the hands and rarely other regions. The disease is manifested by recurring paroxysms, though sometimes the trouble is almost continuous. The attacks consist in the development of areas of intense burning, pain, and tenderness on the feet or hands, associated usually with transient redness or congestion of the hyperæsthetic area. The attacks are brought on or aggravated by warmth, dependent position, and exertion. The pain is frequently so excruciating as to cause complete disability of the extremity affected. Erythromelalgia is usually classed with nervous diseases, though it can perhaps be equally well ranked as a circulatory disorder—a vaso-motor neurosis or vascular hyperæsthesia. Distance from the heart is a factor in causing, and determining the location of, the lesions; and gravity is another factor contributing to ischæmia which probably accounts for the preference for the feet which the disease exhibits. The disease is obstinate and persistent and no effective treatment is known. During the paroxysms relief is usually afforded by elevation of the part, the application of cold (immersion in ice water), and rest.

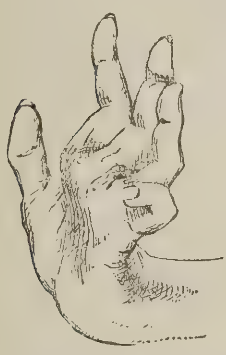

FIG. 2515.—Characteristic Position of the Hand in Hypertrophic Cervical Pachymengitis—the "Preacher's Hand." (Meillet and Richer.)

Chilblains (pernio) are often regarded as related to frostbite, but in some respects they resemble Raynaud's disease and erythromelalgia, and are probably a form of vaso-neurosis. While they sometimes originate after exposure to cold, this is not always the case; anæmic and chlorotic individuals are especially subject. Chilblains are commonest on the feet, but sometimes occur on the hands. The disease is obstinate and the attacks persistently recur, especially in winter. The attack consists in a severe itching or burning pain and tenderness in the areas affected, which are red and erythematous. The pain is aroused or aggravated by warmth, especially by warmth following exposure to cold. In severe cases the affected areas may become œdematous and bullous, and undergo ulceration. For relief of the pain, very hot or very cold water may be applied; also astringent or sedative ointments or lotions, etc. Constitutional treatment should be directed against any anæmic, chlorotic, gouty, or rheumatic conditions.

Vascular Spasm.—In the rare condition sometimes termed "dead finger" one or more fingers undergo sudden, repeated, and transient vascular spasm, so that they become white, bloodless, and cold. The paroxysms last a few minutes, hours, or even days. At times the blanching is preceded by lividity, and is occasionally accompanied by dull pain. The affection was first described by Allan McLane Hamilton in 1874, and since then a few cases have been reported. The treatment is by galvanism, nitroglycerin, or other vaso-dilators.

Acrodynia is a disease of the Orient, occasionally occurring in Europe, characterized by pains in the hands and other extremities, with erythema, thickening and exfoliation of the epidermis, pigmentation, and other changes in the skin.

Hypertrophic Cervical Pachymeningitis.—In this affection the upper extremities are especially involved, usually one becoming affected after the other. In the period of development of the disease there are pains and altered sensation in one or both hands. After the cervical lesions are fully established marked paralytic and atrophic changes develop. The particular distribution of these lesions varies in different cases, but the commonest and most characteristic condition is a paralysis and atrophy of the muscles supplied by the ulnar and median nerves, leaving the musculo-spiral group less involved. The flexors and pronators and the muscles in the palm are paralyzed and atrophied. The unopposed action of the extensors brings the hand and fingers (especially the proximal phalanges) in a position of superextension, forming the so-called "preacher's hand," already referred to; this position is quite characteristic of cervical pachymeningitis, though it may occur in other affections (Fig. 2515). At first the hand can be flexed passively, but later the extensor muscles may undergo contracture. Sensation may be lost or impaired in the affected areas.

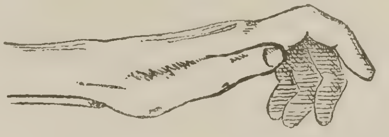

FIG. 2516.—Characteristic Appearance of the Hand ("Ape Hand") in Progressive Muscular Atrophy. (Meillet and Richer.)

Cervical Paraplegia.—In injuries or myelitis of the upper part of the spinal cord the upper extremities may be more or less completely paralyzed, with extensive muscular atrophy.

Progressive Muscular Atrophy.—The hands suffer early, characteristically, and severely in this disease, either successively or simultaneously. The muscles of the thenar eminence are usually the first to be affected; they gradually become atrophied and paralyzed, producing a peculiar flatness of this region. The hypothenar muscles soon become similarly involved. At this stage the hand appears long, thin, and flat, and the thumb lies parallel and in the same plane with the other fingers; the hand in this condition has been likened in appearance to that of the ape (Fig. 2516).

Later the interossei and lumbricales atrophy and become paralyzed, resulting in corresponding loss of the power of abduction and adduction of the digits, flexion of the proximal phalanges, and extension of the middle and distal phalanges. If the flexor and extensor muscles in the forearm are at this stage unaffected, "claw hand" will result (Fig. 2517), though, as the muscles of the forearm usually become involved early, this deformity does not very often occur in progressive muscular atrophy.

Fibrillary contractions occur in the affected muscles. Contractures are not usually present to a marked degree.

Anterior Poliomyelitis.—In infantile paralysis the upper extremity is sometimes involved, but much less frequently, especially permanently, than the lower. Paralysis of irregular and varying distribution occurs, with atrophy of the affected muscles and of bony and other tissues, contractures of the opposing muscles, and retardation of growth. The most injurious and the most characteristic consequences of the disease in infants are the deformities, produced by arrested and irregular development of the parts, that make their appearance as the growth of the child proceeds. In this way, from contractures and irregular development at the wrist, various forms of club hand may be produced.

In the adult form of the disease, permanent paralyses, atrophies, and contractures may delop, but as full growth has been attained the ultimate deformity is less than in infants.

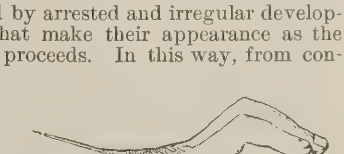

FIG. 2517.—Claw Hand of Moderate Degree in Progressive Muscular Atrophy. (Meillet and Richer.)

Locomotor Ataxia.—In this disease the hands often suffer from want of co-ordination and inability to perform delicate movements, like picking up a pin or buttoning the clothing. Rarely trophic changes, as of the nails, occur in the hand. Charcot's arthropathy occurs rarely in the wrist or joints of the fingers; in this condition an enlarged phalanx may present an appearance similar to that of syphilitic dactylitis. Hyperæsthesia sometimes occurs about the fingers.

Lateral Sclerosis.—In this condition the upper extremities are usually affected much less and much later than the lower, though rarely the disease begins in the upper extremities. There are present paresis, muscular tension, and exaggerated tendon reflexes; the wrist and fingers are usually strongly flexed and the arm is adducted.

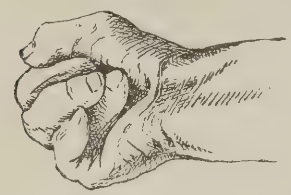

FIG. 2518.—Hemiplegic Contracture of the Fingers. (Meillet and Richer.)

Amyotrophic Lateral Sclerosis usually begins in the upper extremity, with paralysis, muscular atrophy, fibrillar contractions, pain, and paræsthesia, followed at a later stage by muscular rigidity and contractures. Sometimes the fingers are bent into the palm and the wrist is flexed; sometimes there is atrophy of the interossei and claw hand.

Multiple Sclerosis.—The most conspicuous symptom exhibited by the hand in this condition is the intention tremor, or rapid rhythmic tremor when voluntary movements are attempted. The wrist jerk is exaggerated, and paresis and muscular rigidity may be present. Trophic changes in the hand occasionally occur, as swelling of the small joints of the fingers, atrophy of the small muscles, blebs, onychia, sweating, lowered temperature.

Syringomyelia (Morvan's disease) involves especially the upper extremities, and is manifested by paralysis and atrophy of muscle groups, varying in situation, paræsthesiæ and anæsthesia (especially to temperature and pain) in irregularly distributed patches, and trophic changes. Some cases of syringomyelia simulate progressive muscular atrophy, beginning with atrophy and paralysis of the thenar, hypothenar, and interosseous muscles of the hand, producing claw hand; the paralysis later proceeds up the forearm. Enlargement of joints (frequently the wrist) occurs, similar to Charcot's tabetic arthropathy. Œdema, vesicles, bullæ, ulcers, onychias, recurring painless whitlows, and even extensive gangrene and mutilation about the fingers and hand may occur. In a few instances general hypertrophy of the hand has been observed, and in a few others Dupuytren's contraction has been present.

Hemiplegia.—In this affection the primary condition manifested in the hand is paralysis. Later, especially following secondary descending degeneration in the spinal cord, contractures may develop, usually of the flexor muscles (Fig. 2518), though the extensors may be shortened. The muscles are only exceptionally atrophied, aside from decrease in size caused by disuse.

Infantile cerebral palsies and *infantile hemiplegia*, occurring especially during the first two years of life and arising from labor traumatisms (birth palsies) or pathological cerebral conditions, usually affect the upper extremity worse and more permanently than the lower. Trophic effects which cause permanent damage follow the primary paralysis. Growth of the parts involved is arrested or irregular, so that the hand and arm are small and undeveloped, less in size than their fellow, and often deformed from contractures, disproportionate development of different parts, or secondary joint changes. The fingers, wrist, and forearm are usually flexed, and forms of club hand may be produced. Frequently the affected member remains the seat of ataxia, chorea, tremor, or the peculiar motor disorder called athetosis (see below). About ten per cent. of the cases of infantile hemiplegia are followed by athetosis, which is a sequela of this condition rather more frequently than of birth palsy and much more frequently than of adult hemiplegia.

Friedrich's Ataxia is a rare hereditary condition, occurring chiefly in children, in which the hands become involved by extension of the disease from the lower extremities. The hand exhibits an ataxic condition, delicate movements like buttoning the clothes being interfered with. "Manus cavus" often occurs, the palm being arched; the proximal phalanges may be superextended and the middle and distal phalanges somewhat flexed, producing some tendency to claw hand.

In *general paresis* the hands may exhibit anæsthesia, paralysis, tremor, and lack of co-ordination, shown especially by impaired ability to execute delicate movements, as writing.

In *tetanus* the hand participates in the tonic and clonic spasms. As the flexors are stronger than the extensors, in this as in many other spastic conditions the position of the fingers and hand is usually that of firm flexion.

Tetany affects the hands conspicuously. Intermittent paroxysms of tonic muscular spasms occur, associated with pain and paræsthesia. The paroxysms last for from a few minutes to a few days and may persist even during sleep; the intervals between the paroxysms last from hours to months. The mechanical and electrical irritability of the muscles is increased, and pressure on the nerve trunks and arteries excites an attack (Trousseau's symptom). The position assumed by the hand during the spasm depends on the group of muscles affected, but is usually one of flexion. Often the hand assumes the conical shape of the accoucheur's hand about to be introduced into the vagina; the fingers are flexed at the metacarpophalangeal joints and extended at the other joints, the hand is narrowed and the thumb adducted. Sometimes the fist is forcibly closed by general flexion, the thumb being pressed into the palm and the other fingers flexed upon it. Rarely the fingers are extended and separated.

Thomsen's Disease (congenital myotonia) is a rare hereditary affection, manifested by the occurrence of tonic spasms on attempting voluntary movements. The hand may be involved with other parts of the body. On closing the hand firmly, for instance, cramp occurs and the grip cannot be relaxed.

Hysteria.—In this condition the hand, like other parts of the body, may be involved in a variety of ways, by hyperæsthesias, anæsthesias (often dissociated), slight wasting, vascular phenomena (as flushing, pallor, coldness, ordinary œdema, cyanotic or "blue" œdema), paralyses, sudden temporary loss of power in the muscles, tremor (simple or intentional), contractures, etc. Hysterical contractures of the hand may be temporary or persistent, and usually involve the flexor muscles,

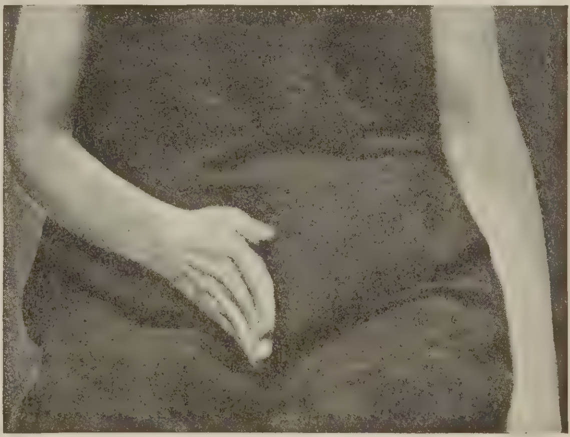

FIG. 2519.—Hysterical Contracture of Extensor Muscles of Hand, of Six Months' Duration. (Dana.)

though sometimes the extensors are affected (Fig. 2519); sometimes the contractures are extreme and very firmly fixed, not yielding to sleep or a mild degree of general anæsthesia; they may continue for months, and cause permanent damage by setting up secondary joint changes.

In *epilepsy* the hand may take part in the spasms. In *chorea* the fingers and hand usually participate actively in the irregular movements and inco-ordination. In the *tics* and *habit chorea* the hand may be involved, though the face is the commonest seat of these disorders.

Paralysis agitans is usually manifested in the hand in a very characteristic fashion. In typical cases the fingers are flexed at the metacarpophalangeal joints and the pulp of the thumb is opposed to that of the index finger; by the constant tremor the opposed thumb and index finger are kept continually rolling over each other, producing the movement described as "pill-rolling." The tremor is usually less during voluntary movements. Muscular rigidity of the digits and hand is often present.

Athetosis, or post-hemiplegic chorea, is a peculiar motor affection of the fingers and toes that occurs most frequently as a sequela of infantile hemiplegia and infantile palsies, less frequently after hemiplegia in adults. It is manifested by slow and deliberate forcible involuntary movements of the digits, in extension, flexion, abduction, and adduction, which take place successively and incessantly, even during sleep. The movements may be complicated and peculiar, and may lead to distorted positions of the hand; they can be only partially and for a short time controlled by the will, and the fingers cannot be permanently kept in any fixed position.

The *treatment* of nervous affections of the hand is in general that of the cause or of the general condition producing the local trouble, together with measures to improve the local condition when no general amelioration is possible.

In wounds in which nerves leading to the hand are divided, the ends of the severed nerve should be carefully sutured together with catgut. If this is not done at the time of the injury, secondary suture, even after months or years, may restore the function of the nerve. If a portion of a nerve is destroyed and the ends cannot be approximated by stretching, plastic procedures or transplantation may be tried.

Developing or impending paralysis and atrophy of muscles and the resulting contractures and deformity may sometimes be arrested, retarded, or diminished by the use of electricity, massage, exercise, passive movements, etc. When deformity is fully developed there is usually little possibility of accomplishing any material improvement, though sometimes the local condition can be somewhat bettered. Thus, division or lengthening of the tendons of contractured muscles sometimes improves deformity and motion. In some cases shortening of the tendons of partially paralyzed muscles, as the extensors, may improve their action. Tendon transplantation, that is, the transference and joining of tendons of non-paralyzed muscles to those of paralyzed muscles, has been tried in the hand in a few cases, in some with good results; thus, in extensor paralysis, some of the tendons of flexor muscles may be cut off and the tendons passed subcutaneously or through the interosseous space to the dorsum of the wrist, where they are sutured to the tendons of the paralyzed extensor muscles. In some cases the use of mechanical apparatus is beneficial. Local trophic changes of inflammatory or necrotic character demand appropriate treatment.

SENILE CHANGES IN THE HAND.

In old age the skin and subcutaneous tissues often become atrophied and thinned, diminishing the size of the hand and fingers. Joint changes are often present, and have been referred to above; they comprise chiefly enlargements (relative or absolute), ulnar deflections, changes in the thumb joint, and other lesions which merge into conditions of rheumatoid character.

Occasionally general palmar induration (as already described) is observed. Trophic changes in the nails—longitudinal ridges ("reedy nail")—sometimes occur. Senile warts (verruca senilis) may develop on the hands as elsewhere; they may be flattish or elevated, pigmented or non-pigmented, sometimes fatty. The back of the hand is a favorite seat for keratosis senilis, which is manifested by warty projections in the form of small papules or larger flattish plates, greasy plates or patches, branny scales, pigmented spots, or in some cases thickening of the entire skin; sometimes the skin of the back of the hand is converted into a dense horny plate. This condition may run into epithelioma. Tremor of the hand, merging into paralysis agitans, is a common senile condition.

CONDITION OF THE HAND IN GENERAL DISEASES.

The changes exhibited by the hand in a large number of general diseases have been already detailed, so that there is little to be added on this subject. In anæmic conditions the hand is pale, cold, dry, and the nails are pale. In conditions of vascular relaxation and atony, weak circulation, or lowered blood pressure, the skin is clammy, cold, purplish, or mottled. In cardiac disease the hands may be congested, cold, clammy, or œdematous, and the fingers may be clubbed. In nephritis the hand is dry, pale, œdematous. In tuberculosis the hand may be emaciated, hot, dry, or sometimes clammy, and the fingers are occasionally clubbed or blunt. Clubbed fingers may occur in other forms of pulmonary disease. The hand is dry and shrivelled in diabetes. Onychias may follow severe acute diseases. In typhoid fever the palms of the hands (and soles of the feet) are usually dry, parchment-like, of a yellow to brownish color, and during convalescence are the seat of active desquamation. In certain forms of idiocy the skin of the hands is loose, wrinkled like a washerwoman's, and looking too large for the hand, while the finger tips are tapering and conical.

John Benjamin Nichols.

HARBIN HOT SULPHUR SPRINGS.—Lake County, California.

POST-OFFICE.—Harbin Springs. Hotel.

ACCESS.—Take boat at Oakland Ferry from San Francisco. At Vallejo change for Napa Valley branch to Calistoga; thence a twenty-mile stage ride brings one to the springs. Time from San Francisco: seven and one-half hours. The location is at the base of a spur of the Coast Range of mountains, 2,000 feet above tide water. Lake County has been justly named the Switzerland of America, and it would be difficult to find a more delightful and picturesque location than that of the Harbin Springs. The mountain air is very invigorating and not subject to extremes of heat or cold, the mean temperature being 70° F. The waters are sulphurous and saline, the principal spring flowing 1,500 gallons per hour. There is also a small chalybeate fount yielding only sixty gallons per hour. The sulphur spring has a temperature of 122° F., and is used for bathing, for which excellent facilities have been provided. Following is an analysis of this water:

ONE UNITED STATES GALLON CONTAINS:

Solids.	Grains.
Sodium chloride	23.05
Sodium carbonate.	5.42
Sodium sulphate	10.19
Potassium carbonate	1.74
Magnesium carbonate	6.18
Magnesium sulphate	11.94
Calcium carbonate	9.10
Calcium sulphate	14.63
Ferrous sulphate	1.75
Arsenious salts	.07
Alumina	1.60
Silica	2.76
Organic matter	Trace.
Total	88.43
Gases.	**Cu. in.**
Carbonic acid gas	4.26
Free sulphureted hydrogen	11.74

It is said that much benefit accrues from the use of this water in chronic rheumatism and gout and other articular affections, as well as in certain varieties of skin diseases.

The chalybeate spring shows the following mineral ingredients:

ONE UNITED STATES GALLON CONTAINS:

Solids.	Grains.
Sodium chloride	7.50
Sodium carbonate	14.22
Sodium bicarbonate	1.45
Sodium sulphate	5.25
Potassium chloride	Trace.
Potassium carbonate	1.73
Magnesium carbonate	4.16
Magnesium sulphate	6.11
Calcium carbonate	2.07
Calcium sulphate	Trace.
Ferrous carbonate	1.90
Alumina	.73
Silica	1.41
Organic matter	Trace.
Total	46.53

Carbonic acid gas, 9.34 cubic inches.

This water is clear and sparkling, and has a pleasant taste. It is tonic, antacid, diuretic, and aperient, and is useful in dyspepsia, anæmia, chlorosis, chronic malarial poisoning, and wasting diseases. In addition, there are two more springs of some importance; they are known as the "Magnesia" and the "Arsenic" springs. The last-named spring has gained quite a reputation in syphilitic and skin diseases, glandular indurations, etc.

James K. Crook.

HARDHACK. (See *Rosaceæ.*)

HARELIP, unlike cleft palate, may be regarded as a strictly congenital malformation. It is a deformity that, from its peculiar prominence, has brought more sorrow to the hearts of parents than perhaps any other of nature's defects. To the surgeon it has been the source of more thought and care as regards the operation for its relief than are demanded by many surgical problems of far greater importance.

Like cleft palate, it may be looked upon as an arrest in fœtal development, confined, with very rare exceptions, to the upper lip. When situated in the lower lip, there are many deformities that may coexist with it, such as combined fissure of the lower jaw and tongue, and a variety of other like complications. Sir William Fergusson, in the fifth edition of his "Surgery," p. 506, speaks of several cases of this kind which had been observed by himself and others in their practice.

Associated with upper harelip are sometimes remarkable deformities about the face; for instance, the fissure may extend up along the nose on one or both sides to, or into, the eyelids, or it may extend out on one or both sides from the angle of the mouth, and may implicate Stenson's duct, a very unpleasant complication.

Mason speaks of a cyanotic condition of the child. This condition, which I have also observed, is, at times, cured by the operation for closure of the fissure. Mr. George Lawson gives the explanation (*Lancet*, June 7th, 1862, p. 599) that during the lull in the circulation, in cases in which faintness occurs, the foramen ovale becomes closed and thus the double current is established.

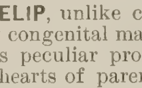

FIG. 2520.

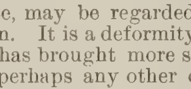

FIG. 2521.

The pathology of harelip is a subject into which the narrow limits of an article like the present one will not permit me to enter except in the most superficial manner. M. Coste[1] states that the mouth is formed between the twenty-fifth and the twenty-eighth day of fœtal life. The frontal lobe becomes much enlarged, and shows a great hollow which divides into two smaller lobes, called by him the incisive centres, and from which the incisive bones and the middle portion of the upper lip are developed. The centres for the superior maxillæ, which form the lateral parts of the upper lip, converge one toward the other, and come nearer to each side of the corresponding incisive centre. At the fortieth day the two incisive centres, in the substance of which the incisive teeth are developed, unite one to the other in the middle line and thus complete the central portion of the upper lip. Thus, if the two lateral portions do not unite with the incisive portions, we have a double, or bilateral, harelip; if only one of these sides fails to unite, then we have a single, or unilateral, harelip.

FIG. 2522.

I have, in a few of my earlier operations, removed the intermaxillary bone, and, on examination of it, have noted an absence of the lateral incisors. This, I believe, has been the experience of most surgeons who have given careful thought to the question whether this island contained all of the upper incisors or not. In two cases that I examined a few years after the operation for cleft palate, in which I had saved the intermaxillary bones, I found in each instance an irregular lateral incisor on the right side, back of the regular row of teeth.

Fergusson, Demarquay, Gurdon Buck, and others report a large number of cases which illustrate the fact that harelip appears in some families through many generations, and I have observed this in the record of my own cases. Like webbed fingers and toes, harelip is often seen without any evidence of consanguinity being present.

There are few surgeons, I suspect, who have examined cases of harelip carefully, who have not been impressed with the effort so often made by mother or nurse to prove that the deformity is entirely due to some fright which the mother has experienced and which in her estimation has produced its effect upon the child in utero. Maternal impressions may be one of the factors in the production of harelip, and yet evidence of such cause is so often wanting as to lead us to doubt.

Acting early upon the suggestion of the late Sir Wm. Fergusson, I have examined many lips and jaws for fissure, and have frequently found slight notching or partial defects on the mouths of one or the other of the parents.

I have frequently had occasion to call the attention of my class to this point in the study of these cases. This is very well shown in Figs. 2520 and 2521, from Mason.* Some cases are not so well defined, the amount of depression in the vermilion border of the lip being much less. I have noticed that close pregnancies form a factor in causing this deformity. In connection with these cases it is not unusual to see in the same patient extra thumbs or fingers, spina bifida, and the like. The late Professor Alden March had a child brought to his clinic, for relief of harelip, who had cleft palate, an extra toe and finger upon each foot and hand, double hernia, and club foot. He thought the child hardly in a proper condition for operation, and quietly said to the poor mother, "My good woman, you had better try it over again."

Accidents, bites of dogs and other animals, treatment of nævi, and other surgical conditions may result in a temporary form of harelip, which may be said to be cured generally in the final treatment given to such lesions. In the case of Miss C——, aged six, suffering from nævus on the upper lip, whom I had treated in various ways without complete success, the final injection of a solution of tincture of iron produced a slough resulting in a fissure such as is seen in Fig. 2522, but which was closed with scarcely any scar by means of two silver harelip pins.

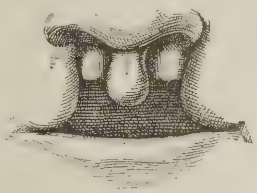

FIG. 2523.

A considerable number of cases is met with in which the kind of harelip is of the double variety, as seen in Fig. 2523, from Mason. In this variety the fissure may be very slight on one side and yet complete on the other, or, in cases in which there is a double fissure of the alveolar arch, as in cleft palate, we may have the horrid horn-like projection as seen in Fig. 2524, from Mason, and in one of my own cases, Fig. 1363, of vol. III.

Cases of median harelip have been recorded by surgeons, but they are exceedingly rare, and their existence has even been doubted by some. In the autumn of 1883 there was brought to my clinic a female child (two and one half years of age) in whom a cystic tumor at the tip of the nose was complicated by a complete median fissure of the upper lip. Fig. 2525 (from a sketch of the little patient) shows the case very well. Sir Wm. Fergusson has very justly remarked that, after the operation has been completed, one cannot judge correctly as to whether the case was originally one of a median fissure or of double harelip, for many cases of the latter defect, when operated on, show a decided tendency to the formation of a cicatrix in the middle line. Fig. 2526, one of my own cases, and quite as bad a case of double harelip as I have ever operated upon, shows this condition clearly. It is a singular fact that in these various kinds of fissure in the upper lip there is really very little loss of substance. One finds this to be true by merely approximating the soft parts temporarily.

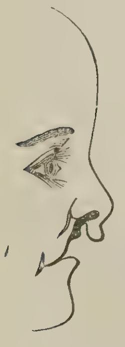

FIG. 2524.

Regarding the period of life when it is best to operate, in cases of harelip, much has been said by the older operators, but with little unanimity of opinion; some advising interference in infancy, others preferring to wait until advanced childhood. At the present time, I am of the opinion that modern surgeons prefer the early operation. My own experience teaches that a good time for the operation is when the infant is about six weeks old, especially if the child be healthy. In a case of double fissure perhaps it is well to wait until the child is six or seven months old. Of one thing I am certain, that in the latter complication we should perform the operation as early as possible, in order to secure the good effect which is produced upon the soft parts when the cleft in the hard palate is obliterated by operative interference,—an effect which, in a period of two years, amounts to a great deal.

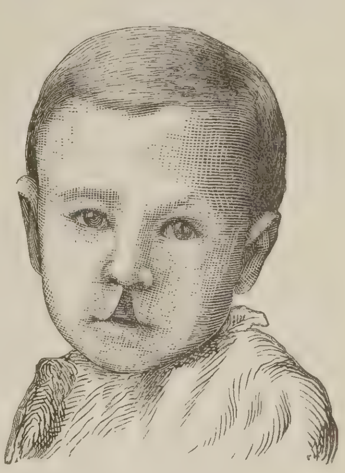

FIG. 2525.

In cases of double harelip I prefer to operate on one side at a time and to save all that is possible of the island or intermaxillary bone. In operating upon one side at a time, the first should be allowed to become firmly healed before we resort to the second operation. Ordinarily, this interval would amount to at least two months. I sometimes in these cases give to the skin covering the island the form of a square, and then, making flaps from the upper lip and cheeks on each side, secure a good, full lip, one which does not appear at all constricted. I am convinced that in doing the operation we should pare the edges of the fissure freely, but not throw the pieces away—that is, not finally detach them; therefore, I believe that the operation which embodies this principle is the best.

Operations upon the adult are exceedingly rare, and and are then generally performed for the purpose of improving an imperfect result following an early operation. In a few instances I have been obliged, for such a reason, to operate on an adult.

In operating for harelip we should in all cases be sure to loosen well the attachment of the cheek to the alveolar process; there should be perfect freedom of movement, and no restraint put upon the parts when the pins or sutures—whichever may be selected—have been introduced. This is generally best done with a long, blunt-pointed tenotome.

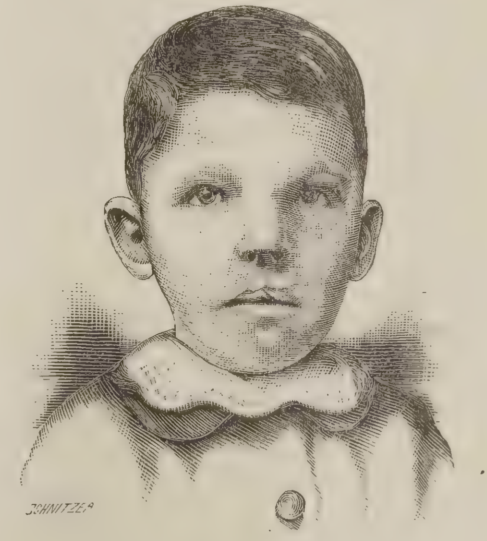

FIG. 2526.

---

* Mason: "On Harelip and Cleft Palate."

The position of the infant at the time of operating is a point of much importance. If the child is strong, I believe it safe and wise to give chloroform, or whatever anæsthetic the surgeon considers to be the best.

Having the child held by a good nurse or competent assistant—as is spoken of by so many writers—is often the easiest and best for the operator; but I am much in favor of placing the little one on a narrow, firm table of proper height, around which the assistants can work more at ease and not be in the way of each other. Standing on the right side of the table and patient, the operator proceeds to free or loosen the fissure on each side, as I have already stated. After this has been thoroughly done, he directs an assistant, opposite to him and at the head of the child, to grasp the left side of the fissure between the forefinger and thumb of his left hand, and then, with his right forefinger and thumb, to hold the right side in the same manner. The surgeon may now, with the so-called harelip forceps, or simple forceps, grasp one edge of the fissure, and, introducing a sharp-pointed narrow knife at the point of the cleft nearest the nose, carry the knife from above downward toward the vermilion border of the lip. He should then repeat the same steps on the other side, in each instance removing sufficient tissue to give good, broad surfaces for mutual contact. In a simple harelip I often pare the edges of the fissure with a strong pair of curved scissors (Fig. 1382, vol. III.). Thus far, if the assistant's thumbs and fingers are not too large, and if he performs his part well, but little blood will have been lost. I consider the compressors of the upper lip for controlling hemorrhage, spoken of by some authors, as really not necessary, but if they are to be employed I would recommend an instrument like that shown in Fig. 2527 (copied from Mason).

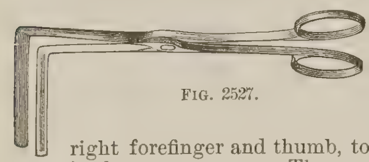

Fig. 2527.

The next step in the operation involves the closure of the fissure. It must ever be borne in mind that the vermilion border of the lip should be well preserved, with no sliding upward or downward on either side, and also that there ought not to be any notching.

As to the kind of suture that should be employed, I must say that my preference is for the silver harelip pins. In introducing them, I prefer that the first should be inserted nearest the vermilion border; it should be passed from the left to the right side of the fissure, and the greatest care should be exercised to bring the parts into good apposition. Of course, these steps may be modified or reversed if there is a single right-sided fissure, or if the surgeon stands in front of the child. Fig. 2528 (from Mason) illustrates my point. The pin should be introduced at least a quarter of an inch back from the freshened edge of the fissure, and it should pass obliquely through the edge of the lip, but should not include the mucous membrane; it should then enter the opposite side and emerge in the same manner. Now, around this pin put a figure-of-eight silk ligature, not too tight, as some allowance must be made for swelling. Then, next above this first pin, introduce in a similar manner one or two more, as may be needed. If two are used, it is well to bring them together by one ligature, crossing from one pin to the other, as by adopting this plan one is not likely to get so much of a slough—that and ulceration being the two great dangers associated with the employment of silver pins.

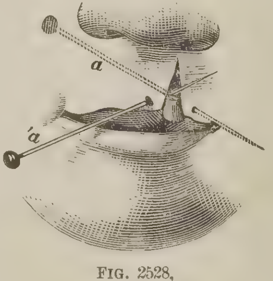

Fig. 2528.

Sometimes it is necessary to introduce between the pins a few fine superficial silk sutures, and also to place two or three in the mucous membrane and one in the vermilion border of the lip, not leaving them in for more than twenty-four or thirty-six hours. In the case of the mucous membrane I prefer to use fine catgut sutures, and I then leave them undisturbed.

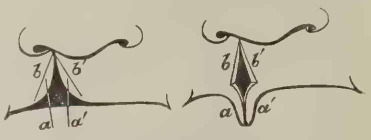

Fig. 2529.—Malgaigne's Operation.

After the pins have been introduced the points should be cut off with bone forceps, and a small portion of absorbent cotton should be put under each end. They are not to be left in longer than three days, as a rule, and should always be watched with care to prevent ulceration or sloughing. It is better to take them out too soon than to leave them in too long.

Some surgeons prefer simple silk, others silver wire; then, besides, many other devices have been suggested. I take it that few surgeons rely upon the rubber or adhesive plaster to hold the parts in apposition while the healing process goes on; but after the pins and sutures have been removed, in order to prevent too much tension on the newly formed tissue, I am in the habit of holding the parts well in apposition by placing narrow strips of plaster across from ear to ear. These hold the cheeks quiet and restrain the movements of the lips. Mr. Mason speaks of the use of collodion over pins and sutures. After the operation the child should be kept quiet by the use of anodynes, if necessary. He should be fed first with a spoon, and, when all is going well, after a few hours, or perhaps one, two, or three days, he should be allowed to nurse or take the bottle. Crying should be prevented as far as possible, and yet it is surprising to note how little harm it does.

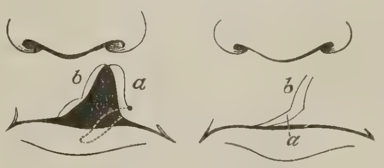

Fig. 2530.—Mirault's Operation.

It is clear that no one special kind of operation can be made to apply to every variety of harelip. Fortunately, we have a choice among numerous modes of procedure which practice has demonstrated to be successful. In the operation known as Malgaigne's, the incision is commenced at the superior part of the lip, and performed from above downward (Fig. 2529, left side, *b*, *b'*). Scissors are used as in ordinary operations, except that, when the operator has reached the lowest point possible without detaching the cut piece, he stops (Fig. 2529, left side, *a*, *a'*). The other side of the labial fissure is treated in the same way. There are then two small flaps each one of which adheres to the lip by a pedicle. After having reunited, by the aid of pins, the two margins of the cleft in their whole extent, except toward their free border (that is, toward the bottom), the surgeon should bring these flaps from above downward and should approximate them face to face (Fig. 2529, right side, *b*, *b'*). The point now is to adjust these flaps (partly by shortening them) in such a manner as to prevent the later development of a furrow. This result, which is so commonly dreaded by surgeons, may be prevented, at this stage of the operation, by preserving a piece varying in size according to the extent of the vacuum to be filled (Fig. 2529, right side, *a*, *a'*). Union is afterward effected by approxiating the parts with one or two interrupted sutures or with a fine harelip pin. If care is taken to place these uniting

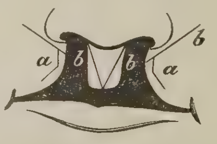

Fig. 2531.—Sédillot's Operation.

agents very near the free margin of the lip, the cicatrices will scarcely be visible.

M. Mirault, of Angers, employed one flap only. A flap is taken from above downward, but is left attached to the prolabium (Fig. 2530, left side, *a*); on the other side of the cleft the margin is completely removed (Fig. 2530, left side, *b*). The flap, *a*, is now turned down, and from being perpendicular, it becomes horizontal, and forms the margin of the lip (Fig. 2530, right side, *a* and *b*).

For double harelip Sédillot suggested a cheiloplastic operation. The sides of the central tubercles being pared, a flap of soft tissue is taken from each side, as shown in Fig. 2531. The flaps, *a*, *a*, are brought down to form the red margin of the lip, and the raw surfaces, *b*, *b*, then come in contact with the raw surfaces on the sides of the central tubercle, *b'*, *b'*.

Dr. A. M. Phelps, of Chateaugay, N. Y., in a paper read before the Medical Society of the State of New York, February, 1885 (see Transactions, p. 255), presented an operation for single harelip which contains some original and striking features.

The steps of the operation are these:

"After first passing a loop through each angle of the lip for the forefinger of the left hand to hold the parts perfectly, with a pair of curved scissors separate the lip from its attachment to the jaw sufficiently to freely relieve the nostril and make all parts easily movable. The mucous membrane should be freely divided in both directions. With an ordinary cataract knife, or a slender, sharp tenotome, puncture the lip at 1 (Fig. 2532), following the dotted lines describing a curve to 2, and from thence to 3. Withdraw the knife after going freely through each nostril at 3, and with a scalpel cut from 3 to 4 through the entire thickness of the lip. The pieces, *B* and *B*, will now turn downward, leaving the **V**-shaped piece as seen in Fig. 2533.

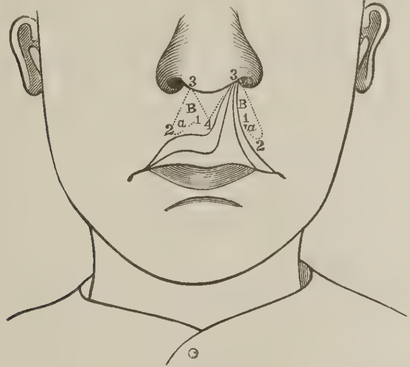

FIG. 2532.

"Now introduce the silk sutures as shown in Fig. 2533, after which cut away the pieces *B* and *B*, and the result will be shown in Fig. 2534. Before cutting away the pieces *B* and *B*, pull the lip up with them and stitch the mucous membrane together with catgut as far underneath as possible. Enough tissue should be left in the median line to compensate for retraction. The temptation is to cut the pieces *B* and *B* too short. It is better to cut them long, and, if necessary, trim them a little.

"The following are a few rules which it is well to observe:

"1. Select only those cases in which one-fourth of the lip, at least, remains between the fissure and the corner of the mouth.

"2. Each curved incision, 1, 2, and 3 (Fig. 2532), should be an equal distance from each corner of the mouth. The curves should be similar, and both should enter the nostril at the same point on each side. On the normal side the incision should enter the nostril near the columna, and but little or none of the nostril be cut away. When the deformed nostril is drawn to a normal position the incisions will then correspond. Fig. 2532 will convey the idea.

"3. The incisions from 3 to 4, making the **V**, should extend to fully one-half the breadth of the lip. If the **V** is made too short, difficulty will be experienced in getting the lip together. This would necessitate a more extensive division of the mucous membrane, or possibly the addition of transverse incisions extending outward into the cheeks under the corners of the nose.

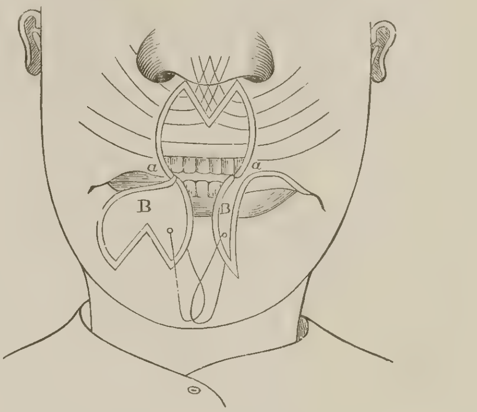

FIG. 2533.

"A fatal mistake would be to get the centre piece too long, as it would make a deformity. Cut it away to just the length to admit of the lip being stitched together, varying it according to the tension in each case, *making it as short as possible.* It would be much better to make the transverse incisions to relieve tension than to leave it too long, should a case not suitable for the operation be selected.

"The steps as followed in single harelip should also be followed in double, using the double curved incisions already described.

"The advantage of the double curved incision is this: When the pieces *B* and *B*, Fig. 2532, are turned downward, the curve at *a*, *a*, becomes straight, and when joined to its fellow of the opposite side, adds just so much to the width of the lip, at a point where it is desired, as the distance is from 1 to 2, Fig. 2532. The widening of the lip at this point, and the curving downward of the white line above the vermilion border of the lip into the point, is what lends the artistic appearance to the lip." An artistic lip and a scar in the median line are the strong points which characterize this operation.

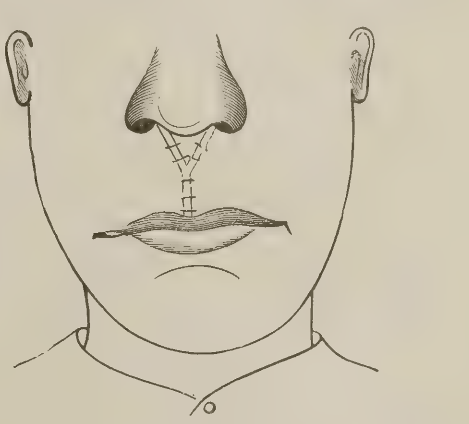

FIG. 2534.

Dr. M. H. Collis,[2] of Dublin, says: "I never throw away a particle of the parings. My incisions are made so as to make every fragment of them useful. On one side they are preserved to make the lip thick, and on the other to increase its depth. The method is somewhat complex, but a reference to the accompanying figures will make it intelligible (Fig. 2535). When dealing with single harelip, I take the larger portion, that which includes the middle bit, and pare it freely from the nostril round the margin from *a* to *b*, until the point of the knife comes opposite the frænum. The incision goes through all the tissues of the lip *except* the mucous membrane. It follows the curved line of the margin of the fissure, and leaves a long wound, which is curved toward the fissure. The flap is left loose and attached only by mucous membrane. On the other or smaller side of the lip, where we generally find the tissues thin, especially as we approach the nostril, the treatment is quite different. I transfix the lip at *d*, close to the nostril, and carrying the knife along parallel to the margin as far as *f*, I detach a moderately broad flap, which I leave adherent above to the ala nasi, and below to the free margin of the lip, well beyond or external to the rounded angle at the fissure. This flap, which (unlike the one at the opposite side) comprises *all* the tissues of the lip, is now divided into two at its centre (*c*, *e*). I thus get two loose flaps, a superior (*c*, *d*), attached to the ala nasi, and an inferior (*e*, *f*), hanging on to the free margin of the lip. The loose end of the upper flap is turned up so that its raw surface faces the wound in the opposite side of the fissure, and the lower end of the lower flap is similarly turned down. The point *c* is brought up to *a*, and fastened there. The point *e* is brought down to *b*, and fastened there. I have thus got on the small side of the lip a wound as extensive as that on the larger side. The upper flap completes the outline of the nostril. The lower one supplements the outline of the free margin of the lip. I thus get a lip nearly double in depth any which I could possibly have got by the ordinary incisions."

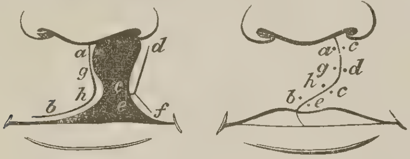

FIG. 2535.—Collis' Operation.

Mr. Thomas Smith recommends an operation which is useful in suitable cases of double harelip. According to his plan the lateral sides are to be pared in the manner shown in Fig. 2536, *a′ a*, and two flaps are to be taken from the central tubercle, but are not to be detached at their lower margins. "The wound is closed by drawing down the flaps from the side of the central tubercle, and attaching them to the raw surface on the lower margin of the lip."

The condition of the infant before operating should be as good as possible. There should be no unfortunate surroundings, especially as regards diphtheria and allied conditions, nor should the operation be done in hot weather, or at any time in the year when epidemics of any kind peculiar to children are prevailing.

As a general rule, one operation is all that is needed, but sometimes failure occurs, and in this we ought not to be discouraged, but, as soon as the child has sufficiently improved, we should try again.

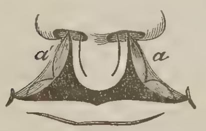

FIG. 2536.—T. Smith's Operation.

Regarding Hainsby's truss, I have had but little experience in its use, and must say that it requires great care, and is apt to annoy the child.

As to a second operation, years after the first, to relieve an unsightly scar or depression in the vermilion border of the lip, I am much in favor of its performance, especially in females.

Albert Vander Veer.

[2] *Ibid.*

HARRIS LITHIA SPRINGS.—Laurens County, South Carolina.

POST-OFFICE.—Harris Springs. Hotel and Cottages.

ACCESS.—Viâ Georgia, Carolina, and Northern Railroad (Seaboard Air Line) to Cross Hill; thence two and one-half miles to springs. Or, viâ Port Royal and Western Carolina Railroad to Waterloo, and thence two miles to springs. These springs are located in a hilly country, and are open for the reception of visitors during June, July, August, and September. They are two in number, known respectively as the "Lithia" and the "Sulphur" Springs. They flow about sixty gallons per hour each. The following analysis was made by Prof. R. Ogden Doremus, of New York, in 1891:

ONE UNITED STATES GALLON CONTAINS:

Solids.	Grains.
Calcium sulphate	83.38
Potassium sulphate	.51
Sodium sulphate	.58
Sodium chloride	.76
Sodium bicarbonate	2.42
Lithium bicarbonate	2.32
Magnesium bicarbonate	3.04
Iron bicarbonate	.32
Silica	2.51
Phosphoric acid	Trace.
Loss on ignition	15.84
Total.	111.68
Total dried residue at 266° F.	98.57
Carbonic acid in bicarbonates	3.35
Total solids per United States gallon	101.92

The combination of mineral ingredients shown in this analysis would suggest a very useful water. It is highly effervescent and agreeable to the taste. It is therefore useful for the table, and mixes well with wines. It is a speedy corrector of acidity to the stomach. It is said that the water causes a notable reduction of sugar in the urine in diabetes mellitus. It also overcomes constipation, and is useful in rheumatism, uric-acid gravel, calculi, etc. The water has an extensive sale.

James K. Crook.

HARRISON HOT SPRINGS.

LOCATION.—British Columbia.

POST-OFFICE.—Harrison Hot Springs. Hotels: St. Alice and Bath.

ACCESS.—By Canadian Pacific Railway to Agassiz, thence by stage.

ANALYSIS FROM THE LABORATORY OF THE GEOLOGICAL SURVEY OF CANADA.

Silica	Trace.	Trace.
Organic matter	......	Trace.
Grains, per imperial gallon, at 60° F	91.960	82.327

These springs are situated on the western slope of the Rocky Mountains, sixty miles from Vancouver. The hotels are excellent and provide every comfort for the tourist or invalid. The baths are well arranged and a doctor and skilled attendants reside at the sanitarium. The climate is mild during the entire year, the thermometer seldom going below the freezing point, and the variations are never extreme. The hotel is situated on Harrison Lake and is surrounded by snow-capped mountains. The scenery is beautiful and the finest fishing and shooting are to be obtained in the neighborhood.

Beaumont Small.

HASTINGS AND ST. LEONARD'S, ENGLAND.—These two places, virtually one town of about 50,000 inhabitants, are situated sixty-two miles southeast of London on the coast. Their claim as a health resort is based upon the mildness of their winter climate, which renders them a comparatively favorable residence for those of feeble vitality, and for sufferers from chronic bronchitis or other form of "mucous membrane delicacy."

The front of the town looks toward the South and the open sea, and an esplanade three miles in length extends along the shore. In the rear are downs which afford shelter from the northerly winds. The country about is picturesque, affording many attractive excursions; there are also various public parks and gardens. Roundabout are hills broken by numerous valleys, thus offering some variety of climate. The soil is more or less sandy, through which the rain water rapidly escapes.

The mean average temperature for the four seasons is as follows: Spring, 45.9° F.; summer, 59.9° F.; autumn, 51.5° F.; winter, 39.9° F.; for year, 49.9° F.

The mean daily range is 10.4°.

The day temperature averages 54.6° F., and the night temperature 44.2° F. The mean relative humidity is 84 per cent. for the year.

The most prevalent winds are from the west and southwest. The average rainfall is 29.95 inches per annum, falling on an average of one hundred and eighty-three days.

The mean amount of bright sunshine (average for eight years) is 1,699.9 hours, or 4.6 hours per day; the least amount is during the winter months.

Sea fogs are not infrequent but do not last long; land fogs are rare. The sea front enjoys the mildest winter climate, on account of its southerly exposure and shelter from the northerly winds; it is therefore the place of residence for the invalid, in winter. The mildness of the winter climate is indicated by the various plants and shrubs which flourish during that season, such as the arbutus, primrose, hepatica, violet, and hydrangea. The drainage is good, and the water supply abundant and of good quality. Along the esplanade before mentioned are hotels, lodging houses, private residences, and shops. In the spring the east winds begin to blow, and these are often "searching," but are somewhat mitigated by the bright sunshine.

Mildness and equability, with protection from northerly winds and a comparatively large amount of sunshine, are the characteristics of this climate from which these towns have derived their popularity as a winter health resort.

The southwest wind which is the prevalent one, except in the spring, is said to render the climate somewhat relaxing.

Patients affected with various maladies frequent this resort; phthisis, chronic bronchitis, convalescence from acute renal diseases, scrofula and anæmia are the principal diseases which are benefited by this climate. Very many phthisical patients are reported as doing well under its influence.

"The long, sunny parade, sheltered from northerly winds, offers facilities for outdoor exercise. Many persons have found that they can pass the winter at least as well here as in Southern Continental health resorts. This is especially the case when the patients can be induced to admit fresh air into their rooms freely both day and night. The 'fresh-air cure' is more practicable in a South of England seaside resort than inland, where the night air is damper and more chilly." ("Climates and Baths of Great Britain," 1895.)

"The contraindications, beyond those which apply to marine stations in general, are singularly few."

Edward O. Otis.

HAWAII.—The Territory of Hawaii, United States of America, consists of twenty islands in the mid-Pacific ocean between north latitudes 18° and 30°, and west (Greenwich) longitudes 154° and 172°. The islands comprising this territory are: Hawaii, Maui, Oahu, Kauai, Molokai, Lanai, Kahoolawe, Niihau, Molokini, Lehua, Kaula, Bird, Necker, Johnson, Laysan, Lysiauski, Ocean, Midway, French Frigate Shoal, and Pearl Reef. The eight first-named islands are inhabited permanently, and constitute the ones usually comprehended as the Hawaiian or Sandwich group. (Three of the eight, Niihau, Lanai, and Kahoolawe, are, however, nothing more than cattle ranches.) The remaining twelve are small islets, little more than rocks or coral reefs, and uninhabited except at such times as they are visited by workmen of guano companies collecting the eggs and the manure of the innumerable sea birds and turtles making these spots their homes. The areas of the eight major islands are:

	Square miles.		Square miles.
Hawaii	4,015	Molokai	310
Maui	760	Lanai	160
Oahu	600	Niihau	97
Kauai	590	Kahoolawe	69

Honolulu, the capital of the Territory, in Oahu is 2,100 miles from San Francisco, 3,810 miles from Auckland, 3,440 miles from Yokohoma, 2,380 miles from Tahiti, and about 4,000 miles from Manila.

History.—The islands were visited by some Spanish navigators as early as 1542, and two Spanish ships were wrecked on them probably in 1527. The actual, that is, useful, discovery of the islands was made by Captain Cook in 1778, who gave them the name of Sandwich in honor of the first lord of the British Admiralty at the time. Hawaii, the native name of the largest member of the group, has, however, been the one generally applied to the archipelago, and is now the legal name of the Territory. At the time of Cook's discovery the different islands were governed by one or more independent chiefs. Shortly thereafter Kamehameha, a chief of Hawaii, subjugated the other chiefs, and established the kingdom of Hawaii, which remained with some vicissitudes an independent government till 1893. Liliuokalani, who succeeded her brother King Kalakua, in 1891, having manifested an intention to change the existing constitution, provoked a revolution, January, 1893, in which she was deposed. A provisional republic was proclaimed and negotiations were begun looking to the final annexation of the islands to the United States. A republic was formed in 1894, and negotiations continued. After some delay, caused by changes in the political ascendencies in the United States, the islands were finally admitted into the Union as the Territory of Hawaii. The annexation took place formally August 12th, 1898.

Population.—Captain Cook estimated the native population as 400,000 inhabitants, an estimate undoubtedly too great. The first census, taken in 1823, showed 130,313 natives. According to the census of 1878 these had decreased to 44,088. A census of the islands in 1896 gave a total population of 109,020 inhabitants, composed as follows:

Native Hawaiians	31,019	Americans	3,086
Mixed Hawaiians	8,485	English	2,250
Japanese	24,407	Germans	1,534
Chinese	21,616	Other nationalities	1,420
Portuguese	15,191		

The present outlook is the gradual extinction of the native Hawaiian race. The decrease in native population gave great concern to the original government and strenuous efforts were made to check it, but without avail. In general appearance the natives are fine specimens of physical development; the women, however, are not fruitful, and few families are found with as many as three children. The original islanders belong to the widely scattered Malayo-Polynesian family. Although more than 3,000 miles of ocean intervene, Hawaiians and the Maoris of New Zealand can readily understand each other's speech. Cannibalism, idolatry, and human sacrifices were practised at the time of discovery, though the cannibalism was only moderate, and to some extent a part of the religion. The religious adhesions of the present population are almost as diverse as the races are polyglot. The census of 1896 gave Roman Catholics 26,363, Protestants 23,773, Mormons 4,886, Buddhists, Confucians, and other Oriental sects 44,306, unknown 10,192. Notwithstanding the recent influx of foreigners due to political changes, the condition of population offers material for serious consideration. Agriculture is the industry of the islands, and laborers are imperatively needed in agriculture. The larger part of the arable land of the archipelago is devoted to sugar production and the conditions under which this industry is practised at present discourage a peasant proprietorship of the land. Without such proprietorship there can be little hope of a permanent population. There are at present a total of about one hundred miles of railroad in operation. Most of the important points on the larger islands are connected by telephone or telegraph. Oahu and Hawaii are connected by submarine cable, and it is not improbable that by the time this article is in print a cable will be in construction to join San Francisco and Honolulu. The valuation in 1900 of the imports into the United States was $20,707,903, and of the exports from the United States to the islands, $13,509,148. The facilities and conveniences of living in Honolulu and Hilo, the chief towns, are the same as those in like cities of the United States. The cost of living is, since annexation, however, higher, largely due to the servant question. The Chinese constitute the chief source from which this element is drawn, and since annexation they are excluded from the islands as from all other parts of the Union.

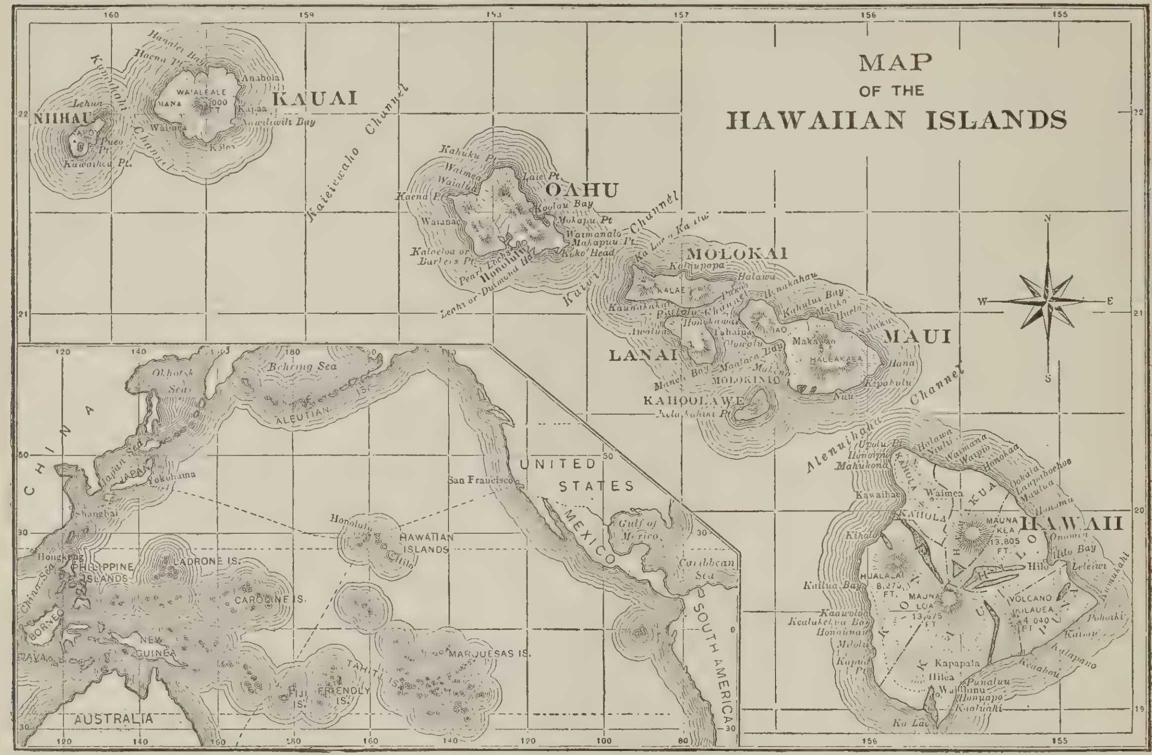

FIG. 2537.

Geography and Geology.—The Hawaiian Islands are of volcanic origin. They rise from the general level of the ocean bottom to the surface a distance of 14,000 to 19,000 feet. This rise is so abrupt that this great depth of water is found from 30 to 50 miles from shore. Above sea level the islands attain elevations that in many places rival the heights of the Alps. The coast line is in places low, in others it rises often sheer 2,000 feet. The following tabular view shows the chief elevations.

Islands.	Name of mountain peak.	Height above sea, feet.
Hawaii	Mauna Kea	13,805
Hawaii	Mauna Loa	13,675
Hawaii	Hualalai	8,275
Hawaii	Kilauea	4,040
Hawaii	Kohala mountains	5,000
Maui	Haleakala	10,032
Maui	Eeka	5,820
Kahoolawe	(Highest point)	1,130
Lanai	(Highest point)	3,000
Molokai	(Highest point)	3,500
Oahu	Kaula	4,060
Kauai	Waialeale	5,000

Geologically, Hawaii is the most recent and Kauai the eldest of the group; the islands increasing in age from the southeast to the northwest. Kauai from its greater age has the best weathered soil, and by its inhabitants is proudly called the garden island. The soil of the islands is weathered lava. It is extremely porous. Two general classes are recognized, dark red soil, from simple weathering, and light red and yellow soils from weathering plus the action of imprisoned sulphurous and other gases. The dark red is the better and more durable agricultural soil. The light red and yellow soils require careful cultivation. But few minerals are found. Sulphur, pyrites, copperas, sal ammoniac, common salt, and a few others are the chief ones. Hawaii has the only active volcano, the world-renowned crater Kilauea. The summit of Mauna Loa has a crater, Mokuaweoweo, occasionally active. From Hilo, the chief town of the island, a good road, thirty miles in extent, runs to Kilauea. Haleakala, in Maui, is an extinct crater, the largest known in the world. Although more than 10,000 feet high, so gentle is the slope that it can be ascended to the top on horseback. Most of the other mountains of the islands are more or less easily rising slopes, and mountaineering is not arduous.

Flora and fauna. The mere enumeration of the varieties of flora on the islands would exceed the length of this article. Hillebrand, in his "Flora of the Hawaiian Islands," names 999 species and 365 genera, and many others have been introduced since his book was published. "The variation in the climatic conditions due to altitude and location . . . together with the arable soil at all altitudes, justify the belief and warrant the assertion that almost every tropical and temperate plant can somewhere be grown successfully on this island" [Hawaii] (Dr. W. C. Stubbs, "Report on the Agricultural Resources, etc, Hawaii," Washington, 1901). Over seventy species of birds, mostly water fowls, have been enumerated. Captain Cook found hogs, dogs, domestic hens, and rats, on the island, also a day-flying bat. Cattle, goats, and hogs, escaped from domestication, run wild (goats were introduced by Vancouver in 1792) and have damaged the forests incalculably.

Climate.—The Hawaiian Islands are climatically within the sea level isotherms of 70° and 75° F. The average sea-level temperature of the group is 4° to 6° lower than the calculated average of the latitude (see table, article *Climate*). The distinguishing characteristic of Hawaiian climate, compared with that of other tropic islands, is the combination, in its temperature, of mildness and equability. There are many other tropic islands that have great or even greater equability of temperature, but they lack in greater or less degree the other element of mildness so pronounced in the perpetual, pleasant summer of the Hawaiian archipelago. The following table shows the temperature of Honolulu compared with that of some other insular localities in or near the tropics.

	AVERAGE TEMPERATURE OF—		
	Year.	Warmest month.	Coldest month.
Honolulu	74° F.	78° F.	70° F.
Praia, Cape Verde Islands	76	80	72
Las Palmas, Canary Islands	70	75	65
Bermuda	70	80	63
Nassau, W. I	77	82	72
San Juan, Porto Rico	81	84	76
Saint Helena	71	76	68
Mauritius	74	79	69
Tahiti	77	80	74
Levuka, Fiji Islands	78	82	75
Réunion	74	79	70

The average temperature and rainfall at Honolulu are:

	Temperature.	Rainfall (inches).
January	70	3.5
February	71	6.0
March	71	3.3
April	73	3.0
May	74	3.0
June	76	1.6
July	77	1.8
August	78	2.0
September	78	2.0
October	76	2.5
November	74	5.5
December	72	4.7
Year	74	38.4

The temperature seldom, if ever, rises to 90° F. According to C. J. Lyons, the territorial meteorologist, a temperature of 90° is to be regarded with suspicion, and a monthly mean of 80° calls for inspection. The average daily difference between the highest and lowest temperatures at or near sea level is from 10° to 14° according to the season of the year. The temperature of a particular locality will depend upon the elevation of the place. Owing to the small land areas of the different islands the rate of decrease in temperature due to altitude is practically that found in ascending in the free air, namely 1° F. for every 300 feet vertical ascent. The altitudes of some of the mountain peaks of the islands place their summits within the limits of perpetual snow. The crests of Mauna Kea and Mauna Loa are seldom entirely free of snow. The rainfall of the islands follows the regimen of tropical islands similarly situated with respect to the prevailing winds. The key to the rainfall is altitude and the prevailing winds of the region and the season. The rainfall is plentiful wherever the land rises sufficiently to be a barrier to the winds of the region. At sea level the rainfall is relatively small, but it increases rapidly with elevation up to 6,000 feet, and then decreases. From the orography of the islands the greatest variety of rainfall distribution is observed. On Hawaii the average annual rainfall varies from 140 inches at Hilo on the east coast to less than 30 inches on the west coast. On Oahu a more striking difference is observed. At Honolulu, 50 feet above sea level, the average annual fall is 38 inches, while about 15 miles east, at Nuuanu, 850 feet above the sea, the average is 132 inches, and less than 25 miles west, in a sheltered valley, the rainfall is only 15 inches. Even on the same plantation, the rainfall on one part will be abundant for the most luxuriant tropical growth and on the other part irrigation will be necessary to grow an ordinary crop. The porosity of the soil is, as already stated, great, so that notwithstanding the torrential downpours that occur on the elevated lands, the soil remains free from dampness. The water runs through it with great rapidity. The average relative humidity of the islands is about 75 per cent. of saturation, varying somewhat with the direction of the wind. It is greater with southerly and less with northerly winds. The prevailing winds of the archipelago are the northeast trades. For nine months, March to November, they blow with almost unfailing regularity. During the other three months the islands are more or less under the influence of the southwest antitrades. These antitrades are the disagreeable winds of the islands. It is only during their prevalence that the sultriness and oppressiveness of the tropics become manifest.

Health.—Statistics as to the prevailing diseases of the islands are not plentiful. Leprosy, an imported disease, is now endemic among the natives. Great care, however, is taken to prevent its ravages and stamp it out. The government years ago established a leper colony on the high table-land of Molokai, and hither all afflicted are sent and carefully cared for.

Among the causes of death given in a recent report for the city of Honolulu, phthisis claimed more than 10 per cent.; old age and heart disease about 7 and 6 per cent. respectively. Among other causes enumerated were pneumonia, bronchitis, diarrhœa, and paralysis.

W. F. R. Phillips.

HAW, BLACK. See *Viburnum Prunifolium.*

HAY FEVER is the popular title for an annually recurring affection which involves the mucous membranes of the ocular and respiratory tracts and is associated with certain symptoms which can be accounted for only by reference to the nervous system. It, or a very closely allied disorder, occurring during the early summer in England, was first described by Bostock in the Medico-Chirurgical Transactions for 1819, under the name of *Catarrhus Æstivus;* and in his work upon the affection now treated of, Dr. Wyman advocates the use of the term *autumnal catarrh* as more correct, and not involving the absurdity of associating a disease with an impossible cause—for the season of hay-making, in the United States at least, is long past before hay fever makes its appearance. But the title has become so embedded in the popular mind that there seems to be no escape from what is indisputably a misnomer. Basing the suggestion upon the view that the affection depends upon engorgement of the nasal mucous membrane, with associated reflex nervous symptoms, Mackenzie, of Baltimore, has proposed as a new name *coryza vasomotoria periodica*, which has the advantage of accuracy at least.

The peculiarity of the affection is its annual recurrence, in the same individuals, with almost ludicrous exactness in point of time, throughout, in many instances, the years of a long life. Thus an examination of the narratives of their cases, written by those who suffer from *hay fever*, will reveal the fact that the attack occurs upon the same day, or even the same hour of the day, in each year, and in none is there a variation of more than a few days. This regularity of return is apparently but little affected by the peculiarity of one year as compared with another. Whether the season is wet or dry, whether as a consequence vegetation is rankly growing or falling into decay, appears to make no difference. Another singular fact is that the sufferer from this disease in Philadelphia or Baltimore may rest assured that, at the precise time he begins to feel the approach of his enemy, his fellow-sufferer in a place as far removed geographically as Boston is subject to attack at the same time, though his climatic surroundings are quite modified.

The attacks are, however, not of similar severity each year, but will vary somewhat. Why this should be so it is hard to determine; but it has been observed that when, as in 1885, there is a prolonged drought in the early summer, succeeded by heavy rains leading to a revival of vegetable growth in the month of August, the season is likely to be a bad one for sufferers from autumnal catarrh.

Age appears to have nothing to do with this affection, some persons experiencing their first attack as early as in their third or fourth year, while others escape the formation of so undesirable an acquaintance until quite mature life. It is a curious fact, revealed by an examination of Dr. Wyman's table of eighty-one cases, that males are more likely to be sufferers in early life than females; which is in accordance with the observation of the writer, although there is no particular significance in it, so far as his knowledge goes.

Another peculiarity of this disease, and one which has been noticed by many observers, is its greater prevalence among those who are not compelled to resort to manual labor for a livelihood. Not that it does not occur in this latter class, for some such are recorded by Wyman, and many have fallen under the observation of the writer of this article and others; but that it is of comparatively rare occurrence among the laboring classes is a patent fact. The writer's experience leads him, however, to think that this difference is becoming less marked of late years, and that not only is the aggregate number of cases increasing, but that periodical catarrh is extending among classes which were at one time in a great degree exempt from its visits.

Having now referred to some of the peculiarities of this troublesome affection, I may next proceed to a description of its *symptoms* and *course*, as ordinarily observed.

About the middle of August the patient experiences itching of the eyes and pharynx, which at times is intense, and is accompanied by most inordinate and frequent sneezing. The irritation of the eyes and throat appears to be without cause, but the sneezing seems to be provoked by bright light, cool currents of air, or some exposure to the causes which ordinarily are regarded as provocative of catarrh. At first these attacks are infrequent and of moderate severity, but they soon become more severe and more frequent. On first getting up in the morning, while dressing, and often during breakfast, the attacks of sneezing are prolonged, and altogether unaccompanied with the grateful sense of relief which in other circumstances is experienced in connection with this manifestation. Every exertion increases these symptoms, and there accompanies them that general feeling of discomfort, with slight acceleration of pulse, which have earned for the disease the misnomer of hay fever; yet there is no record showing the existence of a higher temperature. The amount and severity of these symptoms will vary somewhat with different years, but they will always exceed in both respects those observed in ordinary coryzas.

Usually symptoms of bronchial irritation manifest themselves in about a week, and dryness and injection of the fauces are followed by a tickling cough, accompanied with but little expectoration. After a time the cough becomes more severe, paroxysmal in character, and is often accompanied with much soreness in the chest, which is somewhat relieved when expectoration is established. Like the coryza, the bronchitis varies much in intensity in different individuals, and somewhat in the same persons in different years. In some it does not exceed in severity that attending a mild cold, in others it becomes a most serious affection, and is occasionally accompanied by expectoration of mucus streaked with blood. The observation of the writer, however, has not brought him in contact with a case in which true pneumonic sputa were present, although he is familiar with one in which the expectoration has on two occasions very nearly approached that character. The physical signs on auscultation are those of bronchitis.

In many cases, after a most harassing experience extending over ten days or two weeks, both the coryza and the cough lessen in severity. The former almost entirely disappears, and while the latter may persist as a most exasperating tickling, especially at night, convalescence passes into complete recovery, the whole course of the disease having lasted for from three to four weeks.

But in the vast majority of cases the advent of the cough is accompanied by asthmatic symptoms of more or less severity, and in very many these symptoms cause everything else to appear as insignificant. Indeed, more severe asthma than accompanies some cases of autumnal catarrh is rarely, if ever, seen.

The first asthmatic symptoms generally appear about the 25th of August, and are often brought on by a spell of coughing, some unusual exertion, or in many cases by the change of wind accompanying a thunder-storm. From the time of their first appearance these symptoms do not entirely disappear until the conclusion of the annual attack, which is ordinarily about the end of September, although in some cases prolonged until a later date. All the time there is more or less difficulty of breathing, accompanied with true asthmatic râles. Upon percussion the chest is more than usually resonant, showing the existence of at least a temporary emphysema; but upon applying the ear to its parietes, it is found to be filled with dry cooing and sibilant murmurs, reminding the listener of nothing so much as "a bag of whistles." Indeed, these sounds are generally readily perceptible at a considerable distance, and become more marked at the approach of a paroxysm.

Than a severe paroxysm of dyspnœa, such as is frequently seen in these cases, there is scarcely anything harder to bear or more painful to witness. The approach of the attack is signalled by an increase in the loudness of the chest murmurs, and by increased difficulty of breathing. The patient cannot lie down, and, indeed, very soon cannot lean back in his chair. Sitting or standing, the patient will seek a firm surface on which to lean, and planting his elbows firmly upon it for support, will gasp for breath. The sonorous chest sounds lessen, the inspiration becomes comparatively lengthened, and the expiration much hurried. The collar will be unbuttoned, the face assume a yearning and almost despairing expression, the eyes be suffused and tearful, while the efforts of the arms, shoulders, and all of the muscles accessory to respiration are most severe and accompanied with a very copious perspiration. The sense of fatigue is extreme, and to the expression of anxiety is added one of intense weariness; but the efforts are unrelaxed, for, though wellnigh useless, they are involuntary and cannot be lessened by any effort of the will. No sounds whatever come from the chest, and while the patient feels as if he was breathing in vacuo, the inexperienced spectator will think that actual suffocation is impending. If not interfered with this state of things may last for from a few minutes to several hours. Gradually there will be a return of wheezing noises in the chest, the respiration will become somewhat less shallow, and the sense of suffocation less acute; and if the improvement continues the expression of relief becomes marked upon the face, and the sufferer drops into sleep without much reference to the position he occupies.

But the relief experienced is very generally only partial, and the respiration continues laborious and oppressed, while exercise or any physical effort is impossible without immediate aggravation of the symptoms. This state of things continues until the end of the season, though lessening gradually with the diminution of the bronchitis and the disappearance of the cough. The writer has known this asthmatic period to last for from three to six weeks, during which time the patient could not go up and down stairs, could not sleep at all without the aid of anodynes, nor indulge in the slightest dietary indiscretion. The eating of large amounts of food late in the day, or of indigestible food at any time, is likely to bring on an acute paroxysm, and the same result is very apt to follow a prolonged spell of coughing. Very often sleep can be obtained only in the upright position, either in a chair or propped up in bed with a large number of pillows.

In many cases of periodical catarrh the asthmatic symptoms never attain the severity of those which have been described, but they are present in a more or less modified form in the majority of instances, especially at night. As has been said, when the asthma is a marked feature in the individual cases it overshadows all other symptoms, and we shall not obtain the vividly thrilling descriptions of the sufferings from catarrh, which encumber books upon this special topic, from those who have severe asthma. They will express themselves as quite ready to bear the annoyances of the most violent coryza and the most irritating cough, if they can only secure immunity from the dyspnœa and orthopnœa which they have learned to dread.

After the middle of September there is a gradual declination in the severity of all the symptoms, and by the end of the month they have in great measure disappeared, though in the severer cases there may remain a tickling cough and the liability to attacks of oppression to a much later date. Indeed, it would seem, in the more severe cases, and especially in those which suffer much from asthma, as if there was a tendency to a gradual prolongation of the after-period, so that throughout the winter any severe cold is liable to be complicated with asthmatic symptoms. That this should be the case is quite natural in view of the causal relation existing between asthma and true emphysema. Yet permanent emphysema is rarely present, probably owing to the shortness of the attacks, and to the fact that most patients enjoy a sufficiently long period of health between them to prevent organic changes taking place in the elastic lung tissue.

Observation has convinced the writer of this article that the recurrence of these attacks, unmodified by effective treatment, tends to fasten the habit more firmly upon the system, as well as to increase the length of the after-period. His experience has taught him that if the season is anticipated by a suitable change of residence, and the severity of the attacks modified by appropriate treatment, the force of the annual habit is lessened, and while it may not be entirely obliterated, the acuteness of the periodical attacks will be diminished. It is this fact which leads him to urge careful attention to those cases which occur in children, as in them there is more hope of being able to attain good and permanent results. As a general thing, the first attacks are less severe than the succeeding ones, and there would seem to be more encouragement to expect good results by prompt and *early* treatment.

When we come to consider the *nature* and cause of this curious affection we enter upon a wide field, and one upon which most conflicting theories contend. That this should be the case is natural from the absence hitherto of any researches throwing much light upon any anatomical peculiarities pertaining to the affection. That there are such peculiarities, however, at any rate associated with it, cannot be doubted in the face of the observations recently made by such authors as Harrison Allen, J. N. Mackenzie, Sajous, and others; but it is as yet too early to conclude with certainty that these anatomical peculiarities are undoubtedly the cause of the affection under consideration. According to these observers the subjects of "hay fever" are all alike in presenting certain peculiarities in the anatomy of their nasal cavities. According to Harrison Allen, the nostrils are obstructed by deflection of the septum, hypertrophy of the soft parts and bones, or turgescence of the mucous membrane, and always an undue prominence of the inferior turbinated bone. J. N. Mackenzie, Roe, Daly, Hack, and Sajous hold that there exist in these cases both an unusual development and an unusual excitability of the mucous membrane covering a well-defined sensitive area, which is known to be coterminous with the inferior turbinated bone. According to these observers the symptoms of periodical catarrh are reflexes induced by irritation of this area, in cases which possess at the same time abnormal vaso-motor excitability, and hence J. N. Mackenzie proposes the name of coryza vasomotoria periodica for the disease.

The theory of these gentlemen, though revolutionary in character, has much to recommend it, and is found to be in strict accord with many of the observed facts in these cases. Yet in some respects it is not altogether satisfactory, especially when the question of periodicity is considered, or when regard is had to effects often noticed when a change of climate, or rather of place, is resorted to. Thus it is difficult to see how turgescence of the erectile tissue over the turbinated bone should occur, or, at any rate, produce serious effects, only at one season of the year. Then it is certainly going too far to account for the benefit secured at certain seashore places simply by the tonic effects of the sea air upon the nervous system, and to point to the well-established fact that a land breeze is injurious, and claim that it is so only so far as it is relaxing and enervating. At every place on the seashore there are alternating sea and land breezes; yet relief from autumnal catarrh is experienced at but few of them, and those that experience has proved to be suitable places of resort are such as by their topography receive no breeze from the land until it has passed over a considerable expanse of water.

But these observers, while maintaining the anatomical and nervous basis of the disease, do not deny that pollen may be one source of irritation among many others, and even should the theory they propose not be at present reconcilable with all the facts in any given case, it is reasonable to anticipate that further observation and closer study may tend to complete elucidation of it. Hitherto there has been nothing more definite than the supposition that the affection was produced by one or more kinds of pollen acting upon a personal idiosyncrasy —the latter term, of course, being only a convenient expression to cloak ignorance. This theory has been upheld by the majority of writers in the past, and is still contended for by Morell Mackenzie, Blackley, and many others. According to these writers, at a given season there is a large amount of pollen grains afloat in the atmosphere, which serve as the exciting cause, in cases possessing that personal peculiarity or idiosyncrasy wherein lies the true essential characteristic of the disease. When tested by experience the theory is found to fit in almost every particular.

That there is some peculiar atmospheric condition present only at a given season would seem to be proven by the fact that in the vast majority of cases there is an entire absence of symptoms at all other times. That this condition is imparted from the vegetable kingdom would seem proven, because almost all cases are benefited by a residence, during the time, either at certain places among the mountains, at certain seashore resorts separated from the mainland, where there is little vegetation, or most certainly during a sea voyage. The malign influence of vegetable exhalations in these cases receives support also from the well-known fact that the kindred affection known as "rose-cold" seems to be largely dependent upon such irritants. The writer is acquainted with one gentleman who suffers acutely in September, but is perfectly well in June. His mother-in-law, for very many years and until her death, suffered in precisely the same way, and was also well all the early summer. They were both relieved by removing to Beach Haven, on an island off the New Jersey coast only six miles distant from the home of the mother-in-law. In this coincidence there is, of course, nothing peculiar; but two of the brothers of the gentleman mentioned, with his wife and sister-in-law, have been severe sufferers from acute coryza in June, and are all quite well in September. We have here a group of six cases, five of whom would be properly described as very far removed from the category of nervous persons, who have for many years suffered periodically, in all of whom relief is, at least, associated with the comparative absence of vegetable influences. Of the June cases, two were always better in town, and the attack was not so severe as to require other measures of relief; one is free from attack at Beach Haven; while the fourth, whose attacks are the slightest, gets comfort by keeping most of the time in the house. In none of the June cases is asthma present; but all have noticed great aggravation of their symptoms when exposed to various kinds of pollen, notably that of the horse-chestnut, the ailanthus, and the scented honeysuckle. In one of the June cases, and in one of the September cases, prominence of the inferior turbinated bone has been noted.

The object in citing these cases is not to bolster up the old and exclusive pollen theory, but to submit them merely as cases which show the difficulty which presents itself to any one who attempts a close and exclusive definition which will suit all cases.

Advocates of the purely nervous and anatomical theories maintain that their theory is supported by the results of treatment, and this will be spoken of more at length in its proper place; but the claim is as yet not fully substantiated, and quite a number who have undergone local and tonic treatment are known still to suffer from their old enemy. Whether this will continue to be true when they have undergone a *sufficient* number of applications to the nasal mucous membrane remains to be seen, but it is not as yet proved. It is still *sub judice*, and is subject in some measure to the well-known disposition—or idiosyncrasy shall we call it—possessed by many hay-fever patients, to be cured in succession by many forms of treatment. At the present time (1901) a resort to local treatment is comparatively safe, the results not having proved so satisfactory as was at one time expected.

In his recent work on hay fever, Sajous recognizes the difficulty of precise and exclusive definition, and formulates a theory which is comprehensive, and which may at least serve as a working hypothesis until more extended and complete observation furnishes us with one that is entirely satisfactory. According to this author, hay fever requires, first, an external irritant; second, a predisposition to become influenced by this irritant; and, third, a vulnerable or sensitive area through which the irritant may exert its influence.

It may be safely concluded that autumnal catarrh is largely dependent upon some disorder of the vaso-motor nerves, that the sympathetic system is partially responsible for the trouble, and that many of the symptoms are true reflexes; but what is the precise character of the trouble is not known; undue excitability there may be, and probably is, but that tells us little more than the old term idiosyncrasy. It has, however, the great advantage of directing our treatment into a definite channel. While admitting the implication of the nervous system, it cannot, however, be concluded that pollen has no share in producing the disease. That it has a large and important part as an exciting cause, it seems impossible to doubt. On the other hand, pollen is not the only excitant, but dust, heat, electrical conditions of the atmosphere, and many other things share with pollen the ability to provoke an attack in properly disposed persons.

Treatment has hitherto been of two kinds, namely, palliative at home, or radical by removal to a locality which experience has proved to be exempt from the exciting causes of the disorder. While the former has been unsatisfactory—so much so, indeed, as to lead many sufferers from hay fever to disregard it altogether—there is no doubt that much can be done to lessen the severity of the attacks, and to mitigate the suffering they cause. Leaving out of view, for the present, the local treatment, so much lauded of late as the only radical one, the following line of procedure may be safely followed as rational, harmless, and as proved by experience to be beneficial.

The patient should lead a very quiet life from the beginning to the end of the period, avoiding exposure to draughts, the direct rays of the sun, and any exertion which may tend to quicken the circulation. He should pay particular attention to his diet, especially during the later hours of the day. By this it is not meant that he should go upon a low diet, but that he should avoid anything that is indigestible, or which during digestion gives off a large amount of gas, such as sweet potatoes or lima beans. In many cases watermelons act injuriously, and the individual powers of digestion should always be carefully considered. Keeping this last point in view, there is no reason why rich soups, meats, the less starchy vegetables, and many fruits, should not be indulged in. He will do well to have any peaches he may eat pared before they are brought into the room, and he will be wise if he eats nothing after the early hours of the afternoon.

For the conjunctivitis, or rather the ocular injection, which exists in these cases, a weak solution of brandy and water, or some other mildly stimulating collyrium, will prove most comforting. When obliged to go out in the day-time, dark-colored spectacles will afford considerable relief. Similar locally stimulating treatment will be found beneficial to the coryza. Weak solutions of quinine, of sea salt, or any other suitable substance, will afford temporary relief, and if attention is paid to the specific gravity of the solutions by the addition of a saline, so that they approach that of the blood, they can be frequently repeated without injury, and with positive benefit. In the use of hydrochlorate of cocaine, there is every reason to expect decided benefit. Dr. Da Costa has found it useful in a number of cases, when applied to the nasal mucous membrane, and there would seem to be good grounds to anticipate advantage from its further use in solutions of varying strength. The danger of acquiring the cocaine habit by these applications should, however, not be lost sight of. Stimulating gargles, such as vinegar and salt, are useful by temporarily allaying the intense itching in the roof of the mouth, and lessening the hyperæmia of the mucous membrane of the fauces and pharynx.

When the bronchitic symptoms appear, the use of mild expectorants with opium will be found decidedly useful in allaying the cough, even though they do not abolish it altogether. Neither physician nor patient should allow the fact that the disease is annually recurrent, and that the predisposition cannot be destroyed, to prevent the use of ordinary remedial measures to palliate the severity of the symptoms. Very many cases will be benefited by some such prescription as the following: ℞ Morphinæ sulphatis, gr. i.; extract. belladonnæ, gr. ij.; extract. prun. virg. fluid., syrupi lactucarii, āā fl ℥ i. Dose, a teaspoonful every four hours. Beyond the fact that they divert the attention of the patient, counterirritants applied to the chest do not appear to do much good, while they possess the disadvantage of sometimes provoking troublesome skin affections.

When asthmatic symptoms present themselves, opium, in one form or another, will be found to be by far the most efficient remedy. Two or three doses of one-fourth of a grain each, taken two hours apart in the evening, will be found to diminish the spasmodic tendency most materially, and by cautiously increasing the dose from time to time, or by changing the form of the drug, it will be found possible to maintain the good effects throughout the time of the attack without resorting to a very large dose. In recommending this method of treatment the physician should carefully weigh the risk that the patient runs of acquiring an evil habit, and should always insist that it should be pursued, under competent medical oversight, only when the discomfort is severe. He should, above all, urge its abandonment at the earliest possible day. He should always bear in mind the fact that, while the immediate comfort of the patient may be promoted, his ultimate well-being may be seriously imperilled by a drug which is so potent for both good and evil.

When the physician is called to witness one of those extreme attacks previously described in this article, when the orthopnœa is complete, and the sufferings of the patient are far greater than are usual at any death-bed, he will find that in his hypodermic syringe he possesses an implement of almost magical power. The injection beneath the skin of one-fourth or one-third of a grain of sulphate of morphine will, in the vast majority of cases, afford complete relief in a very few minutes. The practice of the writer has been to use seven minims of Magendie's solution, and he has never witnessed more marvellous effects from any medication. Generally within fifteen minutes the spasm has entirely disappeared, and the patient has fallen into a quiet sleep. Rarely, and only in those cases in which the remedy has been often administered, he has had to use a supplemental injection of four or five minims.

Smoking various kinds of cigarettes, burning saltpetre papers, or some of the various quack compounds so extensively sold often afford some relief, generally just in proportion as an anodyne has been incorporated in the mixture. Chloral will afford relief in some cases, but, apart from the danger which attends its use, it is much less efficacious than the course of treatment above indicated. When resorted to it may be advantageously combined with full doses of one of the bromides. These last-mentioned remedies may often be used with benefit. Twenty grains of the bromide of potassium, repeated every hour until a drachm has been taken, will frequently secure a quiet night. The bromides and chloral may be usefully added to, or alternated with, opiates. Musk, camphor, asafœtida, stramonium, and very many other remedies addressed to the nervous system, have been recommended, and may be tried sometimes with advantage, both from their own intrinsic power, and from the aid they lend to the effort to keep within bounds the dose of opium necessary for the control of spasm.

The treatment above indicated will enable sufferers from hay fever to exist with a minimum of discomfort at home, but in those cases which suffer much from asthma it will be a period of confirmed invalidism at best, and they will long for more radical and more effectual means entirely to abolish the recurrence of the annual attacks. There are very many who merely suffer the inconvenience of a severe coryza and an annoying catarrh, but who are able to go about and attend to business, with discomfort, indeed, but without interruption. Such cases may afford to consider whether they will continue satisfied with palliative treatment, or seek that which, while more severe, is certainly more effectual. But the patient who has had one attack of severe asthma will share the anxiety of his friends that he may escape another such, and will be willing to make great efforts, to endure many discomforts, aye, go even to the ends of the earth, if he may only thereby avoid another attack.

Fortunately, a change of location can be recommended with confidence. Experience has proved that immunity is enjoyed at Bethlehem, and many other localities in the White Mountains, as well as at other elevated locations; at Beach Haven, N. J., Fire Island, N. Y., Halifax, Nova Scotia, and a few other places on the seashore; or, better than all, at sea, out of sight of land. It would be out of place, in an article like the present, to go into a discussion of the reasons for the immunity enjoyed under the circumstances, yet it may be well to refer to certain facts as tending to an elucidation of the matter, or at least as helping us to a knowledge of the conditions essential to immunity. Why certain mountainous regions should be exempt and others not, is not known. It cannot be elevation, for all elevated regions do not afford relief, while those which do are often less high than those where no relief is obtained. It cannot be altogether the absence of pollen, for none of the localities proved to be beneficial are entirely destitute of vegetation. Yet the fact remains, and it is idle to deny it, that autumnal catarrh is escaped at Whitefield, Franconia, Fabyan's, Crawford's, Mount Washington, Gorham, and many other places in the White Mountain region, at many places in the Adirondacks and in the Catskills, at the Straits of Mackinaw, and at some other points in the Northwest. When we come to the seashore, we find that Fire Island and Beach Haven are both situated upon islands of limited extent, somewhat removed from the mainland, and, so far as our present knowledge goes, it is only at places similarly situated on the seashore that exemption from hay fever is enjoyed. These islands are very low, Beach Haven not being more than eight or ten feet above high water. Nor is there an entire absence of vegetation, there being an abundance of marine plants, and the upland flowers, though few in number, are yet amply sufficient to supply pollen to a disastrous degree, did it possess the virulent properties supposed to belong to it by Morell Mackenzie and Blackley. Yet, as was pointed out by the author of this article some years since, very many persons entirely escape their annual attacks of hay fever at Beach Haven, and all enjoy a greater or less measure of relief. While the wind is from the sea complete immunity is enjoyed; when it comes from the land some inconvenience is experienced, but the attacks are always of modified severity.

Although, therefore, it is difficult or indeed impossible to give a satisfactory explanation of the reasons why certain places are safer resorts for sufferers from autumnal catarrh than others, it is well to advise such cases to make trial of one of them, making the selection according to the dictates of individual convenience and inclination. But it is important, when the patient goes to one of these resorts, that he go *before* the time of the expected attack, and observe ordinary hygienic precautions while there. Personal observation leads the writer to believe that it is of importance to anticipate the attack by several days, and that, when it has once begun, it is much more difficult to get rid of it. Yet many persons will arrive at their safe harbor suffering acutely, and find complete relief in a few hours. Nourishing food, light woollen clothing, thin flannel next the skin, the avoidance of undue exertion, and rational medical treatment for any symptoms which arise, will give comfort, even though the exile—for an exile it is when enforced from year to year—may be inconvenient and hard to bear. The writer would especially urge the importance of sending children to some safe place, as he is increasingly convinced that, if there is any hope of breaking up what may be in part a systemic habit, it may be most reasonably indulged in the case of very young persons. To accomplish this is worth every effort, for while autumnal catarrh is not a disease endangering life, and the suffering attendant upon it may be alleviated or borne, its annual recurrence does most seriously interfere with all the avocations of the individual, whether he remains at home or seeks refuge in an exempt locality. Experience would seem to show further that when complete exemption is enjoyed for a series of years, recurring attacks exhibit less severity.

During the years which have passed since this article was written its author has met with quite a number of cases in which the disease has practically disappeared in those who persistently visited exempt localities for a series of years, and his conviction is strengthened that when the habit of the system is interrupted by such means there is a distinct tendency for the disease to wear out (May, 1901).

The new pathological views to which reference has been made, and which identify the disease in question with certain abnormalities and pathological changes within the nasal cavities, have led to local treatment of greater or less severity, instituted with a view of getting rid of the cause entirely. Any abnormal prominences or growths connected with either the mucous membrane or the bones are attacked by the snare or galvanic cautery and destroyed, or if the trouble is found to consist in turgescence of the erectile mucous membrane, various stimulating applications are resorted to, and with most satisfactory results to those who have used them. The method is recommended by such capable observers, and specialists so skilful in their departments, that it is certainly worthy of more extended trial. As reported, the results have been very good, but it is yet too early to utter any *ex-cathedra* opinions upon the subject. Several who have undergone the treatment referred to have fallen under the writer's notice. Some have thought they were benefited, others that they were not improved, and one, at least, believed that he was worse than before. Most of the cases were met at a hay-fever resort. It is but right to add that some of the cases had not undergone the number of local applications which their attendants thought were necessary to work a complete cure. While the application of mechanical and operative measures may be safely tried within certain limits, there would seem to be danger of carrying the practice too far. It should not be forgotten that extensive tracts of cicatricial tissue may become the seat of more serious disease than hay fever. For the latter we have a tolerably certain and satisfactory palliative, if not a permanently radical cure, in temporary change of residence, while at present operative interference is undertaken only with the *chance* of permanent relief. As has been already stated, this form of treatment is less frequently resorted to at the present time, having proved disappointing to its advocates.

Those who desire to familiarize themselves with the natural history of hay fever will do well to consult the admirable work, "Autumnal Catarrh," by Morrill Wyman, M.D. (New York, 1872), in which they will find the best account of the disease and the most careful study of places where exemption from its attacks exists. Those who desire to know all about the pollen theory, and the extent to which it can be carried, will do well to consult "Experimental Researches on the Causes and Nature of Catarrhus Æstivus," by Charles H. Blackley, M.R.C.S. Eng. (London, 1873), and "Hay Fever: its Etiology and Treatment, with an Appendix on Rose Cold," by Morell Mackenzie, M.D. (London, 1885). This last book is most vigorously reviewed in the *American Journal of the Medical Sciences* for October, 1885, by Dr. John N. Mackenzie, of Baltimore, who has also contributed several papers bearing upon hay fever to various journals, in which he ably upholds the neurotic and anatomical theory of the disease. An able and suggestive paper will be found in the number of the *American Journal* for January, 1886, in which Sir Andrew Clark maintains very similar views, but would account for the asthmatic spasm by temporary and sudden congestion of the mucous membranes rather than by muscular constriction of the bronchial tubes. In "Hay Fever and its Successful Treatment by Superficial Organic Alteration of the Nasal Mucous Membrane," by Charles E. Sajous, M.D. (Philadelphia, 1885), there will also be found an exposition of the modern views, and details of the treatment recently so highly lauded for this most troublesome affection. Other papers upon the subject will be found scattered through the journals by Daly, Roe, Allen, Bosworth, Da Costa, Beverley Robinson, S. S. Cohen, and Hack. The work of Dr. W. C. Hollopeter, of Philadelphia, is among the more recent contributions to this subject.

Samuel Ashhurst.

HAYWOOD WHITE SULPHUR SPRING.—Post-Office.—Waynesville, Haywood County, North Carolina. Hotel and cottages.

Access.—From Asheville, viâ Murphy branch of the Western North Carolina Railroad, thirty miles west. The location of these springs is in the heart of the Alleghanies at the foot of the Great Balsam Mountains, where the peaks tower 5,000 to 6,000 feet in height. The altitude at the springs is about 2,800 feet. The surrounding scenery is of surpassing beauty, not excelled in rugged grandeur east of the Rockies. During the summer and autumn seasons the weather here is generally delightful, the temperature ranging from 56° to 80° F. The hotel is usually crowded with visitors at these times, some of them from remote points. There are two springs, one sulphur, the other iron. The temperature of the water is 54° F. No complete analysis has been made, but we are informed that the waters contain, besides sulphur and iron, salts of sodium, potassium, and magnesium. The present hotel, a large and commodious brick building, with surrounding wooden cottages, is located on the banks of the Richland River, a beautiful trout stream. Numerous attractions in the way of shooting, fishing, archery, tennis, bowling, and billiards are at the option of the guests. The medical properties of the water have been amply attested, especially in chronic functional disturbances of the liver, stomach, and kidneys. Rheumatism and neuralgic troubles are benefited by the hot baths.

James K. Crook.

HEADACHE.—Headache is a frequent manifestation of the most varied disorders of the nervous system and of other organs. Being merely a symptom of so many different morbid states, it cannot be consistently characterized or described as a disease, although it is occasionally of such a nature as to possess the significance of an independent affection.

It may be so fleeting or transient as to be more or less ignored by the patient, or it may attain such a degree of severity or persistency as to lead the sufferer to seek medical advice. Familiarity with its various forms is essential, and it is necessary always to bear in mind that headache is a frequent accompaniment of many constitutional diseases. Hence a description and classification of headache with suggestions as to the means of determining its causation must prove of great practical value. According to many modern observers, we know almost nothing of the structures in which the pain of headache is felt or of the mechanism of its production. As the meninges, especially the dura and a large area of the cranium, receive their sensory supply from the terminal sensory branches of the trigeminus, and as the meninges are also supplied by branches of the sympathetic nerve, it is reasonable to assume that headache is the result of direct or indirect irritation of these nerves.

Psychical disturbances, in the form of depressing emotions such as grief, worry, fright, etc., often produce headache; in such instances it must be due to processes originating in the higher cerebral centres through which superficial pain is perceived. Headache must not be confounded with true neuralgia in which the pain is paroxysmal in character and directly limited to the course of the nerve and its distribution. The idea that the location of the pain in any particular region of the head is always directly related to some special underlying, adjacent or remote pathological process (excepting pericranial inflammation), has not been substantiated by clinical experiences.*

No definite rules can be laid down in regard to this matter that will apply in every case. It may be said, however, after perusal of the histories and observation of a large number of cases, that pain located at certain parts of the head occurs more often in this or that condition of disease. Such information, nevertheless, may prove valuable in suggesting certain lines of inquiry when found associated with other symptoms.

---

* Recently, Head in his work on "Referred Pain" has endeavored to prove the existence of certain sensitive areas on the scalp in their relation to diseases of internal organs.

The headache may be confined to the forehead, to the vertex, the parietal, temporal, or occipital region on one or both sides; it may be unilateral as in migraine, or it may affect the entire head, and is then described as general or diffused, or it may occur in various combinations.

Patients usually describe the pain in the head, which frequently dominates all other symptoms, as acute, sharp, throbbing, darting, dull ache, boring, burning, stabbing, etc. It may be transient, paroxysmal, periodical, or continuous, and may vary in degree and location from time to time. As pain is a subjective symptom we can judge of its degree only by the *tout ensemble* of the individual and by its association with unmistakable physiognomical expressions and physical manifestations.

"Traditional psychology may be said to regard pain as a feeling, *i.e.*, a purely mental state or condition, with or more frequently without a physical basis in the nervous system. Physicians do not place much confidence in the patients' statement of the quality or character of the pain, largely because patients have not words, nor experience to prompt the words, in which to describe their pains. The description of pain by a patient seems to be directly proportional to (1) liveliness of imagination, (2) vocabulary, (3) experience" (Witmer). The description is often materially enhanced by the patient's gestures.

HEADACHE, for all practical purposes, may be divided into two classes—functional and organic. The so-called functional forms of headache are by far the more frequent, and include those resulting from various constitutional or psychical disorders, and from causes not situated in the skull or cranial cavity, excepting the disturbances of special-sense organs, such as the eye, ear, and nose, and dental caries. Some special forms of disturbance of the cerebral circulation may also be placed in this category.

The organic form includes all types of intracranial disease, whether vascular, meningeal, or cerebral, and disease of the cranial bones.

The functional forms of headache may be classified and subdivided as follow:

TOXÆMIC.	1. Retained excrementitious substances. 2. Products of defective metabolism. 3. Infectious germs or their toxins. 4. Various drugs. 5. Graves' disease.
NEUROPATHIC.	1. Neurasthenia. 2. Hysteria. 3. Epilepsy.
REFLEX	1. Ocular. 2. Gastric. 3. Nasopharyngeal. 4. Auditory. 5. Dental. 6. Uterine. 7. Sexual.
CIRCULATORY.	1. Hyperæmia. 2. Anæmia.
MIGRAINE.	

TOXÆMIC HEADACHE.

In which the blood is contaminated by various deleterious agents.

1. RETAINED EXCREMENTITIOUS SUBSTANCES.—(The absorption of decomposition and fermentation products developed in the alimentary canal, or the reabsorption of retained excrementitious substances.) (*a*) Constipation. (*b*) Intestinal indigestion. (*c*) Gastric indigestion. (*d*) Uræmia.

(*a*) *Constipation;* (*b*) *Intestinal Indigestion.*—In a very large majority of instances in which headache is complained of, it is due to toxæmia resulting either from constipation, or from intestinal or gastric indigestion. The clinical fact has long been established that auto-intoxication of intestinal origin plays an important rôle in the production of headache, migraine, and vertigo, but such symptoms are evidently more or less dependent upon individual susceptibility. Constipation is not incompatible with apparent health, for some persons may be constipated for a week or more at a time without any complaint of digestive trouble or headache. For this reason, the objection has often been made to the hypothesis of auto-intoxication of fæcal origin. On the other hand, Bouchard, who has made a special study of this subject, believes that constipation should be regarded as a protection against intoxication, and says: "it supposes that all that is absorbable has been absorbed, the aqueous part with what was held in solution." The lengthiest argument, however, will not controvert the familiar fact that thorough purgation causes the rapid disappearance of the headache and associated symptoms in most cases of this character.

In these patients the headache is usually located in the frontal region, but is often diffused over the entire head. As a rule, it is not constant, and may or may not be associated with gaseous eructations.

In some it is accompanied by morbid somnolence during the day and heavy sleep at night, while in others insomnia is complained of. Occasional attacks of vertigo may also occur.

(*b*) *Intestinal indigestion*, with or without constipation, is more frequently productive of headache through autotoxæmia than as a supposedly reflex cause. The urine is often of high specific gravity and may contain an excess of indoxyl.

(*c*) *Gastric Indigestion.*—It would seem that gastric indigestion, on the other hand (although in some instances occasioning toxic absorption), is more likely to produce headache by reflex irritation through the pneumogastric nerve from fermentation of food and gaseous distention of the stomach. Thus, headache, possibly due to both causes, is frequently an accompaniment of dilatation of the stomach on account of the anomalous fermentations that are the consequences of it. The location of the headache is usually supraorbital or frontal.

(*d*) *Uræmia.*—Headache due to renal disease is of very common occurrence. Two forms are found in nephritic subjects—*uræmic* and *congestive*. Either one or both may be present in the same patient. The *uræmic* form is due to the retention in the circulation of excrementitious products, and may manifest itself in any type of kidney disease, whether acute or chronic. The pain is ordinarily situated in the occipital region, extending to the neck. It may or may not be associated with somnolence, nausea, or vomiting, etc., according to the degree of damage to the kidneys and arterial system. In some cases the headache may be accompanied by vomiting, vertigo, and optic neuritis, thus simulating the general cerebral symptoms of brain tumor. The *congestive* form arises in consequence of disturbed cerebral circulation in the presence of cirrhotic kidneys, with arterio-sclerosis, cardiac hypertrophy, and increased arterial tension. (See "Circulatory" form of headache.)

Puerperal Eclampsia.—Headache which is at times persistent and severe is often a premonitory symptom of a convulsive attack in this affection, and may be associated with delirium, excessive somnolence, mental hebetude, or insomnia. Œdema of the face and extremities is often present. This condition is generally regarded as acute renal disease of pregnancy, the headache and other symptoms being ascribed to some form of toxæmia not yet determined. Unless the urine is carefully analyzed, and the functioning power of the kidneys ascertained beyond question, the uræmic form of headache will often pass unrecognized, thus leading to unexpected and serious consequences.

2. PRODUCTS OF DEFECTIVE METABOLISM.—(*a*) Rheumatism. (*b*) Gout. (*c*) Diabetes.

(*a*) *Rheumatism.*—There are two forms of headache which occur in rheumatic subjects. One is due to autotoxæmia, the headache generally being diffused and similar to that occurring in other forms of toxæmia. The other is a true muscular rheumatism or myalgia located in the scalp and affecting particularly the occipito-frontalis muscle and its aponeurosis. The pain is increased by active or passive movement of this muscle, and it is common to obtain a history of other attacks of muscular rheumatism, affecting different parts of the body. These patients may also have suffered from acute or subacute articular rheumatism. The attack may last for from a few hours to several weeks. Like other forms of muscular rheumatism, it is brought about by exposure to cold. One of the worst cases seen by the writer occurred in a rheumatic subject after bathing the head in cold water, and then sitting at an open window for a half-hour or more.

(*b*) *Gout.*—Headache is frequent in gouty subjects. It may be due to toxic products of defective oxidation, or the result of vascular disease affecting the cerebral circulation. It is not unusually accompanied by interstitial changes in the kidneys. Gout, it is claimed, is merely a hypothetical condition and presupposes an excess of uric acid in the general circulation. The headache and the irregular symptom-complex often described as lithæmia is an atypical form of gout. There is more often a sense of pressure and fulness about the head than actual pain. Haig has called special attention to the association of such symptoms with retention of uric acid in the system. It is now well established that the headache, aberrant neuralgic pains, slight stiffness in the joints, and occasional attacks of acute gout, etc., arise in connection with defective metabolism. The most essential etiological factor is deficient oxidation resulting from overindulgence in unsuitable food and overdrinking, and the lack of sufficient physical exercise.

(*c*) *Diabetes.*—Headache occurring in diabetics is often accompanied by hebetude and depression of spirits. As a premonitory symptom of diabetic coma, it is soon followed by delirium and dyspnœa. The prevailing theory is that the latter form of intoxication is due to the presence of acetone in the general circulation.

3. Infectious Germs or their Toxins.—(*a*) Acute infectious diseases. Headache is frequently a prominent symptom in the early period of all acute infectious diseases. It is usually described by the patient as a generalized or frontal headache. As an initial symptom of typhoid fever, it is sometimes so severe and persistent as to demand special attention. The pain is often located in the occiput and back of the neck. It may be accompanied by photophobia, retraction of the head, and muscular twitching, thus simulating meningitis. In the early stage of smallpox, the intense frontal headache is accompanied by pains in the back and limbs. The same may be said of the grippe. General headache also occurs in the early period of acute croupous pneumonia and may simulate meningitis until the lung trouble has clearly developed. During the febrile stage of malarial intermittent or remittent fever, violent headache is often present. In general, it may be said that headache occurs in all conditions accompanied by fever. As a routine practice, the temperature should be taken in every case of acute headache. The character and frequency of the pulse, and the presence of fever are always suggestive of the probably infectious or inflammatory origin of the trouble.

4. Various Drugs.—(Nitrite of amyl, nitroglycerin, alcohol, tobacco, coffee, lead.) *Nitrite of Amyl* and *Nitroglycerin* will be mentioned under the head of "Disturbances of the Intracranial Circulation."

Alcohol.—Headache is often due to acute or chronic alcoholic poisoning. The nervous system is at times so sensitive that a small dose of alcohol may produce violent but transient general headache of a congestive type. Very frequently, after large doses sufficient to produce heavy sleep, the individual awakes with a severe headache the result of such indiscretion. This picture is unfortunately so familiar that it requires no further elaboration. Chronic alcoholic poisoning is often the cause of daily or constant headache. The headache is commonly due to a combination of causes, such as toxæmia, interference with the digestive processes, and cerebral arteriosclerosis. It is often accompanied by cirrhotic changes in the liver and kidneys, and by many of the attendant phenomena of these conditions.

Tobacco.—The habitual and excessive use of tobacco may be the indirect cause of headache, through its deleterious action on the digestive organs, its interference with the cardiac rhythm and the cerebral circulation, and the ultimate production of neurasthenia.

Coffee.—In some individuals the injudicious and excessive use of coffee is productive of headache and a sense of fulness in the head.

Lead.—Headache due to the toxic action of lead is a comparatively rare symptom. In some cases of chronic lead poisoning, however, headache does occur, and its cause must be recognized. It is probably due to the direct action of the lead on the cerebral nerve centres, or indirectly through the production of pathological conditions in the liver and kidneys. A rare form of saturnism, which is productive of serious cerebral symptoms and which may terminate fatally, is known as "Lead Encephalopathy." In this condition the headache is usually severe, and is associated with vertigo and bilateral optic neuritis (which may end in complete blindness) and a series of symptoms simulating the presence of an intracranial tumor. The more severe forms terminate in convulsions, delirium, and coma.

5. Graves' Disease.—Recent studies regarding the pathogeny of the symptom group known as Graves' disease lead us to assume that the condition is due to autotoxæmia from hypersecretion of the thyroid gland, which is often preceded by sudden or prolonged depressing emotions. Headache is not common in this affection, but it is sometimes a troublesome symptom, and may be confined to one side. It is occasionally accompanied by a sense of throbbing in the head, a pulsating noise in the ears, and transient vertigo. The rapid action of the heart and cardiac palpitation, the presence of thyroid enlargement, exophthalmos, tremor and excessive perspiration, will lead to a correct diagnosis.

Neuropathic Headache.

1. Neurasthenia.—Headache is often an important symptom in neurasthenia, but it is not present in all cases. As a rule it is not general, but is commonly located in the frontal or occipital region, and is often accompanied by occasional vertigo and muscæ volitantes. The headache, which is usually slight in degree, is either continuous or occurs at brief intervals. In the majority of neurasthenics actual pain is not complained of, but the sensations in the head are described as the feeling of "a constricting band about the forehead," "fulness in the head" as if there was "something pressing from within against the skull," etc. Frequently it is a sensation of weight or numbness, and occasionally of throbbing. The headache and other sensations increase after fatigue, and are often diminished by rest. Difficulty in concentrating the attention is often present. As a result of these varied forms of cephalic paræsthesiæ, such patients are inclined more or less to indulge in excessive introspection. They often become morbid and apprehensive, dreading the possibility of a brain tumor or other serious cerebral disease. All of these symptoms are modified in proportion to the attention given them by the patient. The presence of other signs of neurasthenia, their development or increase through mental effort or emotional excitement, and the absence of evidence of organic cerebral disease, make the diagnosis clear.

2. Hysteria.—Headache that is confined to a small spot, which has for many years been described as "clavus," is comparatively unusual in this country, and occurs most frequently among the premonitory symptoms of convulsive hysteria. The scalp is sometimes so sensitive that the slightest touch is not tolerated without wincing. In the majority of cases of hysteria, however, the headache corresponds with that of neurasthenia. It may be limited to one side and thus simulate migraine. In some instances, it may be characterized as a veritable psychalgia. The peculiar character of the headache, its dependence upon the momentary psychical condition of the patient, its rapid disappearance or variation in degree, the favorable influence of suggestion or diversion, and its occasional association with other signs of hysteria (paralysis, spasm, convulsive attacks, disturbances of sensibility, etc.) enable us to make a correct diagnosis. The stigmata of hysteria are not always present.

3. EPILEPSY.—While headache cannot be regarded as a symptom of epilepsy, its occurrence is at times of great importance in the diagnosis of obscure cases. An attack of *grand mal* is often followed by severe general headache which may last for several hours. This fact is of value in interpreting the cause of the headache when it is mentioned as occurring in the early morning on awaking. It is at times indicative of a nocturnal epileptic attack, and the diagnosis is positive when such headache is associated with soreness of the muscles and joints of the extremities, a bitten tongue or mucous membrane of the cheek, and wetting of the bed.

REFLEX HEADACHE.

1. Ocular; 2. Gastric; 3. Nasopharyngeal; 4. Auditory; 5. Dental; 6. Uterine; 7. Sexual.

1. OCULAR.—Ocular defects, such as errors of refraction and insufficiency of the ocular muscles, are a common source of headache. The two conditions may be found in various combinations. It has been claimed that fully sixty per cent. of functional headaches due to errors of refraction are caused by astigmatism alone, or in conjunction with other forms of ametropia (De Schweinitz). The headache is produced by strain on the ciliary muscles, and frequently arises in connection with hypermetropic astigmatism. The pain may be situated in any part of the head, but it is most frequently located in the supraorbital region. It may be persistent in character, and is often aggravated by using the eyes. It is relieved temporarily by the instillation of atropine, which paralyzes the ciliary muscles, or permanently, by wearing suitable glasses.

Headache caused by insufficiency of the ocular muscles may affect any portion of the cranium, but is often located in the occipital region. It may immediately follow the use of the eyes, but usually this is not the case, the pain occurring at irregular intervals. At times it may develop into a typical attack of migraine, and is often associated with symptoms of neurasthenia. The claims of certain writers, that the lack of balance in the action of the muscles of both eyes is a prolific cause of headache and various forms of nervous disease, have certainly been much exaggerated. The headache arises as a result of repeated or continuous efforts to obtain and preserve binocular single vision. It is a fact well known to all ophthalmologists that so-called ocular headache does not occur in patients in whom there is a congenital or acquired absence of binocular vision, as such patients are known habitually to suppress the image in one eye. Hence, the causative element of "effort at binocular fixation" is negligible under such circumstances. This occurs with high degrees of strabismus; paralysis of ocular muscles; when vision is greatly diminished or lost in one eye; and when there is considerable difference in the refraction of the two eyes. When headache occurs in such people it is invariably due to some other cause. The writer knows of a patient with ocular headache from muscular trouble in whom the pain entirely disappeared after the accidental destruction of one eye.

The improved methods in the examination of the power and action of the ocular muscles, introduced within recent years, have led to a more accurate and thorough study of these conditions. Curiously enough, the muscular troubles which occasion the greatest amount of discomfort to the patient at times produce no evident changes in the gross appearance of the eyes. Hence it is only after the most careful and painstaking investigation that they can be discovered and rectified. This is accomplished either by the use of suitable lenses to neutralize any existing refractive anomaly, and thus indirectly influence muscular action, or by surgical operation, or both. There must be a peculiar individual predisposition to headache, for there are persons who have both muscular and refractive anomalies without any symptoms of headache.

Headache often results from inflammatory eye troubles such as iritis, glaucoma, etc. In iritis, the pain is generally supraorbital, but may extend to the whole side of the head. Acute inflammatory glaucoma is accompanied by violent pain radiating through the head from the eye. The headache occurring in these conditions cannot be classified as of reflex origin. It is due to direct inflammation of the ophthalmic division of the trigeminus.

2. GASTRIC.—(*Vide supra*) Gastric indigestion.

Headache Superinduced by Hunger.—In some individuals headache arises as a result of hunger. A delay of a few hours in the time of the customary meal causes general discomfort and headache which disappear at once when food is taken. This form of headache is probably produced through irritation reflected from the gastric mucosa, or from temporary impoverishment of the blood diminishing the nutrition of the cerebral sensory centres. Such individuals often manifest a peculiar susceptibility to headache from other causes, especially migraine.

3. NASOPHARYNGEAL.—Any of the following pathological processes may occasion headache: adenoids in the nasopharynx; polypoid obstruction to nasal breathing; lesions of the turbinated bones, especially of the middle and posterior parts of the inferior turbinate; spurs from the nasal septum; or intranasal synechiæ. Hence, headache is not an uncommon condition in mouth-breathers. The pain is ordinarily located in the temporal region or the forehead. When such abnormities are removed the headache has often been known to disappear.

4. AUDITORY.—Impacted cerumen has in rare instances been the supposed cause of headache. In middle-ear disease, the headache affects the vertex or is situated in the temporal or mastoid region on the same side.

5. DENTAL.—Caries of the teeth in the upper jaw is an occasional cause of headache.

6. UTERINE; 7. SEXUAL.—Headache occurring in patients with uterine or ovarian disease should not be looked upon as a symptom of reflex origin. It is merely one of many phenomena associated with a neurasthenic condition which so frequently accompanies intrapelvic disease in women. The headache frequently affects the vertex but is more often general, and is at times accompanied by tenderness of the scalp. Other causes are usually operative independently of any local uterine lesion. The morbid self-consciousness developed in many women who have or think they have uterine or ovarian disease, is often sufficient in itself to engender a depressive form of neurasthenia. The same may be said, *mutatis mutandis,* of affections of the male genito-urinary organs.

According to Head (Allbutt's "System of Medicine," vol. vii., p. 749) headache may be secondary to disease of the organs within the thorax and abdomen. The pains in the head may be very slight, but are always associated with scalp tenderness in certain areas. The degree to which these pains in the head intrude on the patient's consciousness varies greatly. Thus, sometimes he is quite unaware that the scalp is tender, and the associated tenderness is discovered only by examination. He may, however, complain of headache which leaves behind it a feeling of intense soreness.

CIRCULATORY HEADACHE.

1. Hyperæmia. 2. Anæmia.

Headache due to disturbance of the cerebral circulation in the absence of organic intracranial disease.

Headache is at times the result of hyperæmia or congestion of the intracranial circulation. It may also be occasioned by cerebral anæmia. When it is due to increased arterial supply it is called *active.* If it is caused by obstruction of the venous circulation, it is termed *passive.*

(*a*) *Active Hyperæmia.*—This condition has been described as "cephalalgia vasomotoria" by Eulenburg, and is due to paralysis of the vasoconstrictors permitting of distention of the vessels. It may be either acute or chronic, but it is most frequently acute. As a rule, in the severe cases, it is accompanied by throbbing and pulsating general headache, vertigo, tinnitus, muscæ volitantes, photopsia, insomnia, mental confusion, and delirium, all of which are made worse by lowering the head. There may also be photophobia and general hyperæsthesia. The face and scalp are red, and the conjunctivæ injected. There are fulness and throbbing of the temporal arteries, and contracted pupils. The pulse is full, and may be either slow or increased in frequency. Occasionally there is a slight rise of temperature. In some individuals, such attacks occur periodically. The severe forms of this condition are fortunately rare. In the milder degrees it is not uncommon, but the diagnosis may at first be doubtful. Somewhat similar phenomena occasionally occur in the early stage of acute leptomeningitis of the convexity. There may be considerable variation in the intensity of the process, hence the above described symptom-complex is manifested in varying degrees. The condition is usually due to mental overwork, emotional disturbances, alcoholism, excessive use of tobacco, onanism, and injuries to the head. It occasionally occurs as a sequel of sunstroke, and from sudden suppression of menstruation in plethoric women.

The writer has in several instances witnessed a similar but slightly modified array of symptoms occur periodically in young women after removal of both ovaries. A prototype of this group of symptoms can be produced by the administration of various drugs, such as nitrite of amyl, nitroglycerin, etc.

(*b*) *Passive Hyperæmia.*—Venous hyperæmia of the cerebral vessels is an important cause of habitual headache. It may be either acute or chronic, but is most frequently chronic. The pain is of a dull character, and is often accompanied by a sensation of fulness and heaviness in the head. The face and ears may be slightly cyanotic in the more pronounced cases. The attacks also vary in degree, the minor forms not being uncommon. Passive cerebral congestion is generally caused by mechanical hindrance to the return of blood from the head. Thus, it results from growths in the neck making pressure on the jugular veins, cardiac disease, pulmonary emphysema, and persistent cough, as in pertussis. It may also be produced by a tight collar, or by continuous flexion of the head. The headache and other symptoms are aggravated by straining at stool, coughing, sneezing, stooping, or muscular effort.

Cerebral Anæmia.—Anæmia of the brain, as a rule, is a part of a general condition of anæmia and malnutrition. It may be the result of arterio-sclerosis including disease of the coronary arteries. Whether the general anæmia be of a chlorotic nature or from loss of blood, it is almost always accompanied by headache. The condition of cerebral anæmia in which headache occurs, is generally of the chronic form. The headache may be frontal, vertical, or diffused, and is commonly of a dull character. It is often associated with attacks of syncope, tinnitus, dizziness, incapacity for mental work, depression, and irritability. The pupils are usually dilated. The headache often diminishes or subsides when the patient assumes the recumbent position with the head low.

MIGRAINE.

Definition.—This affection has also been termed "sick headache," "hemicrania," and "paroxysmal headache." It is a periodical neurosis occurring most frequently in women, and is characterized by paroxysmal attacks of severe pain usually confined to one side of the head, chiefly in the course of the fifth nerve. At times it is preceded by a variety of transient visual disturbances and paræsthesiæ, and followed by nausea and vomiting.

Symptoms.—The headache does not arise suddenly, but is generally preceded by premonitory symptoms, such as vague indisposition, restless sleep, irritability, depression of spirits, somnolence, sensation of fulness in the head, slight dizziness, etc., and, later, transient ocular symptoms may develop. The headache is dull and slight at first, but gradually reaches such intensity that it is often described as unendurable, and the patient is frequently obliged to go to bed. During the attack all of the senses become more acute, and there is general hyperæsthesia, the sufferer being disturbed by bright light or the slightest sound. The temperature is normal, and the pulse is either slightly accelerated or slow. Sometimes, on the affected side, the face is flushed and hot, the conjunctiva injected, the pupil contracted, and there is strong pulsation of the arteries; or the face is pale and the pupil dilated. But such phenomena are by no means constant; in fact they are quite rare. They usually alternate during the attack and are most frequently bilateral. The former has been interpreted as due to sympathetic vaso-motor paralysis (angio-paralytic), and the latter as being due to vaso-motor spasm (angio-spastic). Too much stress has been laid by some writers upon the value of such manifestations. They are so uncertain and variable that as a rule they are of no special clinical significance. The pain is usually confined to one side of the head. It may, however, affect either side alternately, or both sides may become involved at the same time, the pain varying in degree on the two sides. The left side is more frequently affected. At one time it may have its greatest intensity in the forehead, and at another time it may be situated in the occipital region. Nausea and vomiting generally take place either during the early part of the attack or toward the end. In some patients vomiting is absent. Polyuria occasionally occurs at the termination of the attack. When the pain subsides, sleep follows, and the patient awakes free from discomfort. The headache may last for from several hours to three or four days. Ocular symptoms constitute a prominent feature in a certain number of cases, but they do not occur in every attack. In the most common type of migraine they are entirely absent. The visual disturbances occur in the form of photophobia, blurring of vision, bright lights, vibrating or luminous sensations which commence over a small area and gradually widen out, the flashing increasing in intensity and often assuming a zigzag shape like the outline of fortifications (scotoma scintillans), hemianopsia and transient amblyopia or blindness. This type has often been termed "ophthalmic migraine."

Other abnormal sensations are also complained of, such as disturbed sensation in the extremities, numbness and tingling in the skin, as well as partial aphasia. The eye symptoms and paræsthesiæ when present almost invariably precede the headache (just as certain auræ precede an attack of epilepsy), and last for from a few minutes to half an hour. In rare instances, such sensory phenomena occur paroxysmally without the headache.

Etiology.—It is pre-eminently an inherited disease. The constitutional peculiarity which predisposes certain people to migraine is not clearly understood. That some persistent pathological condition must exist is quite evident. Many of the so-called reflex causes, such as uterine and menstrual disorders, eye-strain, dental caries, or nasopharyngeal disease, are frequently only coincidental conditions. Ocular defects are more frequently the cause of other forms of headache.

Indigestion and intestinal autotoxæmia are the most important acquired factors in the causation and persistency of the affection. Neurasthenia and hysteria, gout and various lithæmic conditions also play an important rôle. The constitutional substratum varies in different individuals. Among the exciting causes of attacks may be mentioned mental overwork and anxiety, excessive fatigue or exhaustion from any cause, constipation, errors in diet, menstruation, and emotional excitement.

Diagnosis.—It is differentiated from other forms of headache by its periodical and paroxysmal character, its usual limitation to one side of the head, and its association with transient visual disturbances and other evanescent sensory symptoms, and the absence of evidence of organic intracranial disease.

Course and Duration.—Migraine usually begins after the twentieth year, but it has been known to commence as early as the fifth or sixth year of life. The interval between the attacks varies from two weeks to several months, the length of time often being modified by treatment. During these intervening periods, the patient may appear perfectly well. In women the attacks seem to occur more frequently at or about the menstrual period. In the ordinary form it has a tendency to subside spontaneously about the menopause in women, and after the age of fifty years in men. This is not the rule, for it sometimes lasts through a whole lifetime. When the affection has persisted for several years, the attacks being frequent and severe, it usually leads to a general neurasthenic condition. It is thus commonly found in association with neurasthenia and hysteria. The ophthalmic form of migraine usually appears later in life, occasionally growing progressively worse, and it has been known to be the precursor of serious organic brain disease. Migraine has occasionally been found in conjunction with epilepsy. In such cases, the migraine attacks have at times alternated with the epileptic seizures or epilepsy has followed migraine which had entirely disappeared.

In rare instances, the attack of migraine is complicated by sudden paresis or paralysis of the third nerve on the same side. The ocular paralysis is usually transient and recurs in varying degrees in subsequent attacks of migraine. In many of the reported cases, the patients have eventually made a complete recovery both from the attacks of migraine and from the accompanying third-nerve affection. But the outcome is not always so fortunate, for in some cases the paralysis gradually increases during the intervals and ultimately becomes permanent.

Pathology.—The pathology is still obscure. The prevailing and most plausible theory is that the attacks are due to periodical discharges of nerve force originating in the cerebral cortex or in the sensory centres, involving principally the intracranial branches of the trigeminus and the pneumogastric nerves. According to a recent "mechanical" theory, the attack is produced by an acute transient closure of the foramen of Munro and a consecutive swelling of the brain (Spitzer).

Treatment.—Patients with migraine should lead a regular life free from excesses of any kind. The avoidance of mental overwork, and the systematic practice of some form of outdoor exercise are always necessary. All sources of reflex irritation should be investigated. Refractive errors should be corrected by suitable lenses, and if there is any defect in the eye muscles it should be remedied if practicable. This does not necessarily imply that every patient with migraine must be subjected to operation or the wearing of spectacles as a routine method. The same rule holds good in regard to operation for deviation of the nasal septum. While some of these patients are in fairly good health during the intervals between the attacks, many suffer from various manifestations of toxæmia due to gout or rheumatism, such as stiffness and pain in the muscles and joints, vague and fleeting neuralgic pains, etc. The neurasthenic state also requires careful management. Certainly such indications are to be met, and treatment is to be instituted accordingly. Particular attention should be given to the regulation of the action of the bowels and to proper diet. Hydrotherapy is also a valuable adjunct in these cases. The more intelligent patients usually judge from personal experience when the attack is approaching, and in time they also learn to avoid exciting causes. Various drugs have been recommended to abort the attack in its incipiency, or to relieve the pain during the paroxysm, and as a rule they are more effectual the earlier they are administered. Among these may be mentioned ℞ Caffeine, gr. ij.; Phenacetin, gr. x., with or without potassium bromide, gr. xv. ℞ Acetanilid, gr. ij.; Caffeine, gr. ij., to be repeated in twenty or thirty minutes if necessary; or ℞ Codeine, gr. $\frac{1}{4}$; Acetanilid, Caffeine, āā gr. ij. At times a brisk cathartic, such as two or three ounces of Rubinat water, or a few ounces of a strong infusion of coffee, or a moderate dose of wine, whiskey, or champagne will abort the attack, if taken early. If the paroxysm is very severe the pain will generally be relieved by the hypodermatic injection of morphine, or morphine or codeine may be given by the mouth if nausea and vomiting are absent. Some patients obtain relief from applications, to the head, of hot-water cloths or a hot-water bag, while others prefer the ice bag. This is purely a matter of individual susceptibility. A mustard plaster over the nucha, or over the side of the neck in the course of the pneumogastric nerve, also at times diminishes the pain. The use of arsenious acid and extract of cannabis indica administered for a prolonged period of time, has proved that they are most serviceable drugs. ℞ Ext. cannabis indicæ, gr. $\frac{1}{6}$; Acid. arsenios., Strych. sulph., āā gr. $\frac{1}{30}$; Quinin. sulph., gr. $\frac{1}{2}$; Extr. taraxaci, q. s. M. ft. pil. No. i. These pills, given after meals for one week—the dose of the various ingredients being gradually increased each week—should be taken regularly for many months or a year.

When the attacks are frequent and severe, the administration of potassium bromide gr. xv., and fluid extract of ergot ♏ xv. t.i.d. proves serviceable during the first few weeks of treatment.

ORGANIC HEADACHE.

Headache is commonly a pronounced symptom in all inflammatory processes which affect the exterior or interior of the skull. It thus occurs in disease of the periosteum, in caries of the petrous portion of the temporal bone, in inflammation in the cavities situated in the skull, as the frontal and sphenoidal sinuses, the orbital cavity and the middle ear, and in diseases of the brain and meninges. Headache as it occurs in the following conditions will be briefly described: 1. Intracranial tumor. 2. Cerebral abscess. 3. Leptomeningitis. 4. Pachymeningitis. 5. Intracranial syphilis. 6. Vascular disease. 7. Encephalitis. 8. Mastoid disease and sinus thrombosis. 9. Disease of the cranial bones. 10. Diseases of the frontal sinus. 11. Caries of the cervical vertebræ. 12. Acromegaly. 13. Spinal-cord disease.

1. INTRACRANIAL TUMOR.—The most persistent and distressing form of headache is that which occurs in patients with intracranial tumor. It is one of the most constant and obtrusive symptoms. In exceptional instances, headache may be absent during the entire course of the disease. But such a condition is very rare, the headache varying in intensity in different cases. Occasionally it may be of a mild character. As a rule it attains great severity, preventing sleep, and at times becoming so unendurable that the patient has been known to commit suicide. Sometimes the pain is paroxysmal, but more frequently it is almost continuous with periods of great exacerbation. The headache is usually diffuse, but it may be limited to the forehead, parietal region, or occiput, changing its location from time to time. The seat of the pain in the cranium does not necessarily imply that the growth is subjacent. When the pain is confined to the frontal region it by no means indicates that the frontal lobes are involved, for such pain often occurs in cerebellar tumor. The presence of persistent occipital pain extending to the neck would lead us to assume that the growth is probably situated in the posterior cranial fossa. If the headache is limited to a circumscribed area it most frequently corresponds with the location of the growth which has also involved the underlying meninges. If it be confined to one side of the head, the probability is that the tumor is on the same side. This is not an invariable rule, however. The pain is aggravated by everything that interferes with the cerebral circulation. It is thus made worse by psychical excitement, alcohol, coffee, muscular activity, coughing, straining at stool, sneezing, etc. Headache can be considered only one of the prominent general symptoms of brain tumor, and in itself it is of no value in localization. The other important general symptoms frequently found in association with the headache are vomiting, double optic neuritis (choked disc), and vertigo. Various symptoms indicating the location of the lesion are usually present. It is universally assumed that the headache is produced by irritation of the numerous branches of the trigeminus supplying the dura. The dura may also be stretched and irritated as a result of intracranial press-

ure. If this be true, in the former condition the pain would probably be circumscribed, while in the latter we would expect it to be diffused. Clinical facts, however, cannot always be reconciled with this view.

2. Cerebral Abscess.—In cerebral abscess headache is the earliest and most constant general symptom, just as it is in brain tumor. It is generally of great severity, but often manifests itself as a persistent dull ache, deeply situated, and referred mainly to the seat of the abscess. The development and growth of the abscess are likely to produce paroxysms of headache of the severest type. During the latent stage the pain may be slight and occur only periodically. The attacks may last for from several hours to several days. As in brain tumor, the pain is aggravated by everything that causes mechanical congestion or increases the intracranial circulation. The headache may be general, but is more frequently confined to the same side as the abscess. In otitic abscess it may be strictly circumscribed to the temporal region, the pain being first experienced in the ear, and later radiating over the entire head. Abscess in the cerebellum may begin with frontal headache, but is usually accompanied by pain in the occipital region and neck. In cerebral abscess the headache is generally associated with other symptoms of intracranial pressure, as optic neuritis, vomiting, and slowness of the pulse. As the disease advances, there may be general or localized convulsions, weakness of memory, restlessness, irritability, or mental confusion. Fever is generally present, but often disappears for varying periods, only to return higher than before. Frequently the temperature is normal or subnormal. The commonest cause of abscess in the brain is middle-ear disease. In such cases the temporal lobe or cerebellum is most frequently involved.

3. Inflammation of the Pia or Leptomeningitis.—This is always due to an infective process. The acute form is often purulent, and of the cerebrospinal type. Extremely severe general headache is a persistent, prominent, and obtrusive symptom. It may precede or follow a chill and rise of temperature. There may be vertigo, vomiting, general hyperæsthesia, rigidity of the neck muscles, inequality of the pupils, and, later, mental confusion and coma. In *chronic leptomeningitis* persistent headache is a frequent symptom, but it is not present in every case. Its severity is probably dependent on the extent of the process. It is usually accompanied by signs of intracranial pressure, such as vomiting and optic neuritis. The disease may attack either the convexity or the base of the brain. In the former, the cranial nerves escape, there is more delirium, and there may be unilateral or general convulsions and hemiparesis. In the latter, several or many of the cranial nerves may be involved, and there is more marked rigidity of the post-cervical muscles.

4. Inflammation of the Dura or Pachymeningitis Externa.—The headache is usually circumscribed, and is often accompanied by nausea or vomiting and slight fever. When only one side of the convexity of the brain is involved the pain is confined to the same side. In severe cases the disease may extend to the pia, and it is then often accompanied by typical Jacksonian epileptic attacks and hemiparesis on the opposite side of the body. It is usually the result of traumatism to the skull, of caries of the petrous portion of the temporal bone, as in mastoid disease, of syphilis, and of ethmoidal caries. *Pachymeningitis interna or hæmatoma of the dura* is also accompanied by headache and somewhat similar symptoms. This disease occurs most frequently in old people with chronic alcoholism, syphilis, or dementia.

5. Intracranial Syphilis.—Headache may antedate all other symptoms of intracranial syphilis, especially syphilitic meningitis, for several months or years. As a rule, it is the earliest and most constant symptom, and often occurs in paroxysms, or there are periodical exacerbations in which it becomes intolerable. Very frequently such exacerbations occur toward evening or at night, and thus prevent sleep. At times the attacks are periodical. At the height of the paroxysm the pain often becomes excruciating, while during the intervals it may diminish to a dull aching sensation or entirely disappear. The headache is rarely circumscribed (unless there is disease of the cranial bones), but is usually distributed over the frontal, temporal, or parietal regions, and eventually over the occiput and neck. Extreme tenderness on pressure upon the skull occurs only when the periosteum or bones are involved at the same time. The pathological process affecting the intracranial structures is that of arteritis, gumma, or gummatous meningitis. It is uncommon for all three conditions to exist at the same time. The meningitis is frequently of the type of a meningo-encephalitis, and may be confined either to the convexity or to the base of the brain. In the former, there are more delirium, and disturbance of consciousness, and localized or general epileptic seizures, sometimes followed by hemiparesis or hemiplegia. In the latter, the cranial nerves at the base often become involved, thus producing facial or ocular paralysis, etc. Chronic syphilitic meningitis is generally local, and occurs chiefly in the neighborhood of a gummatous growth. The main features or general symptoms of cerebral syphilis are similar to those of tumor. Thus, in addition to headache, there are vomiting, double optic neuritis, and various paralyses. Mental hebetude, somnolence, or periods of unconsciousness are often characteristic and almost pathognomonic symptoms that occur in association with the persistent headache of intracranial syphilis. In addition, there often are alterations in character, loss of memory, mental dulness, and absence of the pupillary light reflex.

6. Vascular Disease.—Headache due to arterio-sclerosis is essentially the result of circulatory disturbances in the brain and interference with nutrition. (See Cerebral hyperæmia and anæmia.) In syphilitic endarteritis, however, the headache is not due to the arterial changes alone, but to the associated meningitis or gumma. Vascular disease, such as arteritis and sclerotic degeneration, frequently arises in conjunction with chronic renal disease, chronic gout and rheumatism, and old age.

7. Encephalitis.—This is an acute inflammatory affection of the brain. It has recently been well-described by Oppenheim as "acute primary hemorrhagic encephalitis." The headache is very severe, and generally affects the entire head, or the pain may be greater in the occipital region and neck. It is accompanied by vertigo, nausea and vomiting, apathy and general depression. These symptoms are soon followed by somnolence, which rapidly develops into unconsciousness. Later, there may be monoplegia, hemiplegia, and various other signs indicating involvement of special cerebral centres. Recovery is not infrequent. The disease is rare, and generally affects young people between fifteen and thirty years of age. As it most frequently complicates or follows acute influenza, it has also been termed "influenza encephalitis." It is acute in its onset, beginning like many of the acute infectious fevers.

There is another form of encephalitis known as "acute polio-encephalitis superior." After several days of headache, vertigo, and vomiting, mental confusion and delirium take place. At about the same time the eyes become involved in paralysis of ocular muscles, which at times develops into complete ophthalmoplegia. It usually terminates in death in about two weeks. Recovery is rare. This disease was originally described by Wernicke. It is an acute hemorrhagic encephalitis confined mainly to the gray matter in the floor of the third ventricle and that of the aqueduct of Sylvius. Chronic alcoholism and infection are the usual causes.

8. Mastoid Disease and Sinus Thrombosis.—Headache occurring in these conditions is usually on the same side as the lesion. Beginning in the ear the pain radiates over the entire side of the head. When severe, it generally arises in consequence of the extension of the infective process to the dura. As the local and general pyæmic infection advances, the headache often diminishes *pari passu* with the obtunding of the sensorium. Furthermore it may be complicated by the presence of a subdural, temporal, or cerebellar abscess, and leptomen-

ingitis may ultimately develop with its usual train of symptoms. Mastoid disease and sinus thrombosis are in nearly all cases due to middle-ear disease and caries of the petrous portion of the temporal bone. Sinus thrombosis is also a complication of facial carbuncle and erysipelas of the head.

9. Disease of the Cranial Bones. Periostitis.—Bone disease affecting the exterior of the skull is the result of traumatism in the majority of instances. In a large proportion of cases, however, there may be periostitis due to syphilis, *i.e.*, periosteal nodes over the cranium. Circumscribed gummata of the skull arise in the most part in the epicranial periosteum. In such cases headache is often constant and, as in all forms of intracranial syphilis, is liable to exacerbations during the night. The bone affected is usually tender and painful to the touch. The headache accompanying cranial periostitis may be mistaken for the form of headache due to muscular rheumatism, or vice versa.

10. Disease of the Frontal Sinus.—In catarrh or suppuration in the frontal sinus, the headache is confined to the frontal region as a rule, but may become general, with the greatest intensity over the affected sinus. At first the pain is dull and intermittent in character. It may gradually or suddenly become persistent and severe and prevent sleep. Percussion over the sinus usually increases the pain. Swelling and tenderness of the tissues over the region of the affected sinus are commonly present, and ultimately all of the symptoms of local and general infection may develop.

11. Caries of the Cervical Vertebræ.—Occipital headache is commonly present in caries of the upper cervical vertebræ. The pain may extend to the parietal and temporal regions, and is increased by movement and deep pressure over the vertebræ. It is usually accompanied by rigidity of the neck muscles, or the head may be partially fixed in the median line.

12. Acromegaly.—The headache may be localized in the occiput or the frontal region, or be confined to one side of the head. It may be continuous or intermittent, and is often persistent and severe, usually being worse in the morning. It is almost always accompanied by ocular symptoms, such as impairment of central vision or bitemporal hemianopsia, which often terminates in optic atrophy and complete blindness. Acromegaly is a rare disease, and was first described by Pierre Marie of Paris, in 1886. Since that time many cases have been observed in this country and elsewhere. The diagnosis of the cause of the headache can be made only by a recognition of the associated pathognomonic physical signs of the disease, *i.e.*, enlargement of the hands and feet, enlargement of the cranial and facial bones, hypertrophy of the tongue, and of the muscular and connective tissues of the extremities, slow but progressive weakness, and the visual defects as above described.

The headache may continue for years or persist during the progress of the affection, and is supposed to be due to the enlargement of the hypophysis (pituitary body).

13. Spinal-Cord Disease.—Headache cannot be considered a symptom of spinal-cord disease. When it is present, it is merely a coincidental element in the general constitutional disturbance, or due to some complication. The characteristic tabetic neuralgic pains occasionally attack the scalp, and are due either to involvement of the spinal or cerebral sensory root of the trigeminus, or to irritation in its peripheral distribution.
